The proposal of the Committee on Membership that the by-laws be changed to permit a graduate of a foreign or unapproved school to become eligible for membership in the Society after he "has possessed a license to practice medicine in the Commonwealth and has conducted that practice in the district from which he makes application, for at least one year," was unanimously approved.

The recommendation of the Committee on Society Headquarters that a professional survey be made of the domiciliary needs of the Society, the Medical Library and the *Journal* was approved. A new publicity code designed to help in guiding the public utterances of fellows of the Society was adopted.

MASTERS OF INDUSTRIAL HEALTH

SIR WILLIAM OSLER, whose life can now be viewed with the added respect that a generation of progress has lent, saw with clarity that the advances chronicled in the successive editions of his great textbook were not final achievements but rather steps toward an ever-expanding medical horizon and a new type of practice — preventive medicine. It is doubtful whether he could foresee in detail the development of this kind of Chinese medicine in which the physician is paid to keep his patient well, but he had faith in its possibilities and prophesied that "preventive medicine is the medicine of the future."

Shortly after Osler's death, Harvard School of Public Health appeared as an offshoot of the Harvard Medical School. The institution prospered and came to maturity two years ago with a faculty all its own. Recently, its curriculum committee has prepared an analysis of the objectives and content of public health, wherein is surveyed anew the highway that Osler glimpsed as a freshly blazed trail. Taking into account contemporary knowledge of the theory and practice of physic, the report defines the three basic disciplines essential to a knowledge of public health as ecology, the science of the relations of organisms to each other, epidemiology, the science of the origins and distributions of disease, and biostatistics, the calculus of probabilities by which quantitation is brought to both.

With these studies as a background, the future student of public health can choose appropriate electives depending on whether his chosen career is in such fields as public-health practice, nutrition, tropical medicine and maternal and child health. The analogy with conventional medical training is now complete. Each kind of school stipulates required courses in its basic sciences and offers further electives for the specialist.

Along with the new course in ecology given for the first time this fall, the Harvard School of Public Health will confer the newly established degree of master of industrial health. Besides the sciences already listed, courses for the candidates will cover basic problems in industrial hygiene and organization, and include environmental physiology, sanitation and the control of industrial air hazards.

Something that cannot be taught in courses is also offered to the future graduate when he departs with his degree. This is the opportunity to contribute significantly to the advance of medicine. Most of the great industries have group insurance plans, and the mortality and morbidity data hidden in such files may well be the source of vital statistics pointing to the causes of some of the most serious and crippling diseases. Assuredly, these masters of industrial health will find divisions of their industries in which accidents are a problem, where causes can be determined and effective control measures introduced.¹ Perhaps they will find pulmonary cancers a problem like that among chromate workers.² But

what about arthritis, peptic ulcer, coronary thrombosis, hypertension and vascular and mental diseases whose causes are at present largely unknown? It may well be that in particular departments of an industry death rates and morbidity rates for some one or other of such diseases — arthritis, for example — may be so excessive as to be significant of the factors acting to produce it. There is the opportunity for the "master" of industrial hygiene to contribute to the ever-growing knowledge of epidemiology and ecology and preventive medicine.

The biochemist has recently developed compound E as a brilliant contribution to the treatment of arthritis. It remains for some future scientist, chemist, clinician or specialist, perhaps with a degree of master of industrial health after his name, to elucidate its pathogenesis. The quest continues for causes. The industrial physician — and the practicing physician — will do well to interpret Osler's kind of observations, whether they are made in the plant, at the bedside or in the laboratory, with Karl Meyer's³ kind of philosophy when he set his sights on the main road block preventing the advance of preventive medicine.

Just as in medicine, the foundation of preventive veterinary [or industrial] medicine is a broad knowledge of the nature of disease. The concept of the contagious nature of disease inspired magnificent advances. The reduction in the number of deaths due to infectious diseases attests to its value. But today, the doctrine that there is a single specific cause for each disease entity is untenable. A purely bacteriologic [or chemical] explanation pays little heed to the fact that the essentials of disease are two — an animal and an organism [or a physical or chemical agent], these interact, react, and are acted upon by external forces. The more quickly it is recognized that causation is a constellation of predisposing, provoking, and perpetuating factors, the more certain will progress be made. To reduce the approach to every disease to concern with one provoking factor continues to retard progress.

OCTOBER MEETING OF THE COUNCIL

THE fall meeting of the Council of the Massachusetts Medical Society was held on October 5 with President Arthur W. Allen in the chair. Owing in some part at least to a careful screening of the Society's business by the Executive Committee, the Council nearly broke a record for neatness and dispatch in the performance of its functions.

The deaths of two councilors, Dr. Harold G. Giddings, of Middlesex South, and Dr. Henry A. Robinson, of Norfolk South, was announced, and solemn tribute was paid to their memories.

Various matters of interest and importance were considered by the Council and disposed of according to their merits. Important among these was the approval of the creation of a new representative committee, composed of the secretaries of the district societies, to study the question of redistricting the Society and changing the ratio of representation in the Council.

Dr. Elmer S. Bagnall, of Essex North, a former president of the Society, held in warm regard and widely recognized for the intelligent devotion with which he has served his profession and his community, was unanimously acclaimed as the Society's candidate for the General Practitioner's Award of the American Medical Association.

On recommendation of the Committee on Public Relations, the Council voted to establish a Massachusetts Medical Society citation to be awarded to a layman or a group of laymen for outstanding contributions to medical progress. No more than three such awards are to be made in any one year. It was proposed that this award be named in honor of Lemuel Shattuck, onetime bookseller of Boston and perhaps the country's most distinguished lay contributor to progress in public health. This opportunity was rejected.

The proposal of the Committee on Membership that the by-laws be changed to permit a graduate of a foreign or unapproved school to become eligible for membership in the Society after he "has possessed a license to practice medicine in the Commonwealth and has conducted that practice in the district from which he makes application, for at least one year," was unanimously approved.

The recommendation of the Committee on Society Headquarters that a professional survey be made of the domiciliary needs of the Society, the Medical Library and the *Journal* was approved. A new publicity code designed to help in guiding the public utterances of fellows of the Society was adopted.

MASTERS OF INDUSTRIAL HEALTH

INNER CONFLICT

THE series of articles on disabilities, published at intervals by *The Lancet* and once commented on editorially in the *Journal*,¹ has continued for over a year to present its stimulating messages

written by the disabled persons themselves, they are usually from the pens of laymen. The story of five years of compromise with a duodenal ulcer however is by a physician.²

This doctor, leading "a strenuous professional life that has yielded at least a modicum of success and perhaps even a little distinction," experienced his first attack of acute pain at the age of eighteen. From that time on his existence, far too familiar to many persons, was the usual one of repeated episodes of discomfort and pain, and of the conquest of discouragement.

This victim learned that the details of diet, alcohol, tobacco and exercise are personal ones, that the treatment must be the one best adapted to the needs and the temperament of the individual patient. He learned, as have many others, that bed is more valuable than diet, that rest and relaxation and an unfretted mind are more soothing than powders or drops of belladonna.

Ulcer, the "wound stripe of civilization," the torment of the ambitious and the penalty that the conscientious must too often pay, has become synonymous with the gnawing pain that robs one of his rest and removes the joy from living. Every ulcer casualty is the Spartan youth who kept the fox hidden beneath his cloak, even while it devoured his vitals. Nearly thirty-five years ago, intrepid Serbia, which would not let the captive Balkans sleep, became known as the "Serbian ulcer."

In general, as is known only too well in this country, "the sufferer from duodenal ulcer is characteristically of the type that will not compromise. Unless some catastrophe such as haemorrhage or perforation makes surrender incontestable, he will persist in the thick of the fight, even with one hand tied behind his back."

When his ulcer is not troubling him he cannot remember it, when its symptoms recur it will not let him forget its presence. Infrequently fatal, rarely completely incapacitating, the ubiquitous, unpredictable ulcer can hardly be classed among the dramatic calamities from which man's life and health may suffer. "And yet, it may be said that one's enjoyment of life is reduced by an ulcer to a greater extent than by some of the more serious disabilities" — except perhaps for those persons

who, regardless of their type, are able and willing to spend their lives in that compromise so distant from their natures.

YOUNG MAN, GO WEST

EVEN free enterprise can learn a thing or two when it follows Horace Greeley's injunction to the Young Man. California Physicians' Service,—a Blue Shield Plan,—eager to help the visitor to California's shores, has inaugurated a courtesy travel service available to any of the physicians or lay people connected with any plan that is a member of the Associated Medical Care Plans.

In obtaining hotel rooms or travel reservations, giving advice on the best fishing grounds or tourist resorts, providing forwarding addresses, and even furnishing stenographic assistance, the two main offices as well as the fifteen district offices are at the visitor's service. This year and next are California's centennial years, during which a new pilgrimage of forty-niners is striking west. Members of Associated Medical Care Plans who are directing their steps toward the setting sun should jot the two addresses of Travel Department, California Physicians' Service, on their cuffs: 450 Mission Street, San Francisco 5, and 431 South Fairfax, Los Angeles 45.

Dr. Martin, of Hinsdale, N. H., was fined \$75 for violation of the liquor law in that State, by the Court of Common Pleas and yet he only sold it as a medicine, being himself a temperance man.

Boston M. & S. J., October 17, 1849

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

BACTERIOLOGIC SPECIMENS DELAYED IN THE MAIL

Physicians are advised that diagnostic specimens are not infrequently delayed in the mail, particularly if mailed near the end of the week. When important treatment is dependent upon an early report, it is wise, at least in the metropolitan area, where the distance is not too great, to send the specimen directly to the laboratory by special messenger.

Physicians are reminded that the diagnosis of diphtheria is a clinical and not a laboratory responsibility. Delay in the administration of antitoxin pending laboratory confirmation is very dangerous, and may result in a fatal outcome for the patient. Furthermore, a negative laboratory report does not exclude the diagnosis of clinical diphtheria, for the throat swab may not have reached the actual focus of the diphtheria organism. Since treatment for diphtheria may render a culture negative that would otherwise be positive, specimens should always be taken *before* treatment is begun.

MISCELLANY

STUART McGUIRE LECTURE SERIES AND SYMPOSIUM ON HEMATOLOGY

The twenty-first annual Stuart McGuire Lecture Series and Symposium on Hematology were held at the Medical College of Virginia in Richmond from September 28 to October 1. Sir Lionel E. H. Whitty, Regius Professor of Physics, Department of Medicine, Cambridge, England, delivered the lectures, entitled "The Physiology of Hemopoiesis," "Dyshemopoiesis from Nutritional and Specific Deficiencies," and "Dyshemopoiesis from Noxious Agents." New England was represented at the symposium by William P. Murphy, M.D., of Boston, who spoke on the subjects "The Treatment of Pernicious Anemia" and "Some Frequently Overlooked Sources of Anemia"; Louis K. Diamond, M.D., of Boston, who spoke on the subjects "The Anemias Resulting from Rh Incompatibility" and "Anemias of Childhood"; Thomas H. Ham, M.D., of Boston, who spoke on the subject "Acquired Hemolytic Anemia"; and F. H. L. Taylor, of Boston, who spoke on the subject "Recent Advances in Hemophilia."

NEW DIRECTOR OF RING SANATORIUM AND HOSPITAL

Dr. Benjamin Simon was recently appointed medical director of the Ring Sanatorium and Hospital in Arlington Heights, Massachusetts, succeeding Dr. Charles E. White. Dr. Simon, who received his degree from Washington University School of Medicine, was formerly assistant clinical professor of psychiatry and mental hygiene at Yale University School of Medicine and attending psychiatrist at the Veterans Administration Hospital in Newington, Connecticut, as well as acting assistant superintendent at Worcester State Hospital and clinical director of the Connecticut State Hospital. He is chairman of the New England Regional Survey Committee of the American Academy of Neurology.

BOOK REVIEW

Aesculapius Comes to the Colonies. The story of the early days of medicine in the thirteen original colonies. By Maurice B. Gordon, M.D. 8°, cloth, 560 pp., with 107 illustrations. Ventnor, New Jersey: Ventnor Publishers, Incorporated, 1949. \$10.00.

This history of early Colonial medicine in the United States is arranged by states, according to their dates of founding, beginning with Virginia and ending with Georgia, the last British colony to be founded. The work is a compilation from acknowledged sources which are listed by states in the final chapter. It is noted that certain important sources relating to medicine in Massachusetts have been omitted.

The material in Dr. Gordon's history is well arranged. There is a very good index. The publishing is excellent. A soft, light, nonglare paper is used, making the volume easy to handle. The illustrations on plate paper are tipped into the text. The volume should be in all medical and public libraries.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Blood Transfusion. By Elmer L. DeGowin, M.D., associate professor of internal medicine, State University of Iowa, College of Medicine, director, Blood Transfusion Service, University Hospitals, member of the Committee on Blood and Blood Derivatives, National Research Council, and member of the Advisory Board for Health Services, American National Red Cross, Robert C. Hardin, M.D., assistant professor of internal medicine, State University of Iowa, College of Medicine, and John B. Alsever, M.D., senior surgeon, United States Public Health Service, and chief, professional standards, Hospital Division, United States Public Health Service. 8°, cloth, 587 pp., with 200 illustrations. Philadelphia: W. B. Saunders Company, 1949. \$9.00.

In this new book the authors cover the entire field of blood transfusion, including whole blood, to which they have given over one hundred pages. The authors, internists, with an experience individually of ten years in the subject, believe "that whole blood transfusion is still, and will continue to be the major need in the treatment of patients." The early chapters are devoted to a short history, the clinical use of blood and its derivatives, immunology of blood and laboratory procedures. The remaining chapters discuss in detail the transfusion of whole blood, preparation and administration of plasma, and of the blood derivatives and plasma substitutes, and transfusion services and apparatus. Lists of references are appended to the various subdivisions of the text. There is a good index. The type and printing are excellent. The book should be in all medical libraries and in the collections of all surgeons.

Searchlights on Delinquency. New psychoanalytic studies. Dedicated to Professor August Aichhorn, on the occasion of his seventieth birthday, July 27, 1948. Managing editor K. R. Eissler, M.D., Ph.D., chairman of the editorial board, Paul Federn, M.D. 8°, cloth, 456 pp. New York: International Universities Press, Incorporated, 1949. \$10.00.

This memorial volume contains contributions by thirty-five authors, covering the whole field of juvenile delinquency. There is a short preface by Ernest Jones, a short biographic sketch of Professor Aichhorn, who was a friend and associate of Sigmund Freud and the author of *Wayward Youth*, and a bibliography of his writings. The work is divided into seven parts: general problems, clinical problems, technique and therapy, etiology and development, social psychology, penology, and surveys. There is a paper by Anna Freud entitled "Certain Types and Stages of Social Maladjustment." The book is well published, but the lack of an index mars its excellency. The volume should be in all collections on psychoanalysis and delinquency.

Studi e ricerche sulla manna e mannite naturale. By Domenico Gigante. 8°, paper, 144 pp. Rome: Istituto Poligrafico Dello Stato Libreria, 1948.

This monograph comprises a study of manna, the exudation of the manna ash tree or *Fraxinus ornus*, and mannite or mannitol, its principal constituent, a mild aperient and cholagogue. The study is thorough, considering the pharmacognosy of manna and its chemistry, the dosage of mannite, its method of extraction and preparation and its pharmacology, the action of manna and mannite on gastric function and on intestinal motility, on the liver and biliary tract, and their purgative and diuretic action, their therapeutic use in diseases of the respiratory organs and diabetes, and the use of mannite in functional and radiologic exploration of the biliary tract. Two appendixes consist of receipts for the medical use of manna and mannite and for the dietetic use of mannite in diabetes. A bibliography concludes the text.

Psychodynamics and the Allergic Patient By Harold A. Abramson, M.D., associate physician for allergy, The Mount Sinai Hospital, New York City, consulting physician for allergy, Sea View Hospital, Staten Island, New York, and assistant professor of physiology, Columbia University College of Physicians and Surgeons. 12°, cloth, 81 pp., with 7 illustrations. Saint Paul Bruce Publishing Company, 1948. \$2.50 (An official publication of the American College of Allergists.)

This special small volume comprises two short essays by Dr. Abramson entitled "Psychomatic Aspects of Hay Fever and Asthma Prior to 1900" and "Psychodynamics and the Allergic Patient," constituting in all thirty-six pages. Appended to the essays is the report of a panel discussion by ten well known authorities on allergy, comprising forty-five pages of text.

Atlas of Oral and Facial Lesions and Color Film Library By Ralph H. Brodsky, D.M.D., consulting oral surgeon, Department of Hospitals, New York City, lecturer in stomatology, New York University College of Medicine, associate dentist to the Mt. Sinai Hospital, New York, and founder and executive-secretary, Pan American Odontological Association. 8°, cloth, 127 pp., with 100 illustrations. Baltimore: Williams and Wilkins Company, 1948. \$30.00.

This atlas, with its accompanying collection of one hundred colored slides, presents a new type of teaching unit for the dentist and oral surgeon. The slides depict lesions of the face and oral cavity. The text, supplied with the film slides, discusses the important features of the lesion, its diagnosis and treatment. Each slide is represented in the text by a diaphragmatic drawing. The slides are contained in a plastic case, bound to match the volume and designed to stand on a shelf with the book.

The Doctor Wears Three Faces By Mary Bard. 8°, cloth, 254 pp. Philadelphia: J. B. Lippincott Company, 1949. \$3.00.

This novel relates the experiences of a doctor's wife, covering all the phases of medical practice and ending with a trip to an American Medical Association convention. The story is well written and entertaining and represents the better type of medical fiction.

Introduction to Physiological and Pathological Chemistry With laboratory experiments By L. Earle Arnow, Ph.D., Ph.D., M.B., M.D., director of research, Medical Research Division, Sharp and Dohme, Incorporated, Glenolden, Pennsylvania. With an introduction by Katharine J. Densford, R.N., B.A., M.A., D.Sc., professor of nursing and director of the school of nursing, University of Minnesota, Minneapolis. Third edition. 8°, cloth, 595 pp., with 144 illustrations. St. Louis: C. V. Mosby Company, 1949. \$4.00.

This textbook was first published in 1939. The second edition was reprinted four times during 1943-1945, speaking well for the popularity of the book. It is written in a simple manner for students. The text is divided into three parts: introduction to chemical science, physiologic and pathological chemistry, and introduction to laboratory chemistry. An appendix includes tables of the international atomic weights (1947) and chemical components of human blood, and a long article of thirty-five pages on stain removal from fabrics, with home methods, reprinted from *Farmers' Bulletin*, No. 1474. There is a good index. The material is well arranged, and the book well printed. It should prove useful as a ready reference source for medical libraries.

Operative Surgery By Frederick C. Hill, M.S. (Surg.), M.D., associate professor of surgery, The Creighton University School of Medicine, Omaha, Nebraska. With a foreword by Charles W. Mayo, M.S. (Surg.), M.D., Section on Surgery, Mayo Clinic, Rochester, Minnesota. 8°, cloth, 698 pp., with 255 illustrations. New York: Oxford University Press, 1949. \$12.75 (Oxford Medical Publications).

The author presents a treatise of practically pure operative surgery with the objective of providing a single-volume work on general surgery, in which the gross appearance of surgical lesions is described, the proper treatment indicated and detailed description of operative procedures given. There are short chapters on preoperative and postoperative treatment. The classification used is the age-old type of head to

foot. The author suggests operations he considers most suitable for the various surgical conditions described. The material is well arranged, and the text well written. The book is a personal one based on the author's experience and is not overloaded with redundant references to the surgical literature. It should prove interesting to all surgeons.

An Introduction to Cardiology By Geoffrey Bourne, M.D., F.R.C.P., physician, and physician in charge of the Cardiological Department, St. Bartholomew's Hospital. 8°, cloth, 264 pp., with 65 illustrations. Baltimore: Williams and Wilkins Company, 1949. \$4.50.

This small manual, which endeavors to portray the chief aspects of cardiovascular disease, is based largely on lectures given at St. Bartholomew's Hospital, London, and on the author's personal experience. The material is well arranged, condensed and written. This is a personal book, and references to the literature are omitted from the text. In the introduction the author refers to three standard works that he recommends for collateral reading, among which he mentions *Heart Disease*, by Dr. Paul D. White, of Boston, as being the best detailed textbook on the subject. The book is well published. The printing was done in Great Britain.

Thank God for My Heart Attack By Charles Y. Harrison. 12°, cloth, 144 pp. New York: Henry Holt and Company, 1949. \$2.50.

This popular book, although it may be classed as non-fiction, has all the aspects of a novel. Mr. Harrison, a well known writer, suffered an attack of coronary thrombosis, from which he recovered. In this book he relates his experiences while he was ill and until the time he returned to his work of writing. The text is well written and interesting.

NOTICES

ANNOUNCEMENTS

Dr. Joseph Bernard Doyle announces the removal of his office for the practice of gynecology and obstetrics to 65 Bay State Road, Boston.

Dr. John J. Finn, Jr., announces the opening of an office at 270 Commonwealth Avenue, Boston, for the practice of internal medicine.

Dr. Milton H. Rodofsky announces the removal of his office to 478 Beacon Street, Boston.

Dr. Arthur A. Wills, Jr., has resigned his position as assistant medical director with the Travelers Insurance Company, Hartford, Connecticut, and plans to resume the practice of medicine at 815 Sheraton Building, 10 Post Office Square, Boston.

NEW ENGLAND SOCIETY OF ANESTHESIOLOGISTS

A regular meeting of The New England Society of Anesthesiologists will be held in the Auditorium of Building A, Boston University School of Medicine, Boston, on Tuesday, November 8, at 8:00 p.m. The subject "Decamethonium Iodide. Its Uses in Conjunction with Pentothal Sodium and Nitrous Oxide Oxygen in Abdominal Surgery" by Drs. Francis F. Foldes and Theodore S. Machaj, of the Department of Anesthesia, Mercy Hospital, Pittsburgh, Pennsylvania, will be presented by Dr. Francis F. Foldes.

AMERICAN INSTITUTE OF ARCHITECTS

The six New England chapters of the American Institute of Architects will hold a seminar on hospital design at the Hotel Kenmore, Boston, on December 1 and 2. Leaders in the hospital field will discuss the solution of problems encountered in the design of hospitals of small and medium size. The program will include topics of interest to hospital consultants and administrators and medical personnel, as well as professional architects.

VARIATIONS IN THE FIRST APICAL SOUND SIMULATING THE SO-CALLED "PRESYSTOLIC MURMUR OF MITRAL STENOSIS"*

A Phonocardiographic Study

MARIANO M. ALIMURUNG, M.D.,† MAURICE B. RAPPAPORT, E.E.,‡ AND HOWARD B. SPRAGUE, M.D.§

MANILA, PHILIPPINE ISLANDS, AND BOSTON, MASSACHUSETTS

ALTHOUGH Fauvel,¹ in 1843, attributed the apical presystolic murmur to stenosis of the mitral valve, Duroziez's² description — "flout-tata-rou"— in 1862 has been considered as the classic auscultatory sign. Since then, numerous observations and studies have confirmed the original concepts, and modifications have been added.

A few additional observations are herewith reported, with particular reference to the so-called "presystolic crescendo murmur." We have observed by means of the phonocardiographic technic that auscultatory presystolic murmurs may at times be an auscultatory illusion owing to certain variations in the first heart sound. Although our series is small, we consider these observations pertinent to an accurate clinical evaluation of this physical finding.

PREVIOUS STUDIES

A presystolic murmur at the apex is generally regarded as evidence of mitral stenosis. It has been considered as a pathognomonic sign of such valvular disease, either when found alone or in association with a mid-diastolic rumble.³ Some observers⁴ believe that in lesser degrees of mitral stenosis, the presystolic murmur may actually be an earlier sign than the mid-diastolic murmur. On the other hand, Bland, White and Jones^{5, 6} suggested that a mid-diastolic murmur does not necessarily indicate organic mitral stenosis. They noted that the mid-diastolic murmur disappeared as cardiac size returned to normal and attributed this murmur to dilatation of the left ventricle.

The presystolic murmur is commonly described as having a rapidly increasing intensity, with a

so-called crescendo effect. It is associated with auricular systole, which increases the velocity of blood flow through the stenosed mitral opening, whereas the mid-diastolic murmur generally begins with the opening of the mitral valve (fourth component of the second sound).⁷

Phonocardiography has shown that the crescendo character of the presystolic murmur is an inconstant phenomenon, as reported by Johnston⁸ and Battro and Braun-Menendez.⁹ Quite often, the mid-diastolic murmur is registered with a diminishing character, actually disappearing just prior to the first heart sound. In fact, the presystolic murmur may not be audible in all cases of mitral stenosis, especially when the auricular contraction is feeble. The reason for this effect is that the velocity of blood flow through the stenosed mitral valve is greatly diminished, and the resultant pitch of the murmur falls below the threshold of audibility. Reid,¹⁰ in a survey of autopsy findings at the Boston City Hospital in 1921, found 8 cases of mitral stenosis in which a presystolic murmur had not been heard during life, whereas 2 other patients exhibited a presystolic murmur but failed to show any organic lesion in the mitral valve. In 1895 Phear¹¹ described 46 cases with presystolic murmur in which no mitral lesion was found at post-mortem examination. They were aortic regurgitation in 17, adherent pericarditis in 20 and dilated heart in 9.

A more controversial point is the cause of the presystolic murmur. Mackenzie¹² was the first to notice its disappearance in auricular fibrillation. From this observation, and from its relation to both the "a" wave of the jugular phlebogram and the "P" wave of the electrocardiogram, it was concluded that auricular contraction was the cause. However, the fact that its crescendo character is inconstant and that crescendo murmurs have also been observed in auricular fibrillation itself has led others even to doubt the role of auricular contraction in its production.¹³⁻¹⁵ Reid,¹⁶ in 1921,

described a modification of the first sound that he believed to be due to an early systolic murmur that gave the impression of a presystolic murmur ending in a sharp first sound. Cossio and Berconsky¹⁷ noted on the phonocardiogram either an early systolic murmur initiating the first-sound complex or a low coarse wave. They interpreted the latter, in mitral stenosis, as due to the precordial impact of the cardiac apex during the initial phase of ventric-

FIGURE 1 Presystolic Murmur in Mitral Stenosis

Phonocardiograms taken over the apex in 3 cases of mitral stenosis and insufficiency, show the systolic, mid-diastolic and presystolic murmurs. The last starts definitely before the electrocardiographic Q wave. The presystolic murmur shows no crescendo character in the upper tracing, slight crescendo in the middle tracing and more definite crescendo in the lower tracing. In all cases the first sound itself is markedly accentuated.

11

murmur, all the patients having normal hearts at autopsy. Bramwell and Ellis²⁰ examined 192 athletes at the Amsterdam Olympics in 1931 and discovered in 12 long-distance runners a first sound indistinguishable from a presystolic murmur and accentuated first sound.

According to White,²¹ "marked accentuation and slurring of the first sound, such as not infrequently occurs in an overactive heart may give a semblance of a slight presystolic murmur and cause an erroneous diagnosis of mitral stenosis to be made when excitement, exertion, some nervous factor as neurocirculatory asthenia, or thyrotoxicosis, is responsible." Furthermore, he regards the auditory illusion of a crescendo character of the presystolic accentuation of the mitral diastolic murmur as "due to the combined presence of a sudden accentuation of a murmur that has largely died away and the sharp first heart sound that terminates it." This is illustrated in Figure 1.

Reid²² tried to classify presystolic murmurs into two types: the true and the false. The first type, he states, is the one that has always been interpreted as due to auricular systole in mitral stenosis. It is low pitched, not definitely crescendo, and is simply an accentuation of an earlier diastolic murmur. On the other hand, the false type is usually a crescendo murmur of early ventricular systole. This is the one more frequently noted, since it may be heard both in cases of mitral stenosis and in normal hearts. It is loud, rough and out of proportion to the strength of auricular systole and presents no gap before the first sound.

In addition, a variety of auscultatory phenomena may exist whose unusual combinations may give rise to an acoustic impression of a presystolic crescendo murmur, such as those described by Taquini, Massell and Walsh²³ and by Luisada and Montes.²⁴

PRESENT STUDIES

The present series consists of 8 patients, all of whom were thought to have a presystolic apical murmur, and yet phonocardiography failed to corroborate this auscultatory interpretation. Instead, certain variations of the first sound were noted, which could well explain the auscultatory error. In most of these cases, the murmur was clinically described as definitely crescendo. As a result, in 7 patients with a positive or probable history of rheumatic fever the diagnosis of mitral stenosis was either considered or actually made, particularly when this murmur was associated with an earlier diastolic component. In the sole non-rheumatic case, the presystolic murmur was interpreted as an Austin-Flint murmur in aortic insufficiency of syphilitic nature.

The cases may be divided into three groups, based on their final clinical diagnoses. The first group (Case 1, 2 and 3) consisted of patients who definitely

ular systole, in view of the delayed closure of the auriculoventricular valves. Furthermore, several observers detected identical auscultatory findings in persons with normal hearts. In 1909 Sewall¹⁸ stated that "in the structurally normal heart, especially in conditions of circulation excitement, the first sound frequently begins with crescendo tone, simulating closely the faint and brief presystolic murmur or acute accent initiating the first sound in mitral stenosis." Irons and Jennings¹⁹ reported 4 cases in which a clinical diagnosis of mitral stenosis was made because of a presystolic

had valvular disease. Two had rheumatic heart disease with predominant aortic regurgitation and mitral regurgitation, the other was a case of syphilitic aortitis with aortic insufficiency. In the 2 rheumatic cases the associated apical diastolic murmur with what was believed to be a presystolic crescendo led to the additional diagnosis of mitral stenosis. Without a presystolic element, the diastolic murmur itself would not have suggested mitral stenosis in view of the possibility of its being an Austin-Flint murmur. On the other hand in the third case a suspected Austin-Flint murmur

because of a presystolic murmur that was believed to be present. No mid-diastolic murmur was heard. The phonocardiograms, however, disclosed no presystolic murmur. The cardiac status in both cases was then declared normal.

The phonocardiograms were taken with the Sanborn Tribeam Phonocardiograph both the stethoscopic and the logarithmic microphones and the large open-bell chest piece being used. The subjects were examined in the supine position and the phonocardiograms taken while the breath was held in mid-expiration. For reference tracings

FIGURE 2 Cases of Valvular Heart Disease

Stethoscopic (upper) and logarithmic (lower) phonocardiograms taken at the apex, with simultaneous recording of the jugular phlebogram and Lead 2 electrocardiogram. In A (Case 1), B (Case 2) and C (Case 3) there are systolic and diastolic murmurs but no presystolic crescendo murmur. Instead, the first sound has a crescendo configuration. In addition, a systolic gallop is present in B (Case 2), and a wide splitting of the first sound in C (Case 3).

failed to be confirmed by subsequent phonocardiograms.

The second group (Case 4, 5 and 6) comprised patients with congenital cardiovascular anomalies: coarctation of the aorta in 1, subaortic stenosis in another, and an undetermined anomaly as an element of Marfan's syndrome in the third. In addition, they were all thought to have associated rheumatic mitral stenosis because of the presence of an apical diastolic murmur with the so-called presystolic crescendo. It is interesting to note that the post-mortem findings in the last case showed no valvular lesion at all; instead, an aneurysm of the ascending aorta was discovered.

The third group (Case 7 and 8) illustrates cases in which a diagnosis of mitral stenosis was made

electrocardiographic Lead 2 and either the right jugular phlebogram or the apex cardiogram were registered simultaneously with the phonocardiogram.

It can thus be seen that three types of phonocardiographic registration have been employed in this study — namely, linear stethoscopic and logarithmic.⁷⁻²⁵ The linear phonocardiogram or apex cardiogram represents graphically the mechanical vibrations set up by cardiac action as they exist on the surface of the patient's chest. The stethoscopic phonocardiogram registers the cardiac sound vibrations as they are presented to the ears of an observer by an average acoustic stethoscope. Finally, the logarithmic phonocardiogram is the graphic registration of the cardiac sound vibrations

as they are perceived by the average observer of normal hearing when an average acoustic stethoscope is employed. These phonocardiographic techniques enable one to register and analyze all existing cardiac sound vibrations of both low and high frequency. Logarithmic phonocardiography, however, is the actual representation of what should be perceived on clinical auscultation.

CASE REPORTS

CASE 1 J D, a 14-year-old boy, had a clinical diagnosis of rheumatic heart disease, aortic regurgitation, mitral regurgitation, and probable mitral stenosis. At the age of 4 years, he had his initial attack of rheumatic fever with polyarthritis. This recurred a year and a half prior to the

the cause of the auscultatory illusion of a presystolic crescendo murmur.

CASE 2 C K, a 16-year-old girl, had rheumatic heart disease, aortic and mitral regurgitation and probable mitral stenosis. In addition, a suspicion of an auricular septal defect was considered because of a Grade II to III systolic murmur over the pulmonic area. Her first rheumatic-fever episode had occurred at the age of 8 years. On physical examination, she was found to be underweight and underdeveloped. There was a noticeable bulging of the left precordium. The heart was enlarged to the left. No thrill was felt. At the apex, a Grade II systolic murmur and a Grade I presystolic murmur were described. Likewise, a Grade II aortic diastolic murmur was noted along the left sternal border. X-ray examination revealed a moderately enlarged heart, particularly the right ventricle, with a somewhat dilated pulmonary artery.

The phonocardiograms (Fig 2B) disclosed both systolic and diastolic murmurs over all auscultatory areas, and a

FIGURE 3 Congenital Cases

These are simultaneously recorded stethoscopic (upper) and logarithmic (lower) phonocardiograms with jugular phlebograms and Lead 2 electrocardiograms. In A (Case 4) note the crescendo configuration and splitting of the first sound, better shown in the logarithmic tracing, also, a definite third sound is registered. In B (Case 5) an auricular gallop (AG) closely precedes the first sound, which is prolonged and with an early crescendo configuration. In C (Case 6) the first sound is crescendo in configuration, the split second sound is well shown in the logarithmic tracing.

present admission. He had never had any congestive failure. Physical examination revealed a slightly enlarged heart, with a rate of 80 per minute and a blood pressure of 105/65. No thrill was felt. At the apex, the first sound was masked by a Grade III systolic murmur. A long diastolic rumble with presystolic crescendo was described. There was also a Grade II aortic diastolic murmur.

The phonocardiograms (Fig 2A) at the apex showed a prominent systolic murmur, and a murmur throughout diastole but without any presystolic crescendo. The diastolic murmur was more distinctly registered logarithmically than stethoscopically. However, the first sound had a crescendo configuration, clearly shown in both the stethoscopic and the logarithmic phonocardiograms. The first sound definitely began after the electrocardiographic Q wave, as is normal for the first sound, a presystolic murmur precedes the Q wave. This variation in the first sound must have been

systolic apical gallop. No presystolic crescendo was shown. The first sound assumed a crescendo configuration, starting after the electrocardiographic Q wave. Further investigations showed that the apical diastolic murmur was transmitted from the aortic region. Thus, the diagnosis of mitral stenosis was seriously doubted.

CASE 3 C S, a 43-year-old man, had syphilitic heart disease with aortic insufficiency. There was no history of rheumatic fever. On physical examination, the heart was borderline in size by percussion. The second aortic sound was more intense than the second pulmonic sound. Along the third and fourth left interspaces close to the sternal border, a Grade I early diastolic murmur was heard. Over the apex, although no definite mid-diastolic murmur was noted, a presystolic crescendo murmur was described. The blood pressure was 140/70.

The phonocardiograms at the apex (Fig 2C) disclosed no presystolic murmur at all. Instead, the first sound was widely split, with a typical crescendo configuration of its component elements beginning after the electrocardiographic Q wave.

CASE 4 S K, a 22-year-old man, had a diagnosis of probable congenital subaortic stenosis, in view of an aortic thrill and a harsh aortic systolic murmur dating back to an early age. On physical examination, the heart was found to be only slightly enlarged. At the apex, two extra sounds or short murmurs were described in diastole—one protodiastolic, and the other presystolic. A question of rheumatic heart disease was thus considered, with probable mitral-valve involvement.

Phonocardiograms (Fig 3d) revealed that the protodiastolic element was actually a third sound, whereas the presystolic element was in reality part of the first heart sound. Because the first sound was split, with its latter element of

heard in all areas. Over the base, a high-pitched diastolic murmur was also noted. The congenital cardiac anomaly was not defined during life. However, associated rheumatic disease of the mitral valve was suspected, in view of the apical findings on auscultation. The patient later went into uncontrollable congestive failure. Subsequent post-mortem examination failed to show any mitral lesion, and the only cardiovascular findings were a markedly hypertrophied and dilated heart, and an aneurysm of the ascending aorta.

The phonocardiograms in this case (Fig 3C) revealed that although there was a diastolic apical murmur, it was actually diminuendo in character. However, the first sound itself had a crescendo configuration, explaining the crescendo effect on auscultation.

CASE 7 J C, a 16-year-old boy, was thought to have mitral stenosis because of an accentuated first apical sound and a presystolic murmur, in addition to a so-called "mitral-shaped heart" on x-ray study. However, no left auricular

FIGURE 4 Normal Cases

These are simultaneous phonocardiograms, phlebograms and Lead 2 electrocardiograms. The upper phonocardiograms are stethoscopic, and the lower ones are logarithmic. In A (Case 7), as well as in B (Case 8), the first sound has a crescendo configuration. In addition, it is split and prolonged in B (Case 8).

greater intensity than the earlier one, an auscultatory illusion of a presystolic crescendo murmur was produced. This is better illustrated in the logarithmic phonocardiogram, which represents what was actually heard.

CASE 5 V K, a 47-year-old woman, had coarctation of the aorta. She also had rheumatic heart disease mainly aortic regurgitation. An additional diagnosis of mitral stenosis was considered because of an accentuated first apical sound and a presystolic murmur. X-ray examination showed a slightly enlarged heart, with slight notching of the ribs.

Phonocardiography (Fig 3B) revealed an auricular gallop followed by a prolonged first sound. In view of the close proximity of the auricular gallop to the first sound and the prolongation of the latter, an auscultatory illusion of a presystolic murmur was produced. Again the logarithmic phonocardiogram showed a crescendo configuration of the first sound.

CASE 6 V B, a 25-year-old woman had Marfan's syndrome with arachnodactyly, bilateral dislocation of the lenses oculi and various heart findings. The heart was markedly enlarged, with a heaving impulse that shook both the patient and the bed. At the apex a diastolic thrill was felt and a Grade III to IV diastolic murmur with a presystolic crescendo was described. A systolic murmur of minimal intensity was

enlargement was reported. On the other hand, bilateral pleural effusion and pericardial fluid were noted. Systolic murmurs at both apex and base were also described.

Phonocardiograms (Fig 4d) disclosed no presystolic murmur at all. The first sound itself, however, had a crescendo configuration.

CASE 8 E M, a 34-year-old woman, had a diagnosis of probable rheumatic heart disease with slight mitral stenosis. Two of her children had rheumatic fever. On physical examination she was pale and thin. Her heart was not enlarged. Auscultation revealed what was described as a short presystolic murmur. In view of this finding, her complaints of hemoptysis and slight elevation of temperature were considered as possible manifestations of low-grade rheumatic-fever activity.

However, the phonocardiograms (Fig 4B) clearly showed no presystolic murmur at all. Instead, the first apical sound was split and prolonged, the later elements of the split sound being of greater intensity than the earlier ones. In the absence of any definite presystolic murmur, the diagnosis of mitral stenosis was abandoned. The whole clinical picture was then attributed to pulmonary tuberculosis, which was further substantiated by the fact that the fever was typically nocturnal and that her husband was tuberculous.

as they are perceived by the average observer of normal hearing when an average acoustic stethoscope is employed. These phonocardiographic techniques enable one to register and analyze all existing cardiac sound vibrations of both low and high frequency. Logarithmic phonocardiography, however, is the actual representation of what should be perceived on clinical auscultation.

UNSUSPECTED TRAUMA TO THE HEART DURING INTRATHORACIC SURGERY*

ARCHIBALD L. RUPRECHT, M D,† AND ARTHUR ADELMAN, M D ‡

CLEVELAND, OHIO

IN RECENT decades, cardiac wounds have been carefully studied both in the laboratory^{1,3} and at the bedside.^{4,8} An entity has evolved in which we wish to stimulate new interest by a report of 2 cases of inadvertent damage to the heart during surgical procedures on other thoracic viscera. In each case the injury was fatal, but the signs of cardiac contusion went unidentified. In view of the increasing number of intrathoracic operations being performed, these examples of accidental trauma to the heart merit attention. We are unaware of a description of similar cases, but suspect that less disastrous wounds account for some of the cardiac arrhythmias reported after pneumonectomy and lobectomy.^{9,11}

CASE REPORTS

CASE 1 (L. H. H. 116985) § A 63-year-old man had a diffusely infiltrating carcinoma of the stomach without demonstrable metastases. The only abnormality of the cardiovascular apparatus was moderate arteriosclerosis of the peripheral arteries. A general anesthetic was administered on January 20, 1947, and a total gastrectomy was performed through a thoracoabdominal incision. Throughout the procedure, the patient was turned on the right side and inclined about 15° posteriorly from the lateral position.

The technic of resection was that of postcolic anastomosis. There was difficulty in suturing the esophagus to the jejunum, and to provide adequate exposure of the tissues, the diaphragm was retracted vigorously. At some time during the application of this force, there was an abrupt onset of tachycardia, the heart rate rising from 80 to 120 per minute. Except for this transient disturbance, the patient's operative course was uneventful. During resection, a liter of whole blood and an equal amount of physiologic saline solution were administered intravenously.

When returned to the ward, the patient was in good condition, but within 4 hours he developed the signs of circulatory collapse: the blood pressure fell from the normal level of 120/80 to 70/56, and the heart rate rose to 130 per minute. The reason for shock was obscure, physical examination providing no clues and nothing remarkable being revealed by a radiogram of the chest taken in the upright position. The patient rallied when given a transfusion of 500 cc of whole blood, but throughout the 1st postoperative night, he was apprehensive and complained of breathlessness and a sensation of pressure on the chest. He was provided with an oxygen tent and sedated with morphine.

On the following morning, he described severe substernal pain, and for the first time, an irregularity of the pulse was noted. The blood pressure was 100/70, the heart rate 100, and the respiratory rate 26. Throughout the ensuing day, the patient's condition remained precarious, but no change in the physical findings was detected.

Despite a transient return of blood pressure to normal on the 2nd postoperative morning, the patient's condition soon deteriorated, and shock supervened. The pulse continued to be irregular, but the type of arrhythmia was never determined since an electrocardiogram was not taken. Apprehension increased, and the temperature rose to 103.6°F,

the respiratory rate to 44, and the heart rate to 120. Coma ensued, and death occurred 53 hours after resection.

At autopsy (L. H. H. 3922) the pericardial sac was distended by several hundred cubic centimeters of partially clotted blood. The site of hemorrhage was an injured coronary vein close to the cardiac apex and on the anterior aspect of the left ventricle. Incision of the subjacent myocardium disclosed a superficial and poorly delineated purplish-red focus measuring 4 mm in depth and up to 15 mm in diameter. The cardiac muscle elsewhere was a uniform reddish brown. There was minimal arteriosclerosis of the coronary arteries. The heart weighed 390 gm.

Microscopical sections revealed a contusion limited to the outer third of the left ventricular wall. Where the coronary vein was involved in the injury, its smooth-muscle fibers were necrotic and separated by erythrocytes and polymorphonuclear leukocytes. In the underlying myocardium, there were degenerative changes in many of the muscle fibers, and between these damaged cells were polymorphonuclear leukocytes, extravasated red blood cells and a few lymphocytes. In the deeper portions of the lesion, the small blood vessels were engorged, and there were foci of extensive interstitial hemorrhage. Sections of heart muscle from other regions showed preservation of normal architecture.

The intestinal anastomoses were intact, and all portions of the bowel appeared to have been viable.

Tumor metastases were found in the regional lymph nodes and deep within the substance of the liver.

There were no other significant findings.

The heart was probably injured during anastomosis of the esophagus and jejunum. The patient's position on the table exposed the anterior aspect of the left ventricle to the retracting force used during that phase of the operation. The postoperative course was puzzling, but since no manipulation of the heart was recalled, hemopericardium did not seem likely. In retrospect, the evidence for that diagnosis was either misinterpreted or went unnoticed. Prior to circulatory collapse, there was no reason to listen for a pericardial rub, and subsequently, the quality of the heart sounds was readily attributed to the precarious state of the patient's circulation. Although taken only an hour after onset of shock, the normal radiogram of the heart was regarded as proof that effusion was not present. It has been taught, however, that the parietal pericardium stretches slowly, and when an effusion forms rapidly, the heart may be compressed before enough fluid has accumulated to be demonstrable roentgenographically.^{12,13} It is reasonable to invoke this concept to explain the postoperative collapse. As the parietal membrane was stretched, the patient's distress was relieved, but when further bleeding occurred, the signs of tamponade returned. Although trauma to cardiac muscle may cause a fall in blood pressure,^{3,14} myocardial damage was of secondary importance in this case.

SUMMARY AND CONCLUSIONS

Eight cases in which a presystolic murmur was considered present by clinical auscultation but was not confirmed by phonocardiographic technic are presented

This auditory illusion was due to several forms of variation of the first heart sound, in all of which the whole sound complex assumed a crescendo configuration. These variations consisted in prolongation of the sound with its later elements of unusual intensity, splitting of the sound in such a fashion that the second element was more intense than the first and prolongation of the sound associated with an auricular gallop coming very close to the first sound. In all these variations, however, the first sound always started after the electrocardiographic Q wave.

Knowledge of such cardiac sound variations is important when one considers that they may produce an auditory illusion leading to serious diagnostic error in that the so-called presystolic crescendo murmur at the apex is indicative of organic mitral stenosis. Our clinical cases definitely show that such an error has been made.

It is for this reason that caution in the interpretation of this physical finding is emphasized, particularly in the uncharacteristic cases in which the murmur may be rather short and faint and in which there are no other convincing evidences of mitral stenosis. In such cases a careful phonocardiographic study is most helpful for a correct clinical diagnosis.

ordinarily associated with coronary occlusion. Signs of congestive failure may evolve insidiously,^{14, 20} but in some cases pulmonary edema has a rapid onset.²¹ The weakness of the heart is usually transient, but the patient's cardiac reserve can be permanently diminished.^{5, 14} Angina is probably a rare sequel, but some of the reported cases are difficult to interpret.^{4, 6, 22, 23} After myocardial trauma, the quality of the heart sounds is apt to be impaired.^{7, 8, 14} There may be a gallop rhythm,^{8, 24} and if dilatation of the heart is sufficient to stretch a valvular ring, a systolic murmur may be produced.⁵

The electrocardiographic changes in contusion of heart muscle may be those usually considered diagnostic of infarction,^{15, 20, 25, 26} in either event the record is only one of the electrochemical changes accompanying focal myocardial necrosis. This should be borne in mind if a tracing is obtained on a patient with cardiac distress after an intrathoracic operation. In such a case a special effort should be made to demonstrate the more common signs of myocardial damage: progressive alteration in T waves on serial records²⁴; transient slurring and notching of the QRS deflection³; and, when injury is chiefly to subepicardial muscle, concordant elevations of the ST segments.²⁴ After a surgical procedure in the chest, however, minor changes in the electrocardiogram must be interpreted with caution.

Many disturbances in cardiac action have been noted after bodily insult. Most post-traumatic arrhythmias must be classified merely as changes in heart action following injury to the body. A few may be related to bruises or tears of the pericardium as surgeons sometimes observe changes in mechanism to accompany pericardiolysis. Damage to heart muscle probably accounts for a larger number, a variety of heart rhythms having been noted with myocardial trauma. The list includes extrasystolic arrhythmia,²⁷ auricular flutter,²⁵ auriculoventricular block,⁶ sinus tachycardia^{14, 24} and auricular fibrillation.^{13, 27} Most of these alterations develop promptly and are transient.

Arrhythmias have been noted in a small percentage of persons convalescing from pneumonectomy and lobectomy.^{9, 11} Auricular flutter, nodal tachycardia, premature auricular beats and auricular fibrillation have been encountered and in most cases the disturbance has occurred in the first postoperative week. In the reports of these arrhythmias inadvertent damage to the heart is not mentioned as a possible cause. The inciting factors suggested are shift of the mediastinum, anoxia of the myocardium and irritation of vagal fibers by suture abscesses in the bronchial stump. A further possibility is that reflexes are stimulated by operative injury to tissues at the root of the lung division of these structures causing alterations in the cardiac rhythm in animal experiments.²⁸

A similar effect has been observed in man.³⁰ It is difficult to determine the role of such factors in postoperative alterations in cardiac action, but the obvious possibility of trauma to the heart should not be forgotten.

In the first case reported above, cardiac damage was associated with a transient tachycardia and an unidentified arrhythmia. In Case 2 extensive myocardial contusion was the most likely cause of a persistent, rapid heart action. Bailey and Betts¹⁰ describe the onset of auricular flutter and fibrillation in a fifty-five-year-old man five days after right pneumonectomy for carcinoma. There is evidence that myocardial injury was sustained by this patient, for serial changes in the ventricular complex are reported. Of additional interest is a statement by Massie and Valle¹¹ that in 6 cases in which arrhythmias did not develop after pneumonectomy, the patients exhibited physical or electrocardiographic signs of cardiac difficulty that were not present preoperatively.

The heart may not be bruised frequently during operations in the thorax, but an important factor in the recognition of cardiac insult is an awareness of the possibility.¹ This has been stressed in reports on patients injured in traffic accidents and applies in the type of case under discussion. A diagnosis of cardiac injury should be suspected in any patient who maintains an unexplained tachycardia after an intrathoracic operation or in whom an arrhythmia or pericardial friction rub develops. It seems important to evaluate circulatory shock, chest pain or congestive failure occurring in the postoperative period.

When there is reason for suspicion, a glance at the anesthesia sheet from the patient's operation may be rewarding: an abrupt onset of rapid heart action suggesting a moment of cardiac insult. In the 2 cases presented the onset of tachycardia coincided with damage to the heart. If electrocardiograms are taken before and after operation in similar cases better evidence of cardiac injury may be available, especially when precordial leads can be studied.

A few therapeutic considerations deserve mention. When sinus rhythm is restored after postoperative arrhythmia, quinidine has been recommended as prophylaxis against recurrence of the disturbance in the convalescent period.⁹ A plea for its use could also be made if extrasystoles or other alterations in rhythm were thought to be due to focal damage of the myocardium, just as the drug is given to protect against ventricular fibrillation when ectopic beats are detected after myocardial infarction. If extensive damage to heart muscle could be inferred from the data, one would be inclined to prolong the period of bed rest. Chiefly, however, the treatment of injuries such as these is expectant, the emphasis being on prevention.

CASE 2 (C C H 294957) A 44-year-old man had a bronchiogenic carcinoma at the junction of the lingular and left-upper-lobe bronchi. The patient gave no history of cardiovascular disease, nor did examination reveal evidence of any. On April 29, 1948, left pneumonectomy was performed with the patient supine, an anterior incision being used. Anesthesia was maintained with intratracheal ether.

The chest wall was opened by resection of the anterior half of the left fourth rib, and when the mediastinal pleura had been incised, dissection of the root of the lung was begun. No difficulties were encountered until an attempt was made to isolate the inferior pulmonary vein. Much of this vessel had been surrounded by tumor, and to obtain a segment suitable for ligation and transection, pericardiectomy was necessary. The intrapericardial portion of the vein was overlaid by the left auricle, and until the heart was retracted anteriorly and toward the opposite side, the vein was inadequately exposed. The ring sponge usually employed for this purpose proved ineffective, and use was made of a flat metal blade covered with gauze and placed against the anterolateral aspect of the left ventricle.

Retraction was as gentle as possible, the surgical team being aware of the danger in this maneuver, but the heart was allowed to beat against the blade for a sufficient length

of time to dislodge the instrument repeatedly. During this interval, the pulse rate increased from 90 to 120 per minute, a lesser degree of tachycardia persisting thereafter. Many premature contractions also occurred, but these were quickly abolished by spraying of the pericardium with a 2 per cent procaine solution. The pneumonectomy was readily completed. During the operation, a transfusion of 2 liters of whole blood was given.

Except for the disturbance in cardiac action, resection was uncomplicated, and the patient appeared to have withstood the procedure well. Postoperative bronchoscopy revealed a tightly closed bronchial stump. To adjust the intrapleural pressure, several hundred cubic centimeters of air were aspirated from the left hemithorax, and the trachea, previously displaced to the right, returned to the midline. Approximately 5 minutes later, respirations and heart beat suddenly ceased. Artificial respiration and intracardiac administration of epinephrine were of no avail.

At autopsy (C C H 17536) the incised pericardium lay to the side of the heart. The right auricle and ventricle were dilated and engorged with blood. Over the anterolateral aspect of the left ventricle, the subepicardial fat was hemorrhagic. The underlying muscle was discolored purplish red and was softer than elsewhere, this lesion involving from the outer fifth to half of the ventricular wall and extending from the auriculoventricular groove to within 4 cm of the cardiac apex. In other regions the myocardium was a uniform reddish brown. There was slight arteriosclerosis of the cor-

onary arteries. The heart weighed 450 gm, but there were no valvular deformities.

Microscopical sections from the purplish-red focus in the left ventricle disclosed an extensive contusion. The small blood vessels were hyperemic, and the pattern of myocardial fibers was altered by foci of interstitial hemorrhage (Fig 1). In the subepicardial muscle, the fibers were fragmented and devoid of cross striations, but in adjacent tissue there were less marked alterations consisting of pyknosis of nuclei and a granular transformation of sarcoplasm. There was no infiltration of the myocardium by inflammatory cells. Sections from other portions of the heart were not remarkable.

Tumor metastases were found in the regional and retroperitoneal lymph nodes and within the liver and right adrenal gland.

The left hemithorax was free of air but contained 800 cc. of bloody fluid. The sutures in the bronchial stump and the ligatures about the pulmonary vessels were intact.

The viscera exhibited passive hyperemia.

There were no other findings of note.

Although myocardial injury was indicated by the tachycardia that persisted after cardiac retraction, this sign of muscle damage was not appreciated. It was known that the heart had been bruised superficially, but neither the extent of injury nor its possible relation to sudden death was recognized. The fatal outcome was considered due to the shift of the mediastinum that followed aspiration of air from the left hemithorax. In view of the degree of myocardial damage, however, it is difficult to attach cardinal significance to the shift that occurred. Asystole and ventricular fibrillation have been observed after experimental contusion of the heart,^{1, 3} and it is likely that one of these disturbances was responsible for the patient's death.

DISCUSSION

In these cases, the heart was damaged under special conditions, but the wounds are comparable to those in the literature of traumatic heart disease. Similar lesions are recognized as complications of penetrating and compressing injuries to the chest wall.^{4, 7, 15} Cardiac wounds have a variety of sequelae, the best known being some that implicate the pericardium: hemopericardial tamponade, serosanguineous effusion and pericarditis, either fibrinous or purulent.^{4, 8, 13, 18} Of interest is a case report of pericardial calcification and the constriction syndrome following a severe blow to the thorax.⁶ In general, there is less familiarity with the clinical course of patients whose disability is due solely to myocardial damage.

Contusion of heart muscle is responsible for an entity of wide latitude, the signs and symptoms of these injuries resembling those of myocardial infarction. The basis for this parallel is the histopathological similarity of the lesions, each exhibiting necrosis of muscle fibers, interstitial hemorrhage, leukocytic infiltration and the formation of scar tissue.¹ A contusion may produce no symptoms¹⁹ or only mild precordial discomfort.^{4, 8} Circulatory shock or substernal pain may be the dominant feature,^{6, 14} the picture resembling that

bladder to empty itself. This increased pressure results in an interference with the blood supply and the lymphatic drainage, and this in turn may be followed by the development of gangrene of the organ — usually beginning in the fundus since that portion is farthest from the source of blood supply, or the stone itself may erode the edematous gall-bladder wall. The course of events then leads to perforation of the viscus, which may be of five types: perforation with communication with another viscus (usually duodenum, colon or stomach), formation of a pericholecystic abscess, acute free perforation, perforation into the liver, and external perforation. Although this entire sequence of events may be interrupted at any time if the stone becomes dislodged and the contents of the gall bladder are evacuated through normal channels, the process is usually irreversible.

PATHOLOGY

According to Hallendorf and his co-workers,² histologic evidence indicates that circulatory disturbance plays the most important role in the pathogenesis of gangrenous cholecystitis, and late evidence of infection, a rare and lesser role. Necrosis, engorgement of the venous and lymphatic systems, intramural hemorrhage and edema, with mucosal desquamation, fibroblastic activity and early lymphocytic infiltration followed by a late invasion of polymorphonuclear cells were the consistent microscopical features in their series. It is interesting that when operation was done within the first twenty-four hours of the onset of an attack, extensive edema and marked venous congestion were characteristic features.

In addition, the Boston City Hospital series of gall bladders by definition all had to show a complete necrosis of all layers of the wall in at least one area to be included in this review.

STATISTICAL REVIEW

Fifty-four females and 46 males comprised this series, a sex distribution quite in distinction to

TABLE 1 Age Distribution

that of acute cholecystitis, which occurs five times as frequently in females.³ Eighty-six of these patients were over the age of fifty (Table 1). Again, this is in marked contrast to the age distribution

of acute cholecystitis, which occurs in general in a younger age group. The duration of present illness before seeking hospital admission is shown in Table 2, from which it can be seen that 72 patients entered during the first week of their illness. A history of chronic gall-bladder disease was present in 90 cases. In the remaining 10 cases a history of previous attacks was not obtained either because

of the advanced age or the moribund state of the patient, or because it did not exist. This is in substantial agreement with the work of Stone and Douglass,⁴ who found a history consistent with previous attacks of acute gall-bladder disease in 100 per cent of 38 cases of perforated gall bladders in their series.

The complaints of the patients and their relative frequency were listed; 96 patients (all patients who were reliable on this point) complained of abdominal pain, and 82 were able to localize this pain to the right upper quadrant. In only 26 patients was the usually described radiation of pain to the right subscapular area elicited. The remaining 14 could not localize their pain but complained of pain "all over" the abdomen, 62 of the patients were nauseated, and 60 vomited once or more during the course of their present illness. Chills and fever were found in only 7 cases. Right-upper-quadrant tenderness was demonstrated in 82 patients, and was the most prevalent sign. And generalized abdominal tenderness was found in an additional 15. A right-upper-quadrant mass was found in 61 patients, much more frequently than in other series.⁵⁻⁷

Twenty-seven patients showed varying degrees of distention as noted by the admitting physician. This finding is stressed because the presence of distention in several cases was responsible for shifting the suspicion of disease from the gall bladder to another and innocent organ. In this regard, gall-stone ileus, the result of perforation of the gall bladder into the intestinal tract, has received widespread attention in the literature. Blain and Harkins,⁸ in their series of 41 cases of gall-bladder perforation, had 11 cases (or 27 per cent of the series) associated with signs of intestinal obstruction. However, only 5 of these 11 cases were examples of classic gallstone ileus. The other 6 were produced by per-

SUMMARY

Two cases of fatal contusion of the heart during surgical procedures on other thoracic viscera are reported. These examples of inadvertent cardiac damage merit attention in view of the great volume of intrathoracic surgery being performed. The prevention of such wounds depends upon an awareness that they are occasionally produced, and to favor the recognition of other injuries of this type, some aspects of cardiac trauma are reviewed.

ACUTE GANGRENOUS CHOLECYSTITIS

WILLIAM J. CLIFFORD, M.D.*

BOSTON

GANGRENE of the gall bladder is a complete necrosis of a portion of the wall in one or more areas, and is frequently followed by perforation. Since 1844, when James Duncan,¹ of the Royal Infirmary in Edinburgh, reported a case, the clinical application of the pathology of this disease has been a source of interest and concern to internists and surgeons. And particularly in recent years the question of the proper time for surgical intervention has been much discussed.

This paper is a report of 100 consecutive cases of acute gangrenous cholecystitis at the Boston City Hospital, where the character of the gall bladder was adequately described by the surgeon, or the specimen clearly reported by the pathologist, or where the patient ultimately came to post-mortem examination. The pathology had to be quite precise to be included in this series. In cases in which a cholecystostomy only was done, the character of the gall bladder had to be adequately described at some length so that no confusion regarding the nature of the pathology existed. In short, cases in which the operative note failed to supply ade-

quate knowledge about the organ were not included in this series. When the organ was removed or when the patient came to autopsy examination, the gross and microscopical report of the pathologist formed the basis for inclusion. The etiology and the pathogenesis of acute gangrenous cholecystitis are reviewed below, and a statistical analysis of this series of cases is reported because the results are sometimes at variance with previously published statistics, because it appears that acute gangrenous cholecystitis as a clinical entity per se is not generally appreciated and because further emphasis on the lethal nature of the disease seems necessary.

ETIOLOGY

Attacks of acute biliary colic result from obstruction of the cystic duct, usually by a stone rather than by any primary inflammatory condition. Irrespective of what creates the first obstruction, it is apparent that profound vascular and lymphatic stasis may occur so abruptly that virtual infarction ensues. Acute obstruction leads to increased intravisceral tension, and colicky pain results from the strenuous efforts of the muscular gall

*Senior assistant resident, Third Surgical Service, Boston City Hospital.

bladder to empty itself. This increased pressure results in an interference with the blood supply and the lymphatic drainage, and this in turn may be followed by the development of gangrene of the organ — usually beginning in the fundus since that portion is farthest from the source of blood supply, or the stone itself may erode the edematous gall-bladder wall. The course of events then leads to perforation of the viscus, which may be of five types: perforation with communication with another viscus (usually duodenum, colon or stomach), formation of a pericholecystic abscess, acute free perforation, perforation into the liver, and external perforation. Although this entire sequence of events may be interrupted at any time if the stone becomes dislodged and the contents of the gall bladder are evacuated through normal channels, the process is usually irreversible.

PATHOLOGY

According to Hallendorf and his co-workers,² histologic evidence indicates that circulatory disturbance plays the most important role in the pathogenesis of gangrenous cholecystitis, and late evidence of infection, a rare and lesser role. Necrosis, engorgement of the venous and lymphatic systems, intramural hemorrhage and edema, with mucosal desquamation, fibroblastic activity and early lymphocytic infiltration followed by a late invasion of polymorphonuclear cells were the consistent microscopical features in their series. It is interesting that when operation was done within the first twenty-four hours of the onset of an attack, extensive edema and marked venous congestion were characteristic features.

In addition, the Boston City Hospital series of gall bladders by definition all had to show a complete necrosis of all layers of the wall in at least one area to be included in this review.

STATISTICAL REVIEW

Fifty-four females and 46 males comprised this series, a sex distribution quite in distinction to

of the advanced age or the moribund state of the patient, or because it did not exist. This is in substantial agreement with the work of Stone and Douglass,⁴ who found a history consistent with previous attacks of acute gall-bladder disease in 100 per cent of 38 cases of perforated gall bladders in their series.

The complaints of the patients and their relative frequency were listed; 96 patients (all patients who were reliable on this point) complained of abdominal pain, and 82 were able to localize this pain to the right upper quadrant. In only 26 patients was the usually described radiation of pain to the right subscapular area elicited. The remaining 14 could not localize their pain but complained of pain "all over" the abdomen; 62 of the patients were nauseated, and 60 vomited once or more during the course of their present illness. Chills and fever were found in only 7 cases. Right-upper-quadrant tenderness was demonstrated in 82 patients, and was the most prevalent sign. And generalized abdominal tenderness was found in an additional 15. A right-upper-quadrant mass was found in 61 patients, much more frequently than in other series.⁵⁻⁷

Twenty-seven patients showed varying degrees of distention as noted by the admitting physician. This finding is stressed because the presence of distention in several cases was responsible for shifting the suspicion of disease from the gall bladder to another and innocent organ. In this regard, gall-stone ileus, the result of perforation of the gall bladder into the intestinal tract, has received widespread attention in the literature. Blain and Harkins,⁸ in their series of 41 cases of gall-bladder perforation, had 11 cases (or 27 per cent of the series) associated with signs of intestinal obstruction. However, only 5 of these 11 cases were examples of classic gallstone ileus. The other 6 were produced by per-

foration with resulting inflammatory or paralytic ileus or mechanical obstruction as by adhesions. In this series there were 4 cases of proved gallstone ileus, and 23 cases of paralytic ileus produced in a fashion comparable to that described in the last group of Blain and Harkins.⁹ These cases will be reported in detail later. Distention, then, on either basis is not uncommon in gangrenous cholecystitis.

Jaundice was present in only 9 cases and was obviously of little diagnostic significance in this

Totals	100		100

condition. The majority of patients (69) had white-cell counts ranging from 10,000 to 25,000. The temperature and pulse ranges are shown in Table 3.

Eighty-five patients had perforations at the time of examination, or evidence of previous perforation such as localized abscesses, gallstones within the lumen of the intestine, stones free in the abdominal cavity, free generalized peritonitis and multiple and recent adhesions indicative of recent perforation. Eighty-five patients showed peritonitis, and in 23 cases in this group a generalized peritonitis was observed. The remaining 62 patients had well demonstrated evidence of the body's attempts to define and restrict the spread of infection, such as adhesions or omentum walling off the perforated viscus and resulting in a localized type of peritonitis.

Acute free perforation carries a mortality three times that of localized peritonitis.⁴ Fortunately, free perforation is less frequent than localized peritonitis.⁹ This is explained on the basis of the position of the gall bladder sheltered as it is by the liver, because of the inherent distensibility of the organ, and because the omentum is accessible and readily mobilized to envelop the affected viscus. For these reasons acute gangrenous cholecystitis is not an emergency of the high order of acute appendicitis. Nevertheless, free perforation occurred often enough in this series to warrant its serious consideration by the attending surgeon in deciding to operate.

Stones were present in 89 patients in this Boston City Hospital Series. Ninety-eight per cent of the Mayo Clinic Series showed stones in the gangrenous gall bladder or cystic duct, and Hallendorf² points out that this high percentage was the result of a careful search of the edematous and distorted specimen for stones that had been overlooked by the surgeon or the pathologist on the day of operation.

It is my impression that the more carefully the specimen is searched for stones, the more frequently they will be discovered. Most investigators^{5, 10, 11} agree that gangrene and perforation rarely occur except in association with stones.

Figure 1 shows the mortality figures in this series of 100 cases. Several striking facts are immediately apparent. In this particular series 8 patients not coming to operation died. This figure may be misleading, for in a check of the records of these patients it is noted that at least 6 and possibly 7 were in extremis on entry, or had severe concomitant disease, and it appears in retrospect that the surgeons based their decision not to operate on the firm conviction that the patient was beyond human succor. Three of these patients refused surgery.

Among the 47 patients operated on within the first forty-eight hours of their present illness, there

FIGURE 1 *Mortality in 100 Cases of Acute Gangrenous Cholecystitis*

were 5 deaths, 3 after cholecystectomy, and 2 after the less radical procedure of cholecystostomy — a mortality of 10.6 per cent in this group. From this time until the beginning of the third week 40 patients were operated on, and the over-all mortality of this group was 50 per cent irrespective of the type of surgical procedure elected.

Again, the mortality dropped appreciably in the group of cases coming to operation within the third to the sixth week, with 1 death among 5 cases — a mortality of 20 per cent.

DISCUSSION

Of all cases of acute cholecystitis 13 to 24 per cent go on to gangrenous cholecystitis,^{12, 14} which should negate the contention that perforation is a rare and seldom fatal complication. In 12,000 consecutive routine autopsies at the Los Angeles

County Hospital 1 in 375 persons succumbed to a perforated gall bladder.⁹

The treatment of this disease is surgical. In the etiology of cholecystitis infection plays a late and minor role.^{16,17} Furthermore, it has been shown experimentally in dogs¹⁸ that sulfonamides given parenterally will not be recovered from the gall bladders of animals whose cystic ducts are completely obstructed. Zaslow, Counsellor and Heilman¹⁹ have proved the same lack of recovery in human beings with penicillin and streptomycin. This is a significant observation, since in most cases of acute cholecystitis and in all cases of acute gangrenous cholecystitis obstruction of the cystic duct is present. Therefore, the value of these drugs is definitely limited in cases in which obstruction is present.

The mortality of acute cholecystitis is commonly in direct proportion to the percentage of gangrene and perforation. It seems better judgment to operate on all patients with acute cholecystitis early — that is, within the first forty-eight hours if possible, and at least as soon as they have been adequately prepared. Indeed, this view is now maintained by surgeons of large experience with this disease.^{4,9,12,20-22}

The over-all mortality in this Boston City Hospital Series was high (34 per cent), the mortality for those operated on was 28.2, and that for the group not operated on was 100 per cent. The advanced age of the patients, with the frequent association of acute gangrenous cholecystitis and degenerative diseases, particularly the cardiovascular diseases, and the generally poor state of nutrition of these older people tend to raise both the morbidity and the mortality. The mortality, however, is a largely preventable one. When it is realized that gallstones are never benign, that gall bladders containing them should be removed promptly and that patients with acute gangrenous cholecystitis should be promptly operated on the mortality figures should be lowered considerably.

Early adequate preoperative preparation, proper anesthesia, quick and gentle surgery and careful postoperative care by surgeon and internist will also lower the mortality substantially. Most surgeons^{2,10} agree that whenever possible a cholecystectomy should be performed. If in the judgment of the surgeon the general condition of the patient will not stand this procedure, the less desirable cholecystostomy should be elected.

In the Boston City Hospital Series almost 75 per cent of the patients presented themselves early in the course of the present illness, which leads one to believe that by earlier recognition of this entity of gangrenous cholecystitis, prompt operation with its lowered mortality may be offered more frequently to these patients.

Proceeding further with this course of reasoning one might postulate that all diseased gall bladders,

especially those with stones, should be removed early. The myth of "silent stones" is gradually disappearing in the face of accumulating statistics.

SUMMARY

The etiology and pathogenesis of acute gangrenous cholecystitis are briefly reviewed.

Acute gangrenous cholecystitis occurs almost equally in males and females, usually over the age of fifty, who often have a past history of biliary disease of long standing. Their chief complaint is pain in the right upper quadrant, frequently with nausea and vomiting. Right-upper-quadrant tenderness, a mass in the same location and an elevated temperature, pulse and white-cell count complete the clinical picture.

Perforation is a frequent late complication occurring almost invariably in gall bladders with stones.

The lowest mortality of all groups in this series, operative and nonoperative alike, was found in patients operated on within the first forty-eight hours of entry.

KAPOSÍ'S VARICELLIFORM ERUPTION*

Report of a Case

STANLEY S. FREEDMAN, M.D.,† AND JOHN T. BARRETT, M.D.‡

PROVIDENCE, RHODE ISLAND

IN 1944 Dr Herbert A. Wenner¹ wrote "The integument of infants and children ill with eczema is frequently infected by bacterial opportunists and less frequently by filtrable viruses." The former is easily recognized, the latter, because of its infrequent occurrence may easily be overlooked. The case presented below is that of an eight-month-old baby who had had intractable atopic eczema since the age of six days. At the age of eight months his eczema became complicated by the disease now known as Kaposi's varicelliform eruption, which is said to be due to a filtrable virus.

This skin disease was first described by Kaposi² in 1887, who depicted it as "an alarming complication of infantile eczema." Although at that time it failed to attract wide attention, it has aroused great interest in recent years. Thus, one now finds a considerable number of cases described in the pediatric, dermatologic and allergic literature.

CLINICAL DESCRIPTION

The features of Kaposi's varicelliform eruption are striking. The original description by Kaposi was vividly repeated in the case presented below. Almost all the reported cases have occurred in infants and young children, although the disease has also been reported in adults.^{3,6} Invariably, there is a pre-existing atopic eczema. The frequent coexistence of allergic eczema and Kaposi's varicelliform eruption is probably coincidental and may be accounted for by the fact that in young children atopic eczema is by far the most chronic and the most frequent skin disease. In a review of 67 cases of Kaposi's varicelliform eruption by Barton and Brunsting⁵ in 1944 only 53 occurred in patients having pre-existing allergic dermatoses. The remaining 14 patients had nonallergic skin diseases.

Typically, the disease manifests itself with an elevated temperature, which reaches 105°F on occasion and may remain elevated for eight to twelve days. There is restlessness and prostration. Nausea and vomiting or diarrhea, or both, may occur. Intense pruritus is a constant finding. The skin lesions occur early on the pre-existing eczematous sites, and only later invade adjacent intact skin. The lesions are discrete vesicles and range

from 2 to 3 mm in diameter. They appear in crops, may become umbilicated and may assume a dark-brown discoloration. The vesicles contain clear fluid, except when, as a result of external contamination, infection renders them turbid. Sometimes, a number of vesicles, especially near skin folds or near the mouth, coalesce, break down and form large, bleeding, raw, granular surfaces (Fig. 1). Complete remission of the acute process takes place in all patients who survive. The lesions fade away

FIGURE 1 Photograph Taken on the Tenth Day of the Disease, Showing the Large Granular Bleeding Surface in the Left Popliteal Space

after about two weeks, leaving, however, the original eczema to plague patient and doctor alike.

Complications have been reported. These include bronchopneumonia, suppurative lymphadenitis, otitis media and alopecia.

Fatal cases do occur. Fries,⁶ reviewing 82 cases in the literature, states that in these there was a 20 per cent mortality. In a recent New York City epidemic of 43 children, 2 died, giving a mortality of 4 per cent. Wenner¹ reports 1 death in his 3 cases. McLachlan,⁷ in 1936, reported 5 deaths in 16 cases — a mortality of 31 per cent.

‡Senior resident pediatrician, Department of Pediatrics, Rhode Island Hospital.

ETIOLOGY

Until recent years the etiology was obscure. Kaposi² frankly stated that he was "ignorant of its causation." A variety of infectious agents have been under suspicion. Pyogenic staphylococcus, streptococcus, fungi and, recently, filtrable viruses have been implicated. Existing evidence, however, favors the idea that certain strains of filtrable viruses will, when conditions are favorable, invade the body of a patient ill with eczema and produce this disease. The specific virus involved is controversial: some observers implicate the virus of vaccinia, and others the virus of herpes simplex.

Fries et al.,⁶ in 1948, reported 16 cases of Kaposi's varicelliform eruption. All 16 cases occurred in eczematous babies. These cases were part of an epidemic of 43 cases of Kaposi's varicelliform eruption that occurred in New York City in 1947. As will be recalled, New York City conducted a mass vaccination program in 1947 in which 6,350,000 persons were vaccinated against smallpox. The outbreak of this disease started three weeks after the program began, and ended three weeks after the program was completed. It is interesting to note that none of the 16 patients discussed by Fries had been vaccinated prior to the outbreak, and when vaccination was attempted after recovery, all gave immune reactions. These facts appear to implicate the virus of vaccinia as the etiologic agent.

In 1941 Ronchese⁵ reported 2 cases of this disease, which he also believed to be caused by the virus of vaccinia. He argued against the virus of herpes simplex, and asked "Why is herpes simplex so common and Kaposi's varicelliform eruption so rare?" and "Why does Kaposi's varicelliform eruption not recur, whereas recurrences are characteristic of herpes simplex?"

In recent years, however, a number of observers^{1, 4, 9, 10} have succeeded in identifying the virus of herpes simplex from the vesicular lesions in a significant number of cases. An exhaustive study on the etiology of this disease was presented by Wenner¹ in 1944. He observed 3 infants who had infantile eczema complicated by Kaposi's varicelliform eruption. He was able to isolate a filtrable virus in the cutaneous lesions of all the infants, and in the brain of one who died of the disease. From serologic studies and from immunization studies done on rabbits he concluded that the viruses thus isolated were "closely related with the virus of herpes simplex."

In 1947 Ruchman, Welsh and Dodd⁹ reported 4 cases of Kaposi's varicelliform eruption, and in each the virus of herpes simplex was recovered from the cutaneous lesions. In 1948 Ruchman and Dodd⁴ reported 5 additional cases. In 3 the virus of herpes simplex was isolated. In the remaining 2 cases,

in which isolation of the virus was unsuccessful, the antibody titer against herpes simplex rose during convalescence. These authors consider the virus of herpes simplex the etiologic agent.

In 1947 Barker and Hallinger¹⁰ and in 1948 Ruchman and Dodd⁴ called attention to the wide range of infections in which, in recent years, the virus of herpes simplex has been demonstrated.¹¹⁻¹⁵ In the study of Barker and Hallinger the suggestion is made that cases of Kaposi's varicelliform eruption in which the virus of herpes simplex is demonstrated should be named systemic herpes simplex, rather than Kaposi's varicelliform eruption. In the opinion of these authors the latter represents a "wide variation of a syndrome," whereas these virus infections produce definite systemic symptoms in addition to diffuse cutaneous manifestations.

After reviewing the literature, we have reached the conclusion that although the clinical features of this disease are well defined, the causative agent may vary in different cases. Thus, the syndrome of Kaposi's varicelliform eruption may be caused by the virus of herpes simplex or vaccinia, or even by a virus as yet unidentified. In the final analysis it is the identification, by laboratory methods, of the specific virus involved that determines the exact etiologic agent.

CASE REPORT

G. R., a 7-month-old male infant, entered the Rhode Island Hospital on November 8, 1948, because of an unusual skin eruption, accompanied by an elevated temperature of 8 days' duration. The mother stated that the rash was "entirely new and different from the old eczema, which he has had all his life."

The family history was not remarkable. There were 8 siblings. The parents and siblings were well and had always been free from allergic manifestations.

The baby was full term, delivery was normal, and the birth weight was 9 lb., 14 oz. Atopic eczema was noticed at the age of 6 days, first appearing on the face, and quickly spreading to the shoulders, arms and legs. The lesions were always severe and had persisted until the admission, with only brief periods of incomplete healing now and then. There were no other prior illnesses. He had not been inoculated against any contagious disease. There was no contact with a recently vaccinated person. Skin tests produced minimal reactions (erythema but no whealing) to cow's milk and egg white and a negative reaction to wheat. In spite of extensive dietary manipulations, during which milk, wheat and eggs were excluded, there was no sustained improvement in the eczema. Development and nutrition, however, were normal. On two previous occasions the baby had been hospitalized for eczema, but only temporary improvement had resulted each time.

The present illness had begun with an elevated temperature and with the appearance of an unusual rash, which was superimposed upon the pre-existing eczema.

Physical examination revealed a well developed and well nourished infant who exhibited constant scratching. The throat was normal. The eardrums were bright red but not bulging. The posterior cervical lymph nodes were soft and measured 0.5 cm in diameter. The inguinal and axillary lymph nodes were somewhat enlarged. Cardiac rhythm and sounds were normal. The lungs were clear. The abdomen and extremities showed no abnormalities.

The skin lesions, when they first appeared, consisted of discrete raised flecks of ecchymosis, and occurred on the face only. In a day or two the lesions became vesicular, larger and more raised, and extended to all sites of the pre-existing eczema. Many but not all of the vesicles showed brownish

discoloration (Fig 2) In a few areas, especially those about the mouth and natural body creases, the vesicles had ruptured and had become confluent, producing large bleeding surfaces The contents of the vesicles were serous and not purulent Later, a few of the vesicles invaded neighboring healthy skin Beneath the lesions thus described was the old oozing eczema The temperature ranged between 101 and 105°F and continued for about 12 days

The height of the disease was reached on the 7th day after the onset, when the patient appeared to be very listless and

cent neutrophilic myelocytes Examination of the urine showed a specific gravity of 1.022, with a pH of 5, a trace of protein and sugar and a positive acetone reaction Smears made from the vesicular exudates demonstrated a rare pus cell, a rare gram-positive coccus and a rare gram-negative rod (the latter two were considered contaminants) A culture taken of the exudate produced a growth of *Staphylococcus aureus*, coagulase positive (This was thought to be a skin contaminant) A blood culture was reported positive for *Staph. albus*, coagulase negative No facilities were available for virus studies

DIAGNOSIS AND TREATMENT

The diagnosis of Kaposi's varicelliform eruption is easily made, when one remembers the clinical features, the characteristic lesions and the almost exclusive occurrence in eczematous children The treatment is symptomatic and supportive Special attention should be given to the prevention of scratching This requires careful restraining of arms and legs, and a minimum of bedclothes We found that a covered cradle placed over the trunk and extremities was helpful The gentle application of a suitable mild antipruritic lotion, such as phenolized calamine lotion, or a drying agent such as Burow's solution 1:40, will also help The use of antibiotic drugs, such as penicillin, we think is indicated, not against the prevailing virus organism but for the protection against complications Although the disease is not considered to be contagious, direct contact should be avoided, and in the hospital, barrier technic should be instituted *

SUMMARY

Another case of Kaposi's varicelliform eruption is herewith presented The diagnosis was made on the basis of its clinical features The prevailing views on its etiology are reviewed

It is believed that if this rare condition is kept in mind the diagnosis will be made without much difficulty It is likewise thought that by the employment of antibiotic drugs, complications and deaths will be avoided

183 Waterman Street

Fries recently mentioned a communication from Dr. Marion B. Sulzberger, who reported the demonstration by Baer and Miller of the effectiveness of local and systemic administration of aureomycin in 2 severe cases of Kaposi's varicelliform eruption that were presumably due to the virus of herpes simplex

MEDICAL PROGRESS

MECHANICAL AND THERMAL INJURY FROM THE ATOMIC BOMB*

HERMAN E. PEARSE, M.D.,† AND J. THOMAS PAYNE, M.D.‡

ROCHESTER, NEW YORK

THE energy released by the explosion of an atomic bomb is of a degree unsurpassed by anything known to man. In addition to large amounts of radioactive energy, great quantities of thermal and mechanical energy are released. It is the latter two that cause the great physical damage and large numbers of casualties. Photographs of

Radiation injury is not considered here. This arbitrary separation of the medical effects of the bomb makes the approach to the problems raised more simple, but it should be borne in mind that one person may have all three types of injury and, as pointed out by Parsons,⁴ can be killed "three times over." For purposes of clarity, therefore, the remainder of this paper is devoted only to the traumatic and thermal effects of the bomb.

Trauma of the primary type, due to blast alone (Table 1) is difficult to evaluate. Apparently the

the destruction done by the atomic bombs in Japan emphasize the magnitude of the mechanical and thermal effects, and give mute evidence of the human demoralization and disorganization that takes place after such catastrophes.

Injuries to personnel from the atomic-bomb explosion have been divided into three categories: radiation injury, trauma and burns (Table 1).

*From the Department of Surgery, University of Rochester School of Medicine and Dentistry.

This paper is based on work performed under contract with the United States Atomic Energy Commission at The University of Rochester Atomic Energy Project, Rochester, New York.

This paper is adapted from lectures that were given on January 27 and April 7, 1949, for the Medical Indoctrination Course, Armed Forces Special Weapons Project, and are to be published by the Government Printing Office in the *Radiological Defense Manual*, Volume III.

ATOM BOMB BLAST DAMAGE

FIGURE 1 *Relatively Constricted Zone of Damage (in Black), Which Should Be Compared to the Spread of Thermal Effects (Fig 3)*⁵

blast did not have the trip-hammer effect of other high explosives but was more like a sudden, violent gust of hot air, which lasted over a relatively long period.⁵ Pulmonary and other visceral blast effects were not noted, nor was the incidence of perforated eardrums excessively high.¹

The distribution and amount of secondary trauma were dependent on the distance from the ground center of the explosion. Figure 1 illustrates the approximate zones of damage. Within a radius of 2.4 km, there was complete collapse of the native wooden buildings. Within this zone, the incidence

explained by the fact that they were relatively minor, and permitted the patient to seek treatment

ATOM BOMB THERMAL DAMAGE

FIGURE 3 Range of Thermal Damage, Which Was Probably the Greatest of That Due to Any of the Forces Unleashed by the Atomic-Bomb Explosion (Compare this with Figure 1³)

The lacerations were of interest in that they were largely due to flying glass fragments. These frag-

FIGURE 2 Scarring Resulting from Multiple Lacerations Caused by Flying Glass Fragments, As Photographed Some Twenty-One Months after Injury

The wounds were probably infected as evidenced by the wide scars. (Photograph by Signal Corps, United States Army)

of mechanical injury was very high, dropping off gradually to less than 14 per cent beyond 2.7 km.⁵

The injuries consisted of fractures, lacerations and contusions. The low incidence of fractures — at least in the hospital given as the usual example (Table 1)

TABLE 2 Components of Atomic-Bomb Flash⁵

Temperature	Estimated at over 4000 C
Transmission	Largely by radiation
Spectrum	High in ultraviolet High in infrared High in visible light and brilliancy
Duration	Less than a second

— is probably because persons with major fractures were unable to seek treatment, or perished in the collapsed buildings. There is no evidence that these fractures were unusual in any respect. The contusions did not seem to be remarkable. The high incidence reported for these injuries is probably

FIGURE 4 Flash Burn of Moderate Severity and Extent, Photographed Early in the Course of Healing

The distribution of the lesion shows that the patient was walking in an axis, perpendicular to the explosion, with the right side facing the bomb, the left arm swinging forward, to expose the medial surface, and the right arm hanging down by the side. The lack of burning in the sternal depression demonstrates the effect of even the little protection afforded by the protrusion of the right anterior chest wall. The eyes were not severely damaged, the swelling probably being attributable to the inflammatory effects of adjacent burns. (United States Army Medical Museum)

ments were so small that clothing protected the patient in some cases. In other circumstances

fragments were of such size as to make removal difficult. Multiple lacerated wounds were very common (Fig 2).

The exact amount of morbidity and mortality attributable to the traumatic factor in the Japanese explosions will probably never be known, because, immediately after the blasts, fire and disorganization prevented adequate and early rescue measures. It seems reasonable, however, to suppose that both the morbidity and mortality from the traumatic factor could be greatly reduced by a properly organized and functioning rescue system instituted early. Once the casualty is in the hands of medical personnel, treatment itself should present no unique problem other than that of materiel. It might be

The largest and most important category (numerically) of atomic-bomb injury is the burn. This group of injuries also can be divided into primary (due to the bomb, per se) and secondary (due to burning buildings and so forth) (Table 1). Tsuzuki⁶ estimated that about 90 per cent of patients treated within the first few days were burned. LeRoy² estimated that less than 5 per cent of the

FIGURE 5. Mild Flash Burn of Exposed Portions of the Skin, As It Appeared Sixty-Three Days after the Nagasaki Explosion. The protected portions are outlined by the undershirt. The burned portions of the face, shoulders and arms were of "walnut-stair" color.⁷

important to treat these cases (particularly the lacerations) vigorously and in a definitive manner, all possible effort being made to effect healing within the first two weeks, for thereafter, the major effects of irradiation sickness begin to appear. Even though the casualty received a sublethal dose of ionizing irradiation, his unhealed wounds would break down, infection would supervene, and death might ensue from a relatively minor injury.

FIGURE 6. Residue of a Mild Burn with Color Changes between the Burned Area and the Area Protected by the Slip, Photographed Two Years after Burning.

Note the scarring beneath the right scapula where the skin was burned through adherent or moist clothing. (Photograph by Signal Corps, United States Army.)

burns were caused by the fires in buildings and debris. There then remains a group consisting of about 85 per cent of all casualties treated within the first week who were suffering from primary atomic-bomb burns.

The energy that produced this high incidence of primary burns had certain characteristics. The heat was intense, and largely radiant, with extremely high ultraviolet, visible and infrared components. The exposure was very brief⁸ — probably less than a second (Table 2).

As with the traumatic factor, the thermal effects were closely related to the distance from the ground center of the explosion (Fig 3), but had a longer radius. This explains the high incidence of severe burns uncomplicated by blast or ionizing irradiation. These are the reparable casualties.

Because the thermal energy was largely radiant, effects were modified by shading of buildings, and the angle of incidence of energy. Clothing served as sufficient protection in some cases; light-colored

clothing being better than dark, however, if the clothing was adherent to the skin by perspiration, burning occurred even through this protection.

The burns produced were of varied severity and distribution. "Profile" burns were common (Fig 4), the parts directly exposed to the flash being burned most severely. Mild burns occurred, without vesication. These burns might be sustained beyond 3 km from the center and were intensely erythematous within the few days immediately after exposure. However, they gradually became

FIGURE 7 Contracture and Ulceration, Resulting from an Inadequately Treated Flash Burn on the Dorsum of the Right Arm. Photographed Two Years after Burning⁵ (Photograph by Signal Corps, United States Army)

pigmented finally attaining a "walnut-stain" hue. This was most commonly seen on the face and therefore was called the "mask of Hiroshima." The pigmentation began to fade within a few months in some persons but in others has persisted for years⁶ (Fig 5).

More severe burns, corresponding to second-degree, moderate temperature burns, were frequent, but apparently did not carry the high mortality for large areas seen in the latter type of burn (Fig 4). Vesication was present, and often appeared within a matter of minutes. More severe burns were sustained, and complete transfascial burns were found among the dead.

The course of these burns was, in some cases, benign, many healing with little or no treatment, despite some superimposed radiation sickness. However, the healing was more often arrested, or the burn turned to a serious one by the subsequent lack of treatment and resulting complications. The sequelae were remarkable for the large number of contractures and the high incidence of keloids (Fig 6, 7 and 8) — higher than that noted in flame burns in Tokyo and other Japanese cities.⁸ Both these complications may well have been due

to the lack of adequate treatment and the extremely poor nutritional state of the people. These keloids seem to become inactive with the passage of time.

The low incidence of flame burns has been explained on the basis of the time lag between the bomb burst and the onset of fires. It is said that people escaped the fires if they were not severely injured. Those trapped in burning buildings perished, and no reliable figures are available on their number.

The care of a single traumatic or burned casualty, or a small group of casualties of such types as might result from an atomic-bomb explosion, would present somewhat of a problem. Certain essential supplies and facilities would be required. These

FIGURE 8 Keloids Following an Extensive Flash Burn of the Back, Photographed Twenty Months after the Injury^{5,8}. The uneven distribution of the keloid over the burned area is characteristic. (Photograph by Signal Corps, United States Army)

would include surgical dressings of all types, morphine and sedatives and so forth, antibiotics and similar agents, whole blood and plasma, hospitalization or adequate shelter of some type, or both, medical and technical personnel. The volume of materiel and the number of personnel required to treat a single severely burned patient (approximately 40 per cent of the body surface) in a modern hospital is illustrated in Fig 9. Many such patients do not survive, despite this treatment.

The figures given for casualties at Hiroshima and Nagasaki are presented in Table 3. From these

it can be calculated that the severely burned group alone, at Hiroshima, probably exceeded 34,000. If it were necessary to treat all these cases in a manner similar to the case illustrated in Figure

FIGURE 9 Composite Representation of Materials and Personnel Required in the Treatment of One Patient with a 40 Per Cent "Moderate-Temperature" Burn
Data represent the actual situation for a patient treated in a university hospital in the summer of 1947. Subsequent hospitalizations for corrective measures are not included in this diagram.

9 the requirements in personnel and equipment would be staggering (Fig 10). It seemed important, therefore, to re-evaluate the modern therapy of burns, in terms of the burns produced by the atomic bomb. This lesion has been called the flash burn. It is produced by a wave of radiant heat of extremely high intensity, applied over a very brief period. Experimentally, various types of burns have been defined. It has been found that the more intense the heat source, the briefer the period required to produce a burn of a given severity. This is shown graphically in Figure 11, and has been worked out in some detail for the lower-temperature zones, by Henriques and Moritz.⁹ However, the darkened area (adjacent to the question mark) represents the flash zone, and is now being studied in detail in the laboratory. Experimentally, many problems arise in the production of flash burns in the laboratory. The

TABLE 3 Atomic-Bomb Casualties²

GROUP	NO. AT HIROSHIMA	NO. AT NAGASAKI
Population	300,000	200,000
Dead	80,000	40,000
Injured	40,000	25,000
Patients in need of immediate care	85,000	50,000

search for a suitable source is one of the most difficult. Certain criteria must be met to produce an ideal flash: transient duration on the order of 0.1 second, extremely high intensity of a known degree,

a known or obtainable spectral distribution, and safety and convenience of handling. Three general principles of flash production were tried: the release of electric energy from a bank of condenser to create a flash, the creation of a constant high-intensity source directed upon a target for known intervals by means of a shutter or trip mechanism, and the use of substances that burn rapidly with an intense flame. The various sources tried, with appropriate comments, are listed in Table 4. The flash produced by burning magnesium powder has been used clinically to produce a burn, and this agent was therefore chosen.¹¹ The burns produced by the burning magnesium flash have several interesting characteristics, which are strikingly demonstrated in the histologic picture. Most

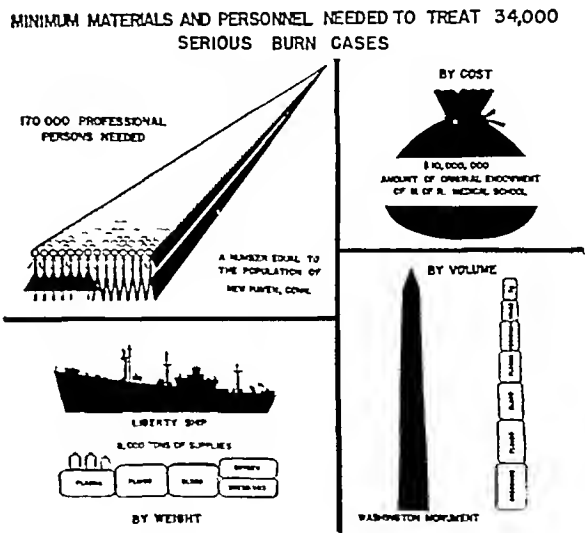

FIGURE 10 Multiplication of the Data in Figure 9 by an Estimated Number of Severe Burns from an Atomic-Bomb Explosion over a City of 300,000.

remarkable is the abrupt and diagrammatic demarcation between burned and normal skin. The normal, basophilic epidermal cells change on a straight line, to the acidophilic burned cells, which have all the characteristics of thermal injury (Fig 12). In the deeper skin, this demarcation is at the burn border, in the crypts and hair follicles. It is present in the dermis but is less easily demonstrated. There is no gradual transition zone as in the moderate temperature burns. Another characteristic of the flash burn is the method of healing. The burn of the epidermis and dermis represents a coagulative, "fixed" type of necrosis, with eschar formation and subsequent sequestration, rather than the organization seen in the noncoagulative necrotic tissue of the moderate temperature burn.

clothing being better than dark, however, if the clothing was adherent to the skin by perspiration, burning occurred even through this protection.

The burns produced were of varied severity and distribution. "Profile" burns were common (Fig 4), the parts directly exposed to the flash being burned most severely. Mild burns occurred, without vesication. These burns might be sustained beyond 3 km from the center and were intensely erythematous within the few days immediately after exposure. However, they gradually became

to the lack of adequate treatment and the extremely poor nutritional state of the people. These keloids seem to become inactive with the passage of time.

The low incidence of flame burns has been explained on the basis of the time lag between the bomb burst and the onset of fires. It is said that people escaped the fires if they were not severely injured. Those trapped in burning buildings perished, and no reliable figures are available on their number.

The care of a single traumatic or burned casualty, or a small group of casualties of such types as might result from an atomic-bomb explosion, would present somewhat of a problem. Certain essential supplies and facilities would be required. These

FIGURE 7 Contracture and Ulceration, Resulting from an Inadequately Treated Flash Burn on the Dorsum of the Right. Photographed Two Years after Burning⁵ (Photograph by Signal Corps, United States Army)

pigmented finally attaining a "walnut-stain" hue. This was most commonly seen on the face and therefore was called the "mask of Hiroshima." The pigmentation began to fade within a few months in some persons but in others has persisted for years⁶ (Fig 5).

More severe burns, corresponding to second-degree, moderate temperature burns, were frequent, but apparently did not carry the high mortality for large areas seen in the latter type of burn (Fig 4). Vesication was present, and often appeared within a matter of minutes. More severe burns were sustained, and complete transfascial burns were found among the dead.

The course of these burns was, in some cases, benign, many healing with little or no treatment, despite some superimposed radiation sickness. However, the healing was more often arrested, or the burn turned to a serious one by the subsequent lack of treatment and resulting complications. The sequelae were remarkable for the large number of contractures and the high incidence of keloids (Fig 6, 7 and 8) — higher than that noted in flame burns in Tokyo and other Japanese cities.⁸ Both these complications may well have been due

FIGURE 8 Keloids Following an Extensive Flash Burn of the Back, Photographed Twenty Months after the Injury.⁸ The uneven distribution of the keloid over the burned area is characteristic. (Photograph by Signal Corps, United States Army)

would include surgical dressings of all types, morphine and sedatives and so forth, antibiotics and similar agents, whole blood and plasma, hospitalization or adequate shelter of some type, or both, medical and technical personnel. The volume of materiel and the number of personnel required to treat a single severely burned patient (approximately 40 per cent of the body surface) in a modern hospital is illustrated in Fig 9. Many such patients do not survive, despite this treatment.

The figures given for casualties at Hiroshima and Nagasaki are presented in Table 3. From these

The burns are of the "flash" type, produced by a source of high intensity and brief duration. They are of all degrees of severity and although some may heal speedily with little treatment, this is by no means a general condition. Sequelae and over-all mortality probably will vary with the treatment.

Every effort should be made to evacuate the thermal and traumatic casualties early, and to treat them vigorously, to reduce the incidence of complications from delay.

NEW HAMPSHIRE MEDICAL SOCIETY

PROCEEDINGS OF THE ONE HUNDRED AND FIFTY-EIGHTH ANNIVERSARY

House of Delegates, June 13, 14 and 15, 1949

The House of Delegates convened at Wentworth-by-the-Sea, Newcastle, on June 13, 1949, at 7:45 p.m., with Dr. Francis J. C. Dube, of Center Ossipee, as Speaker.

The following delegates answered the roll call:

The President, *ex-officio*
 The Vice-President, *ex-officio*
 The Secretary-Treasurer, *ex-officio*
 Samuel Feiner, Asbland
 James Jessup, Laconia, alternate for Roger P. Brassard
 W. J. Paul Dye, Wolfeboro
 Francis J. C. Dube, Center Ossipee
 Howard Sawyer
 Albert C. Johnston, Keene
 Walter H. Lacey, Keene
 Marjorie A. Parsons, Colebrook
 William H. Gifford, Colebrook
 Leslie H. Sycamore, Hanover
 Leslie E. McKinlay, North Haverhill
 Reginald K. House, Hanover
 Robert E. Biron, Manchester
 Norman W. Crisp, Nashua
 Harris E. Powers, Manchester
 Richard T. Mulvanity
 James B. Woodman, Franklin
 Francis Brown, Henniker, alternate for Warren H. Butterfield
 William D. Penbale, Concord
 Frederick S. Gray, Portsmouth
 Donald W. Leonard, Exeter
 Fred Fernald, Nottingham
 Edna Walck, Dover
 Albert E. Barcomb, Rochester
 B. Read Lewin, Claremont
 Addison Roe, Newport

The speaker declared a quorum present. The president appointed James Jessup as alternate for Roger P. Brassard of Laconia, Howard Sawyer, as alternate for Speaker Dube and Francis Brown, of Henniker, as alternate for Warren H. Butterfield, of Concord.

On motion duly made and seconded it was voted to omit the reading of the minutes of the previous meeting, because of the publication of the proceedings.

The speaker made the following appointments to the Committee on Credentials, Drs. Samuel Feiner, Harris Powers and Albert E. Barcomb, to the Committee on Officers' Reports, Drs. Donald W. Leonard as Chairman, Edna Walck and Fred Fernald, to the Committee on Communications and Memorials, Drs. Norman W. Crisp, Richard T. Mulvanity and Marjorie A. Parsons, and to the Committee on Nominations, Drs. W. J. Paul Dye (chairman), Samuel Feiner, Reginald K. House, Robert E. Biron and Frederick S. Gray.

The Secretary-Treasurer, Dr. Carleton R. Metcalf, then presented his report as follows:

The total membership on December 31, 1947, was 591, that on December 31, 1948, was as follows:

	PAID	
Belknap County	30	
Carroll County	15	
Cheshire County	2	
Cook County	1	
Grafton County	92	
Hillsborough County	175	
Merrimack County	80	
Rockingham County	64	
Strafford County	38	
Sullivan County	22	
Not in County Society	2	
	590	
	UNPAID

With a flash burn of average severity the epithelium grows out freely (and indeed beautifully) from normal borders and hair follicles, beneath the unorganized eschar, so that healing is rapid. Yet if

Despite the fact that more and more is being learned about the flash burn, little change in the accepted treatment of burns can be made as yet. It is possible that many of these burns will heal rapidly (if they are not too deep), provided adequate shelter and diet are given the patient

FIGURE 11 Use of the Separation of the Epidermis from the Dermis As an End Point (Henriques and Moritz) to Demonstrate the Relation of Time and Temperature in the Production of Thermal Injury

This graph is a simplified, composite representation of this concept. Studies of thermal effects within the moderate temperature ranges are fairly complete, however, in the extremely high ranges, little has been done. In this zone (shaded in the graph and indicated by the question mark), many factors come into play, which can be ignored in the zones of lower temperature and longer time.

the area is large and the injury deep enough to destroy the epithelium in the crypts and hair follicles, this characteristic demarcation results in delayed repair from lack of epithelial islands.¹⁰

FIGURE 12 Biopsy of Skin Taken Immediately after the Production of a Magnesium Flash Burn on the Side of an Anesthetized Pig

The abrupt lateral demarcation is seen in the epidermis—normal epidermis being to the left and burned to the right. This picture is characteristic of the flash burn.

The prevention of infection—by adequate dressings and antibiotics—will probably pay high dividends in the prevention of morbidity, sequelae and uncalled-for deaths. The entire problem is being studied from several approaches with some promise of a more practical and effective solution.

TABLE 4 Summary of Various Sources Tried¹⁰

SOURCE	DURATION OF FLASH, sec	APPROXIMATE TEMPERATURE, °C	BURN PRODUCED	COMPLICATION
FT14 xenon flash tube	0.002	6,300	None	Unable to focus energy
Exploding wire	0.00001	20,000	None	Unable to focus energy
Thermite	Variable	3,500	None (not used)	too brief blast wave
Gun powder	To 1.0	3,000	None (failure)	Spatter low intensity
Magnesium	0.34	3,500	Severe	Low intensity
Carbon arc	Constant	4,000	Severe	Smoke
				Small area burn

Other factors about these experimental flash burns are their similarity to the ones noted clinically. For instance, severity diminishes as the distance from the source increases. Clothing and heavy creams seem to be adequate protection at reasonable distances from the source. Severity also decreases with the angle of incidence.

CONCLUSION

Thermal and mechanical injuries account for the majority of the casualties from an atomic bomb. From the experiences in Japan, 90 per cent of all persons requiring medical attention in the first week will have burns and 60 to 85 per cent of all patients will be burned.

The burns are of the "flash" type, produced by a source of high intensity and brief duration. They are of all degrees of severity and although some may heal speedily with little treatment, this is by no means a general condition. Sequelae and over-all mortality probably will vary with the treatment.

Every effort should be made to evacuate the thermal and traumatic casualties early and to treat them vigorously, to reduce the incidence of complications from delay.

In accordance with instructions from the House of Delegates last year the following measures have been carried out \$60 00 was given to the Cancer Committee, \$200 00 was given as a retaining fee to our counsel, Frank J. Sulloway, \$100 00 was contributed for membership in the Council of the New England State Medical Societies.

If we are to continue our membership in the Council, the annual fee of \$100 00 will again be due this year. I have asked Dr. Tuttle, who is reporting on the Council, to take this question up in his report.

I have appeared two or three times before committees of the State Legislature to give my personal opinion on some of the bills that had been entered, but none of the bills have been of medical importance.

Naturally, of course, we have been confronted with the threat of so-called socialized medicine. The House of Delegates met this on a state level by employing the firm of Woodbury and Putnam, of Concord, experts in public relations. Both Mr. Woodbury and Mr. Putnam are here this evening to tell what they have done, how much it has cost and what budget they recommend for the coming twelve months. It will probably be necessary to increase our dues from \$10 00 to \$15 00 a year to educate the people of New Hampshire on the important subject of socialized medicine. We shall, presumably, be concerned with this subject each year for a good many years to come.

The House of Delegates decided to employ Mr. Woodbury and Mr. Putnam at a meeting in Concord last spring, and since that decision was made these two gentlemen have worked in close co-operation with the Public Relations Committee.

I have notified the Veterans Administration that the Society will go along with them on the fee schedule and the agreement for home-town care of veterans with service-connected disabilities. A year ago the House of Delegates voted to do this until further notice.

The committee that arranged this annual meeting has again decided to omit the exhibits, it has continued the plan of having a considerable number of members give brief addresses, it has scheduled the annual dinner for Tuesday evening, and, in general, it has tried to make the meeting of greater interest to a larger group.

The National Physicians Committee has disbanded, and the American Medical Association has taken over the work of educating the public on medical legislation at the national level.

Before the war we used to send delegates to the other state-medical-society meetings in New England, we did not do this during the war on account of the difficulties of travel and have not yet adopted the custom since the war ended. Do you wish now to send delegates to the annual meetings of the other New England states?

Please be sure to read the letter written by Mr. Sulloway, which accompanied your program and which concerned cases of alleged malpractice. It is highly desirable to report to Mr. Sulloway at once any dissatisfaction on the part of any patient.

The little booklet containing the Constitution and By-laws is out of print. It was previously published in 1937. If you wish a new edition of this booklet, the Committee on Constitution and By-laws ought to bring it up to date and report at the meeting of the House of Delegates a year from now.

The expense of the *Transactions* has been going steadily up. It now costs approximately \$3 00 a copy, and it is a question whether very many men read the volume. It would probably be possible to cut the expense of this book if we omitted the various papers that are read at the annual meetings. Do you wish to make any change in the contents of our annual volume?

There are only a few hotels in New Hampshire that can accommodate a convention as large as ours where many who attend wish to stay overnight. Three of these are Hotel Wentworth at Newcastle, Mount Washington Hotel at Bretton Woods and the Mountain View House at Whitefield. The suggestion has been made that we have an annual meeting at Hanover. If this suggestion interests you, it would be well to confer with Dr. Bowler on the subject of food and sleeping quarters.

Dr. Roe stated that \$1600 00 has been advanced to the Woodbury-Putnam Agency to educate the public and inquired what was being done about educating the doctors and also what had happened to the National Physicians Committee.

Mr. Angus B. Woodbury replied that the doctors did not need any education. As far as the public is concerned, this campaign had been what might be called a "quickie." The firm had done the best job that it could, with the time and the money available. He stated that the firm had published news letters, and had tried to report on the progress of the campaign. The different co-ordinating committees, in the separate county societies, should get out the different literature to all the doctors in their areas. During the coming campaign, the firm had plans for getting closer to the doctor.

The Speaker asked Dr. Lull what had happened to the funds that had gone to the National Physicians Committee.

Dr. Lull answered that he had no knowledge of what had happened to the funds, they were not turned over to the American Medical Association.

Dr Harris Powers stated that two checks, dated March 23 and April 21 had been sent to the National Physicians Committee these were in the amount of \$53 00, and both had been returned as soon as the organization had been abandoned

On motion duly made and seconded it was voted to accept the report of the Secretary-Treasurer

On motion duly made and seconded it was voted to dispense with the reading of the reports of the councilors since these will be published in the *Transactions*

President Clarence E Dunbar then spoke as follows

Our hopes for a peaceful year were blasted when we listened to the election returns last year and found that some considered that this meant a mandate from the people to institute socialized medicine The American Medical Association requested that representatives from all the state societies assemble in Chicago on February 12 and Drs Reginald House and Harris Powers were selected to represent New Hampshire Upon their return, they presented the facts of the case before a special meeting of the House of Delegates held in Concord, and the House voted to authorize the Public Relations Committee to engage lay assistance Accordingly, the Angus-Woodhury firm was selected I believe that the results of the campaign organized by this firm fully justify the actions of the House in making this decision

Conferences have been held with representatives of the hospitals dentists, nurses and Blue Cross and Blue Shield, and all have promised full co-operation. In particular, Mr Spaulding, of the New Hampshire-Vermont Hospitalization Service, has given us all possible aid

At the annual meeting of the Council of the New England State Medical Societies, held in Boston on April 20, it appeared that New Hampshire was leading the other states in organizing the campaign

At all times, the attempt has been made to try to emphasize the positive—that is, our campaign is for better medical care rather than against anything As the Public Relations Department of the American Medical Association expresses it

The medical profession has some beams that need strengthening They've been dramatized by recurrent attacks on the doctors A few of the danger spots are excessive fees maldistribution of doctors night and emergency calls that go unanswered rebates insufficient postgraduate education in certain areas, poor press relations, lack of co-operation with laymen and related health groups in planning for medical care neglecting to publicize and implement our 12-point health program and omitting to tell the people about the many progressive activities of the profession on their behalf

I am happy to say that some of the county societies already have done considerable work along these lines

One of the great complaints of the average layman is that the cost of medical care is too high Ordinarily, the patient is satisfied with an explanation that modern medical practice demands more diagnostic procedures and necessarily increased costs for the better services rendered However, unfortunately, we must admit that occasionally some doctors have demanded fees that are out of line with the usual charges in their locality and the patient may have just cause for complaint To remedy this condition in some states, grievance committees have been organized to hear these and other controversial matters that might be brought before them These committees have been very successful wherever organized Therefore, I recommend that the state county and city societies give serious consideration to this plan

To further this idea of better public relations, it is strongly recommended that the Society organize a statewide health conference of doctors laymen and consumers similar to the conference held in Massachusetts last

February A thousand people participated Dr Conlin, of the Massachusetts Medical Society, stated "At no time previously has there been a mass, concentrated attempt here to bring consumers and distributors of health services—the people who are receiving and the people who are doing—together for an exchange of information" Its success was indicated by the Conference's unanimous vote to continue with a similar session a year hence

I have in my possession reports of the preliminary meetings, a list of organizations, representatives invited, by-laws, a complete program and outlines of all panel discussions, which I would gladly turn over to a committee if the House sees fit to organize such a conference

If it does not seem practical to organize such a conference on a state level, it is suggested that city or county societies might well conduct such a meeting on a smaller scale

It must not be assumed, because it now appears that the complete Ewing plan cannot get through this session of the Congress, that we can now sit back and rest We must continue to fight for better medical care and against compulsory health insurance for years to come

To do this means organization, and proper organization costs money Some states are spending several hundred thousand dollars a year in perfecting their plans According to the latest figures available, state dues run from \$10 to \$100, with an average of \$27 County dues run from nothing to \$65, with an average of \$15 I do not doubt that many societies have raised their dues since these figures were compiled

Many states employ full-time executives to assist their secretaries (even Vermont with a smaller membership than ours), and I believe that we should give this plan proper consideration Vermont and New Hampshire have combined successfully in Blue Cross and Blue Shield work, and Dr Bowler suggested that the two states, and possibly Maine also might get together, to organize for the future

To meet our increased responsibilities, the House must give thought to the matter of increasing our dues

In conjunction with the annual meeting of the American Medical Association there is held a conference of presidents and other officers of state medical associations and a conference of county medical society officers New Hampshire should participate more actively in these conferences By the payment of only \$10 00, New Hampshire may be recognized as participating in the Conference of Presidents and I recommend that the Society make this contribution

Many voluntary societies are contributing much to aid the fight against compulsion, and I urge their support by all members In particular, I ask support of the campaign of the American Diabetes Association Also, work has already started on the Crooked Mountain Restoration Center of the New Hampshire Society for Crippled Children and Handicapped Persons, and although some have been critical because of the choice of the site, I believe that all should lend their aid to the project

The American Medical Association is a member of the World Medical Association The United States Committee, Inc. has been organized to support the W M A in its advancement of medicine, health and peace Membership in this committee is open to all, and all members will receive all the publications of the association Membership costs only \$10 00 a year Application blanks may be obtained from Dr Louis H Bauer, secretary, U S Committee Inc., W M A, 2 East 103rd St., New York 29, N Y

It has been many years since our by-laws have been brought up to date, and as there have been some changes I recommend that the House consider their revision and reprinting for distribution to the membership

In conclusion, I wish to thank all the officers and members of the various committees for their splendid work during this past year, and to wish the incoming president a very successful year

On motion duly made and seconded, it was voted to accept the report of the President

The report of the Delegate to the American Medical Association was then presented, as follows

As three sessions of the American Medical Association have been held since the last regular meeting of the Society it is not possible in a report of reasonable length to discuss all that transpired. Only matters believed to be of the greatest interest are mentioned.

At the session last June in Chicago the resolutions on paying physicians engaged in examinations for the armed forces, adopted by this society, were introduced by your delegate and were approved by the House.

A second resolution of this society on single examination acceptable to the armed forces was adopted, with exceptions that did not change the intent of the resolution.

The revised constitution and by-laws were adopted. To conform with them it is recommended that the term of office of the delegate begin on January 1 after the annual meeting at which he is elected. It is believed that no amendment to our constitution and by-laws is necessary to make definite dates for his term of office.

The Council on National Emergency Medical Service requested each state and county society to appoint and organize a similar committee. Our state society has such a committee, but it is urged that every county society also organize one if it has not done so already.

The special Committee on Intern Placements, of which your delegate was a member, approved regulations regarding appointment of interns. In the interest of promoting general practice and making better specialists, it was recommended that all specialty boards require at least one year of rotating internship. It was also recommended that more rotating internships be for two years.

A committee to study conditions of general practice made an extensive report, including in its recommendations that every general hospital be organized so as to give the general practitioners adequate staff privileges and representation.

As it is desirable that some definite procedure be established to choose the outstanding general practitioner in the country each year, it was urged that each county society name a candidate. Each state society would select one general practitioner from this group and submit his name and qualifications to the American Medical Association for the final choice.

It was stated that 32 per cent of the physicians in the country were not members of the American Medical Association. The comparable figure for New Hampshire of 18 per cent is better, but is far too high. Every effort should be made by the county societies to enroll all eligible physicians.

It was voted to urge each state society to defray the cost of the activities of its auxiliary and to pay the annual dues of the national auxiliary, thus making the wife of every member automatically a member of the state and national auxiliaries.

After the Chicago session, the chairman of the Board of Trustees of the American Medical Association appointed your delegate to represent New England on the Association's committee to co-operate with the Red Cross Blood Bank Program. The meetings of this committee have focused attention on the necessity of having available adequate supplies of blood. Our state being very deficient in this respect, it is strongly recommended that a committee be appointed to correct the condition. A statewide blood bank should be sponsored or established at once by our society, either with or without the co-operation of the Red Cross.

At the St. Louis interim session in December your delegate served as a member of the Reference Committee on Reports of Officers. The House of Delegates discussed hospitals practicing medicine, the shortage of physicians in the armed forces and the care of veterans for non-service-connected disabilities. However, the provision of medical care in the American way was the key note of the session, as evidenced by the following:

The House reiterated its approval of nonprofit, voluntary prepayment medical service plans.

At a three-hour hearing resolutions favoring a national enrollment agency and a national insurance company for Blue Cross-Blue Shield Plans were not approved because it was not believed that sufficient factual data had been supplied so that an intelligent decision could be made on this most important subject.

A statement was issued that we are determined to protect and foster the high standards of medical care for the

public, that we are steadfastly opposed to the regimentation and socialization of American medicine, and that we are confident that an intelligent and informed public will join us in our crusade to improve the health and welfare of the American people.

An educational campaign relative to the achievements of American medicine and the dangers of compulsory sickness insurance was begun.

The employment of suitable public-relations counsel to assist in this campaign and the assessment of \$25 on each member of the American Medical Association to finance it were voted.

In January Whitaker and Baxter were employed as public-relations counsel, and they have a vigorous program well underway. At last we have taken the offensive in our battle against socialized medicine.

The session in Atlantic City last week stressed better medical care on a voluntary basis, as evidenced by the approval of the revised twelve-point program for the advancement of medicine and public health, the approval of Associated Medical Care plans that are to become autonomous trade associations, the approval of the development of a national enrollment organization with the understanding that any insurance-company plan must be approved as any other plan, and the recognition of medical care plans operated by lay groups, through the adoption of twenty principles as guides for county and state medical societies in judging whether or not to recommend these plans for approval.

Legislation to enable veterans entitled to medical and hospital benefits for non-service-connected disabilities to obtain these benefits in civilian hospitals of their own choice, under the care of physicians of their own choice, was discussed. A health-insurance plan, the premium to be paid by the Government when the veterans are unable to pay the premiums, was proposed, and after a lengthy discussion the whole matter was referred to the Board of Trustees for study. Resolutions against the governmental participation in business in competition with private enterprise were adopted. Dr. Fishbein was praised for his contributions to the advancement of medical science, but at the same time approval was given to the order that he stop writing and talking about controversial issues. Plans for a new editor and Dr. Fishbein's retirement are being formed. The revised Principles of Medical Ethics were approved. It was brought out that it is unethical to buy appliances, devices or medicines at wholesale and sell them at retail. However, a physician may charge for his services. Every effort should be made to satisfy the needs of the armed forces for physicians from the 8000 educated in whole or in part at Government expense and the 7000 deferred so as to complete their medical education—all of whom have had no military service.

It was suggested that state societies be strengthened where necessary. Your delegate believes that this may be accomplished in our state by the employment of an executive secretary to meet the increasing demands made on our secretary. It is recommended that the president, vice-president and secretary of the Society study this proposal, confer with the officers of the Maine and Vermont medical societies regarding a joint executive secretary and report their conclusions to the House of Delegates.

To strengthen New England's position in the House of Delegates it has been suggested that a common meeting room be obtained and that other delegates be entertained at the meetings. Your delegate asks if New Hampshire's proportionate share of this expense may be included with his other expenses.

The Committee on Hospitals and the Practice of Medicine made a detailed report and recommended the establishment of the same principles governing the proper relations between physicians and hospitals that were adopted by the Massachusetts Medical Society.

It was urged that each state society pass resolutions approving the American Medical Association's Educational campaign. The state and county medical societies should pass resolutions, if they have not already done so, stating their opposition to compulsory health insurance and the socialization of medicine.

Your delegate served during this session as chairman of the Reference Committee on Hygiene and Public Health. He was one of three nominees by the Board of Trustees for membership on the Council on Medical Service but

withdrew in favor of Dr McGoldrick, the present incumbent, who was re-elected

In conclusion, we must not be lulled into a false sense of security because federal health insurance will not be enacted now. The drive for the invasion of the rights of the individual will be continued, and we must oppose it to save not only the medical profession but our country.

Dr Leonard, for the Committee on Officers' Reports, moved that the report of the delegate to the American Medical Association be accepted.

This motion was duly seconded and was carried.

The Committee on Officers' Reports then moved that a committee to be known as the State Blood Bank Committee, be appointed by the President, consisting of three members, whose duties it will be to co-operate with the Blood Bank Committee of the American Medical Association and the American Red Cross, and to draw up plans and initiate action for the establishment of a self-supporting New Hampshire State Blood Bank.

This motion was duly seconded and was carried.

The Committee on Officers' Reports moved that the President be authorized to appoint a committee to obtain specific information regarding the terms, cost of office space, clerical help and other conditions involved in the employment of an executive secretary by the New Hampshire Medical Society, alone or in conjunction with another state medical society. Dr Sycamore and Dr Bowler moved that the motion be amended to include the words "And that the Committee be instructed to report to the House of Delegates at the earliest possible moment, at a special meeting." Dr Leonard accepted the amendment.

The amended motion was duly seconded and was carried.

Dr Leonard, for the Committee on Officers' Reports, then moved that for the promotion of good public relations, the House of Delegates signify that the delegate to the American Medical Association consider his share of the expense of a general meeting room for the New England delegates at the annual convention as a legitimate part of the expenses allotted to the delegate by the Society.

This motion was duly seconded, and after some discussion was carried.

Dr Leonard moved that the New Hampshire Medical Society express full approval of the education campaign being conducted by the American Medical Association through the agency of Whitaker and Baxter.

This motion was duly seconded and was carried.

Dr Leonard stated that the Committee on Amendments to the Constitution and By-Laws had reported that no amendments had been proposed, and the Committee, therefore, had no action to recommend. Dr Leonard moved that the report of the Committee on Amendments to the Constitution and By-Laws be accepted.

This motion was duly seconded and was carried.

Dr Leonard then observed that the Committee on Child Health reported no joint action by the Committee beyond the consideration of plans for the future by the individual members. The Committee, therefore, proposed to defer its formal report to the next annual meeting.

He then called attention to the fact that the minutes of the 1947 meeting of the House of Delegates contained no report of the Committee on Child Health for 1947. In 1946, the Committee reported as follows:

The Committee on Child Health has been relatively inactive. A most important step toward the betterment of the health of children in New Hampshire is the study of child-health services of the American Academy of Pediatrics, which is now in progress. We urge the co-operation of the members of the Society in this study.

Dr Leonard, for the Committee on Officers' Reports, offered an amendment to the present report, to include mention of the recent announcement of the findings and recommendations of the three-year study mentioned in that report of the Committee in 1946. The announcement and a reprint from the *Quarterly Review of Pediatrics*, for May, 1949, had been received by the Chairman. The Academy report indicated that there were only eleven pediatricians in New Hampshire and that three fourths of the private care of children of the nation was in the hands of general practitioners, nearly half of whom had no hospital training in child care, even a fourth of the pediatricians themselves had little hospital training in the medical care and health supervision of children. Three quarters of the nation's practicing pediatricians were in cities of 50,000 or more population — half in communities having medical schools. A third were in Massachusetts, New York and Pennsylvania. The general practitioner, who was principally responsible for protecting the health of children, actually had little time for preventive measures, since only 9 per cent of his time was given for well-child care.

The committee making the study recommended strengthening of basic teaching budgets of medical-school pediatric teaching departments toward a better preparation of medical students, the extension of medical teaching and services to outlying areas, and provision of fellowships for graduate study with hospital training in pediatrics prior to entering practice.

The Committee on Officers' Reports offered this amendment, and moved that the requested deferment of the report of the Committee on Child Health be granted.

This motion was duly seconded and was carried. The report of the Committee on Control of Cancer was presented, as follows:

The annual cancer conference conducted by the Committee held a very successful meeting this year on April 12. The various talks given by the Boston and New Hampshire

As three sessions of the American Medical Association have been held since the last regular meeting of the Society it is not possible in a report of reasonable length to discuss all that transpired. Only matters believed to be of the greatest interest are mentioned.

At the session last June in Chicago the resolutions on paying physicians engaged in examinations for the armed forces, adopted by this society, were introduced by your delegate and were approved by the House.

A second resolution of this society on single examination acceptable to the armed forces was adopted, with exceptions that did not change the intent of the resolution.

The revised constitution and by-laws were adopted. To conform with them it is recommended that the term of office of the delegate begin on January 1 after the annual meeting at which he is elected. It is believed that no amendment to our constitution and by-laws is necessary to make definite dates for his term of office.

The Council on National Emergency Medical Service requested each state and county society to appoint and organize a similar committee. Our state society has such a committee, but it is urged that every county society also organize one if it has not done so already.

The special Committee on Intern Placements, of which your delegate was a member, approved regulations regarding appointment of interns. In the interest of promoting general practice and making better specialists, it was recommended that all specialty boards require at least one year of rotating internship. It was also recommended that more rotating internships be for two years.

A committee to study conditions of general practice made an extensive report, including in its recommendations that every general hospital be organized so as to give the general practitioners adequate staff privileges and representation.

As it is desirable that some definite procedure be established to choose the outstanding general practitioner in the country each year, it was urged that each county society name a candidate. Each state society would select one general practitioner from this group and submit his name and qualifications to the American Medical Association for the final choice.

It was stated that 32 per cent of the physicians in the country were not members of the American Medical Association. The comparable figure for New Hampshire of 18 per cent is better, but is far too high. Every effort should be made by the county societies to enroll all eligible physicians.

It was voted to urge each state society to defray the cost of the activities of its auxiliary and to pay the annual dues of the national auxiliary, thus making the wife of every member automatically a member of the state and national auxiliaries.

After the Chicago session, the chairman of the Board of Trustees of the American Medical Association appointed your delegate to represent New England on the Association's committee to co-operate with the Red Cross Blood Bank Program. The meetings of this committee have focused attention on the necessity of having available adequate supplies of blood. Our state being very deficient in this respect, it is strongly recommended that a committee be appointed to correct the condition. A statewide blood bank should be sponsored or established at once by our society, either with or without the co-operation of the Red Cross.

At the St. Louis interim session in December your delegate served as a member of the Reference Committee on Reports of Officers. The House of Delegates discussed hospitals practicing medicine, the shortage of physicians in the armed forces and the care of veterans for nonservice-connected disabilities. However, the provision of medical care in the American way was the keynote of the session, as evidenced by the following.

The House reiterated its approval of nonprofit, voluntary prepayment medical service plans.

At a three-hour hearing resolutions favoring a national enrollment agency and a national insurance company for Blue Cross-Blue Shield Plans were not approved because it was not believed that sufficient factual data had been supplied so that an intelligent decision could be made on this most important subject.

A statement was issued that we are determined to protect and foster the high standards of medical care for the

public, that we are steadfastly opposed to the regimentation and socialization of American medicine, and that we are confident that an intelligent and informed public will join us in our crusade to improve the health and welfare of the American people.

An educational campaign relative to the achievements of American medicine and the dangers of compulsory sickness insurance was begun.

The employment of suitable public-relations counsel to assist in this campaign and the assessment of \$25 on each member of the American Medical Association to finance it were voted.

In January Whitaker and Baxter were employed as public-relations counsel, and they have a vigorous program well underway. At last we have taken the offensive in our battle against socialized medicine.

The session in Atlantic City last week stressed better medical care on a voluntary basis, as evidenced by the approval of the revised twelve-point program for the advancement of medicine and public health, the approval of Associated Medical Care plans that are to become autonomous trade associations, the approval of the development of a national enrollment organization with the understanding that any insurance-company plan must be approved as any other plan, and the recognition of medical care plans operated by lay groups, through the adoption of twenty principles as guides for county and state medical societies in judging whether or not to recommend these plans for approval.

Legislation to enable veterans entitled to medical and hospital benefits for nonservice-connected disabilities to obtain these benefits in civilian hospitals of their own choice, under the care of physicians of their own choice, was discussed. A health-insurance plan, the premium to be paid by the Government when the veterans are unable to pay the premiums, was proposed, and after a lengthy discussion the whole matter was referred to the Board of Trustees for study. Resolutions against the governmental participation in business in competition with private enterprise were adopted. Dr. Fishbein was praised for his contributions to the advancement of medical science, but at the same time approval was given to the order that he stop writing and talking about controversial issues. Plans for a new editor and Dr. Fishbein's retirement are being formed. The revised Principles of Medical Ethics were approved. It was brought out that it is unethical to buy appliances, devices or medicines at wholesale and sell them at retail. However, a physician may charge for his services. Every effort should be made to satisfy the needs of the armed forces for physicians from the 8000 educated in whole or in part at Government expense and the 7000 deferred so as to complete their medical education—all of whom have had no military service.

It was suggested that state societies be strengthened where necessary. Your delegate believes that this may be accomplished in our state by the employment of an executive secretary to meet the increasing demands made on our secretary. It is recommended that the president, vice-president and secretary of the Society study this proposal, confer with the officers of the Maine and Vermont medical societies regarding a joint executive secretary and report their conclusions to the House of Delegates. To strengthen New England's position in the House of Delegates it has been suggested that a common meeting room be obtained and that other delegates be entertained at the meetings. Your delegate asks if New Hampshire's proportionate share of this expense may be included with his other expenses.

The Committee on Hospitals and the Practice of Medicine made a detailed report and recommended the establishment of the same principles governing the proper relations between physicians and hospitals that were adopted by the Massachusetts Medical Society.

It was urged that each state society pass resolutions approving the American Medical Association's Educational campaign. The state and county medical societies should pass resolutions, if they have not already done so, stating their opposition to compulsory health insurance and the socialization of medicine.

Your delegate served during this session as chairman of the Reference Committee on Hygiene and Public Health. He was one of three nominees by the Board of Trustees for membership on the Council on Medical Service but

withdrew in favor of Dr McGoldrick the present incumbent, who was re-elected

In conclusion, we must not be lulled into a false sense of security because federal health insurance will not be enacted now. The drive for the invasion of the rights of the individual will be continued and we must oppose it to save not only the medical profession but our country.

Dr Leonard, for the Committee on Officers' Reports, moved that the report of the delegate to the American Medical Association be accepted.

This motion was duly seconded and was carried.

The Committee on Officers' Reports then moved that a committee to be known as the State Blood Bank Committee be appointed by the President, consisting of three members, whose duties it will be to co-operate with the Blood Bank Committee of the American Medical Association and the American Red Cross, and to draw up plans and initiate action for the establishment of a self-supporting New Hampshire State Blood Bank.

This motion was duly seconded and was carried.

The Committee on Officers' Reports moved that the President be authorized to appoint a committee to obtain specific information regarding the terms, cost of office space, clerical help and other conditions involved in the employment of an executive secretary by the New Hampshire Medical Society, alone or in conjunction with another state medical society. Dr Sycamore and Dr Bowler moved that the motion be amended to include the words "And that the Committee be instructed to report to the House of Delegates at the earliest possible moment, at a special meeting." Dr Leonard accepted the amendment.

The amended motion was duly seconded and was carried.

Dr Leonard, for the Committee on Officers' Reports, then moved that for the promotion of good public relations, the House of Delegates signify that the delegate to the American Medical Association consider his share of the expense of a general meeting room for the New England delegates at the annual convention as a legitimate part of the expenses allotted to the delegate by the Society.

This motion was duly seconded, and after some discussion was carried.

Dr Leonard moved that the New Hampshire Medical Society express full approval of the education campaign being conducted by the American Medical Association through the agency of Whitaker and Baxter.

This motion was duly seconded and was carried.

Dr Leonard stated that the Committee on Amendments to the Constitution and By-Laws had reported that no amendments had been proposed, and the Committee, therefore, had no action to recommend. Dr Leonard moved that the report of the Committee on Amendments to the Constitution and By-Laws be accepted.

This motion was duly seconded and was carried.

Dr Leonard then observed that the Committee on Child Health reported no joint action by the Committee beyond the consideration of plans for the future by the individual members. The Committee, therefore, proposed to defer its formal report to the next annual meeting.

He then called attention to the fact that the minutes of the 1947 meeting of the House of Delegates contained no report of the Committee on Child Health for 1947. In 1946, the Committee reported as follows:

The Committee on Child Health has been relatively inactive. A most important step toward the betterment of the health of children in New Hampshire is the study of child-health services of the American Academy of Pediatrics, which is now in progress. We urge the co-operation of the members of the Society in this study.

Dr Leonard, for the Committee on Officers' Reports, offered an amendment to the present report, to include mention of the recent announcement of the findings and recommendations of the three-year study mentioned in that report of the Committee in 1946. The announcement and a reprint from the *Quarterly Review of Pediatrics*, for May, 1949, had been received by the Chairman. The Academy report indicated that there were only eleven pediatricians in New Hampshire and that three fourths of the private care of children of the nation was in the hands of general practitioners, nearly half of whom had no hospital training in child care, even a fourth of the pediatricians themselves had little hospital training in the medical care and health supervision of children. Three quarters of the nation's practicing pediatricians were in cities of 50,000 or more population — half in communities having medical schools. A third were in Massachusetts, New York and Pennsylvania. The general practitioner who was principally responsible for protecting the health of children, actually had little time for preventive measures, since only 9 per cent of his time was given for well-child care.

The committee making the study recommended strengthening of basic teaching budgets of medical-school pediatric teaching departments toward a better preparation of medical students, the extension of medical teaching and services to outlying areas, and provision of fellowships for graduate study with hospital training in pediatrics prior to entering practice.

The Committee on Officers' Reports offered this amendment, and moved that the requested deferment of the report of the Committee on Child Health be granted.

This motion was duly seconded and was carried.

The report of the Committee on Control of Cancer was presented, as follows:

The annual cancer conference conducted by the Committee held a very successful meeting this year on April 12. The various talks given by the Boston and New Hampshire

men were received with interest and discussed freely. The luncheon at noon and all the expenses of this meeting were assumed as usual by the New Hampshire division of the Field Army of the American Cancer Society.

The large group of women in the Field Army have continued their well developed functions, including lay education, distribution of pamphlets and posters, making surgical dressings for indigent patients, transportation of patients to clinics and hospitals, and increasing their large membership. They have supplied reading material for every library in the state and have continued work in high-school cancer education.

There has been a gradual increase of patients attending the state cancer clinics during the past year. On account of the rapid increase in hospitalization expenses during the last two years, the Cancer Commission has found it necessary to apply to the governor and council for extra funds to finish out this fiscal year, and these funds have been allocated without opposition.

As usual, three letters on pertinent cancer subjects have been mailed to each member of the New Hampshire Medical Society. The first one gave information regarding the method of applying to the Cancer Commission for financial aid for medically indigent cancer patients. Immediately after this was issued there was a prompt increase in the number of requests for assistance. The second letter was a discussion of the treatment of carcinoma of the cervix and a warning against attempting an inadequate operation. It stressed the point that operation should be on early cases and should consist of an actual Wertheim operation. The letter stated that a panhysterectomy is not the treatment for cancer of the cervix at any time and is not the accepted form of treatment. It also quoted authorities stating that the choice of treatment of carcinoma of the cervix was still x-ray and radium. The third letter suggested the very important use of every doctor's office as a cancer-detection center and suggested a minimal examination for the patients who come to the doctor for an examination that might detect the presence of cancer. We believe that this is an important service that could be rendered the public by the doctors in New Hampshire.

Owing to the increasing number of members in the New Hampshire Medical Society and to the increased postal rates, your committee spent \$2.75 more than the \$60.00 appropriation, and we request an appropriation of \$70.00 for the next year.

GEORGE C. WILKINS, Chairman
GEORGE F. DWINELL
RALPH E. MILLER
WALTER H. LACEY

Dr. Leonard, for the Committee on Officers' Reports, moved that the annual appropriation for the Committee be increased to \$70.00, and that the entire report be accepted.

This motion was duly seconded and was carried.

The report of the Committee on Industrial Health was then presented as follows:

The Committee has made some gain during the past year in the development and promotion of industrial medicine and health among New Hampshire industries, and it is believed that, with continued effort, New Hampshire will equal, if not exceed, the accomplishments made in our neighboring states and other states in the United States.

A meeting of the Committee was held on February 16, 1949, at the State House, Concord, New Hampshire. Problems discussed and accomplishments of the Committee are included in this report.

Industrial Medical and Nursing Services

During the past year, there were in New Hampshire an average of approximately 89,000 persons engaged in types of industries in which occupational disease and health hazards are known to exist. It is well known that a medical and nursing service program conducted in an industrial plant will decrease substantially occupational disease cases, injury rates, and provide other benefits

that are of economic value to the industry. Table 1 shows the number of workers in New Hampshire who are provided medical or nursing service, or both.

TABLE 1 *Service Provided Workers in New Hampshire*

SERVICE	NO OF WORKERS	WORKERS PROVIDED WITH SERVICE
		%
Medical or nursing, or both	23,150	26
Full time physician at plant	3,000	1
Part time physician	11,850	13
Full time industrial nurse (total)	23,150	26
With direct medical supervision	14,650	16
Without direct medical supervision	8,500	10

The size of the plant necessarily influences the extent of health services provided for employees. Table 2 shows the percentage distribution of workers according to size of plants and the percentage of workers provided medical or nursing service, or both.

TABLE 2 *Distribution of Workers Receiving Service*

SIZE OF PLANT*	PERCENTAGE OF WORKERS ACCORDING TO SIZE OF PLANT	PERCENTAGE OF WORKERS PROVIDED MEDICAL OR NURSING SERVICE OR BOTH
6-250	47.2	Less than 1
250-499	23.7	22
500-1,000	18.9	38
1,001-2,500	5.8	100
2,501 and over	4.1	100

*According to number of workers.

The above data indicate that the larger plants provide medical and nursing services, whereas there are many plants with a working force between 500 and 1000 persons that provide no medical or nursing service for their employees. These plants include shoe, textile, wood products and other industries. Similarly, there is a greater number of plants employing 250 to 500 persons that provide no medical or nursing service for their workers.

Although pre-employment and periodic physical examination of employees is the essential basis for a medical and health program in industry, only 60 per cent of plants providing nursing services also provide for physical examinations of their employees. Table 3 shows the number and percentage of industrial workers who receive the benefits of physical examinations.

TABLE 3 *Workers Receiving Physical Examinations*

TOTAL NO. OF EMPLOYEES PROVIDED MEDICAL OR NURSING SERVICES	TOTAL NO. OF EMPLOYEES PROVIDED WITH PRE-EMPLOYMENT PHYSICAL EXAMINATION	PERCENTAGE OF WORKERS HAVING PHYSICAL EXAMINATIONS
23,150	13,850	60

One plant in New Hampshire employs a full-time physician as medical director, in addition, there are at present 39 full-time industrial nurses who are providing services for 23,150 industrial workers employed in 22 industrial plants in New Hampshire.

Justification for industrial plants to provide medical and nursing facilities for their employees is well established. To mention one example, a survey conducted by the

National Association of Manufacturers concluded that no plant, however small, can afford to be without a health program. The annual net profit to the average plant of 500 employees from the operation of a health program is \$5610. The yearly loss to a company of 500 employees that operates without a health program may be \$39,000. Benefits derived from these services according to this survey included compensation-insurance reduction, lower absenteeism, less labor turnover, reduction in occupational diseases and in accident frequency.

The Committee believes that one of the objections raised by industry to the establishment of medical and nursing programs was the fact that no accurate figures were available concerning the cost and benefits of such services. It was pointed out during Committee discussions that where industrial medical services were provided for employees on a fee basis, industry could not budget for this expense, having no information on the yearly cost, and hence, industrial officials were reluctant to inaugurate medical programs. However, if medical service was on retainer basis, a method of payment that is being used in the majority of the plants throughout the United States, industry would have definite information concerning the cost of the service and would be able to plan and budget for the program. It was further noted in the discussions that this is particularly true with the smaller plants and that some consideration should be given by the physicians in the State to this method of payment. Several members of the Committee indicated that payment for their services was made both ways — namely, on a fee basis or on a retainer basis — and that, as far as they were concerned, either method was satisfactory. However, some physicians are not in a position to know, in all plants, the approximate cost on a yearly basis, and it was pointed out that it might be well for the physician to provide his services for a year on the fee basis, at which time, he would have sufficient information to estimate the approximate cost on a yearly retainer basis.

The Committee realizes that concrete information should be made available for industrial officials relative to the cost of establishing medical dispensaries and operating costs, including fees or retainer salaries for physicians, nurses' salary, equipment, supplies and other expenses. In an attempt to provide this information, the Committee in co-operation with the Department of Health, is now preparing a publication on the benefits and costs of industrial and medical nursing services in industries in New Hampshire. Figures being collected from several plants in the State show the actual costs and benefits derived from medical service programs. Data will be available on initial cost of inaugurating medical and nursing services, operating costs and benefits derived, including decrease in absenteeism, decrease in accident and occupational disease, improvement of employee relations with management and increased production.

It is the belief of the Committee that, if specific information and data are available for industrial officials, they will recognize the value of such services and take steps for their inauguration in the plants.

Medical Services for Small Plants

The Committee has under consideration a program whereby several small plants located near together can combine and operate a central industrial medical dispensary staffed with a full-time nurse and a part-time physician. It has been demonstrated in other sections of the United States that such a program can be successful when several small plants combine their efforts and facilities for the establishment of a medical and nursing dispensary for the use of all plants participating. It is expected that this program will get under way during the coming year, and we shall have more information to report next year.

Preplacement Physical Examinations

The Committee, in co-operation with the Division of Industrial Hygiene, has published a booklet entitled, "Health Evaluation Examinations in Industry." The purpose of this publication is to inform industrial officials of the benefits derived from pre-employment and periodic physical examinations of their employees, and to indicate

to them basic data included in a complete physical examination. In addition, certain screening techniques are given whereby the industrial nurse can evaluate the health status of her applicants for employment as an aid in proper placement of employees in plants where complete physical examinations are not performed by a physician. It is recommended that all suspicious or doubtful cases be sent to a physician for a complete medical examination. It is believed that such screening techniques are better than no medical examination, and that they will demonstrate the value of physical examinations for all employees to industrial officials. Copies of this publication have been mailed to industrial officials, physicians, nurses and other organizations and persons interested in industrial medicine and health.

Chest X-Ray Examination of Industrial Employees

The Committee has worked closely with the New Hampshire Health Department in its program of providing free chest x-ray study for industrial employees. As of June 1, 1949, 15,532 industrial employees in 55 plants had received chest x-ray examinations. The provision of these facilities, through the co-operation of the Health Department and the New Hampshire Tuberculosis Association, is a program that should receive full support from the Society. The Committee strongly endorses this program and urges its continuation.

New Hampshire Industrial Nurses' Association

The New Hampshire Industrial Nurses' Association, in co-operation with the New Hampshire Health Department, has prepared and published a pamphlet entitled "Personnel Policies and Practices for Industrial Nurses in New Hampshire." The Committee endorses the aims and objectives of this organization, and has worked closely with it in the promotion and improvement of industrial nursing in New Hampshire.

Industrial Health Committee, New Hampshire Manufacturers' Association

The Committee has kept the Industrial Health Committee, New Hampshire Manufacturers' Association, informed regarding its activities, and it is planned, in the near future, to have a joint meeting of the two committees to discuss and evaluate programs for the improvement of the medical and nursing services in industry, and for the development of joint activities for the betterment of the health of the industrial workers in New Hampshire.

Information on Toxic Chemical and Other Substances Used in Industry

The Committee believes that information should be prepared, published, and circulated among physicians, nurses and industrial officials relative to the toxic chemicals and substances used in industry. Many of the new materials developed during the war are being used in the plants throughout the State, and it is believed that information about their toxicity, symptoms of poisoning and other information should be made available to give better protection for the industrial workers who are exposed to these substances. Of particular importance are the radioactive isotopes, the increased use of fluoroscopic equipment and x-rays, and the development of methods for the use of beryllium. The Committee has requested the Division of Industrial Hygiene to prepare in mimeographed form pertinent information on such substances for distribution.

Reporting of Occupational Diseases

The passage of the Occupational Disease Compensation Law, two years ago, by the Legislature emphasizes the need for reporting occupational diseases to the Health Department. The Committee believes that, for the fair and just awarding of compensation for occupational disease, all facts relating to the case should be determined and evaluated. It is desired to point out that the Bureau of Labor holds hearings on compensation cases, and that the medical evidence rests largely with the physicians who have seen the case. There should be a definite relation between the patient's exposure to a toxic

substance and some assurance that the quantity to which he was exposed was sufficient to give symptoms of poisoning and that the medical findings definitely relate to the physiologic reaction of the substance in question. It is the belief of the Committee that proper evaluation of all cases can be obtained through the technical assistance of the Division of Industrial Hygiene, which has instruments available to measure and evaluate the degree of exposure and to perform laboratory analyses for the determination of toxic substances present in commercial or other products. For these reasons, the Committee believes that the reporting of occupational diseases to the Health Department is important, so that studies and investigations can be made and methods inaugurated to prevent future cases.

DAVID W. PARKER, M.D., *Chairman*

Dr. Leonard, for the Committee on Officers' Reports, moved that the report of the Committee on Industrial Health be accepted.

This motion was duly seconded and was carried.

The report of the Committee on Maternity and Infancy was then presented, as follows:

STUDY OF MATERNAL DEATHS, STILLBIRTHS AND INFANT DEATHS UNDER ONE YEAR FOR 1948

This is the fifteenth year in which the Committee has conducted an annual study of maternal deaths, infant deaths and stillbirths. Maternal deaths are appraised carefully through the analysis of data from the physicians reporting the deaths. It has been impractical and im-

taining suggestions to the individual physician reporting the case, may be helpful in the conduct of future similar cases.

This report is made possible only through the co-operation of physicians in furnishing as full and descriptive information and facts as possible. Any faulty judgment on the part of the Committee may be due entirely to lack of pertinent information obtained from the physicians.

This year all but one physician returned the data requested. If the Committee is to continue to conduct this study in future years it is essential that physicians respond as promptly as possible and give as full information as possible.

All cases studied are reported through the Division of Vital Statistics of the State Department of Health, where the death certificates are received and filed.

MATERNAL DEATHS

There were 14 maternal deaths in 1948. The number of births in 1948 was 12,784, giving a maternal death rate of 1.1 per 1000 live births. This rate is identical to that recorded for 1947, when the number of maternal deaths was 15 and 13,638 births were reported. The peak in births was apparently reached in 1947 with a slow and slight downward swing this year with 854 fewer births than in the previous year.

The table of the causes of maternal deaths for 1948 reveals a more varied listing of causes than in most years. However, in grouping similar causes together, it is interesting to observe that 6 out of the 14 deaths were due to nephritic conditions or damage to kidney tissue before or during pregnancy or to puerperal toxemias. The line between an out-and-out nephritis aggravated by a pregnancy and a true toxemia of pregnancy is at times difficult

to draw. It was the opinion of the Committee that the treatment given nephritic patients or those showing symptoms of toxemia, early or late in pregnancy, was generally fearful and inadequate. The Committee believes that heroic medical treatment to such patients should be instituted as soon as the signs and symptoms appear. There seems to be, as there has been in past studies, an uncontrollable temptation on the part of some physicians to empty the uterus at all costs and ignore the necessity of treating the patient. The Committee condones the interruption of the pregnancy in toxemias as part of the accepted treatment, and by the most safe and logical means, but it decries the forceful dilatation of the cervix followed by forceps delivery under any circumstances. Due and deliberate consideration should first be given to the degree of prematurity and, above all, to the medical control as far as possible of the condition by the use of magnesium sulfate intravenously alternated with glucose and sedation and when convulsions are imminent, a rapid digitalization. The decision when and how the pregnancy should be terminated is admittedly a very difficult one, and the Committee believes that in all such cases competent consultation should be sought with an obstetrician.

In 2 of the maternal deaths a definite diagnosis of rheumatic heart disease was made before pregnancy. In 1 of these the patient sought no prenatal care and died of hemorrhage and congestive heart failure after a home delivery. This was the only home delivery in this series and one of the very few recorded for several years.

There were 2 ectopic pregnancies. One occurred without warning and in the absence of a history of pregnancy and no external bleeding. The other was undiagnosed before death despite a previously performed dilatation and curettage and a definite history of pregnancy and external bleeding.

Of 3 hemorrhages of childbirth, 2 were placenta previa and 1 was due to a self-induced abortion.

The Committee classifies the causes of death in accordance with the data and facts presented and may, in some cases, differ in the diagnosis from that recorded on the death certificate and as coded according to the International List of Causes of Death by the Division of Vital Statistics. In 1948, however, there was complete agreement and the table, therefore, shows only one listing of these causes.

The Committee further classifies maternal death causes, for purposes of this study, into the four groups shown in Table 1.

Only 1 case was classified as undetermined because of insufficient data. The largest number of cases was classified as unavoidable, with the patient's negligence taking a close second place. The Committee believed that in 3 cases there was definite evidence that the obstetric treatment and conduct of the case were inadequate. It may be of interest to review these cases briefly. Causes listed in this group were 1 ectopic pregnancy, 1 hemorrhage of childbirth (placenta previa), and 1 puerperal eclampsia.

The ectopic pregnancy occurred in a twenty-five-year-old woman who had given a history of having missed a period. Irregular and profuse vaginal bleeding had occurred about two weeks before the final episode, at which time she was admitted to a hospital and had a dilatation and curettage. A diagnosis of possible miscarriage was made. After discharge she continued to have moderate, irregular bleeding. Suddenly, a severe vaginal hemorrhage developed, and because of a confused history, including the imbibing of alcoholic beverages, she was thought to be suffering from acute alcoholism. She became rapidly weaker and when admitted to the hospital again did not respond to treatment and died in apparent shock three hours after admission. A diagnosis of acute alcoholism, with question of shock was made. Autopsy revealed rupture in an ectopic pregnancy and pelvic hemorrhage. The Committee believed that a diagnosis should have been made at the time the dilatation and curettage were performed and again when the vaginal hemorrhage occurred. Any patient who bleeds during the first two months of pregnancy should always arouse a suspicion of an ectopic pregnancy.

The case reported as placenta previa in this group was in a woman who was pregnant for the tenth time. She did not seek prenatal care and claimed to have had a

substance and some assurance that the quantity to which he was exposed was sufficient to give symptoms of poisoning and that the medical findings definitely relate to the physiologic reaction of the substance in question. It is the belief of the Committee that proper evaluation of all cases can be obtained through the technical assistance of the Division of Industrial Hygiene, which has instruments available to measure and evaluate the degree of exposure and to perform laboratory analyses for the determination of toxic substances present in commercial or other products. For these reasons, the Committee believes that the reporting of occupational diseases to the Health Department is important, so that studies and investigations can be made and methods inaugurated to prevent future crises.

*Number of births in 1948, 12,784.

When that division has compiled and prepared data for study, the Committee meets, discusses, appraises and evaluates the case from factual data at hand. It has been necessary in some cases to request additional information on the conduct of the case after a preliminary meeting. All possible data is sought, that the Committee may determine objectively the proper classification of the maternal death. The Committee wishes to reiterate its

department is the availability of a thoroughly trained anesthetist. Physicians should be encouraged to receive special training in this field so that the supply of much needed personnel will be ready to meet the demands.

The Committee believes that cesarean sections should not be performed without competent consultation with a qualified obstetrician.

The Committee wishes to point out that the third stage of labor is the most dangerous of all the stages. When the placenta is expelled great care should be taken that any exertion of pressure always be in the anteroposterior direction. An early Credé maneuver on the uterus should not be done unless it is done during contractions of the uterus and then in the anteroposterior plane. No placenta, it is urged again, should ever be delivered unless the fingers of one hand are between the fundus of the uterus and the symphysis pubis. If these things are observed the Committee believes that inversion of the uterus will be prevented. Although the incidence of inversions is small, the shock and sudden death of the patient developing this condition is so dramatic that a repeat performance would be disastrous so far as the physician is concerned. The Committee observes that inversions of the uterus are included as causes of maternal deaths in most past reports.

The Committee wishes to thank all physicians who reported maternal deaths for their co-operation in furnishing the necessary and detailed facts on each case. Thanks is also extended to hospitals for making records available and preparing copies of such records for use of the Committee. Any recommendations or comments from physicians throughout the State that would assist the Committee in submitting a more helpful report are welcome.

The Committee wishes to acknowledge with appreciation the co-operation of the Department of Health through its Divisions of Maternal and Child Health and Vital Statistics for assistance in furnishing data and personnel in the preparation of this report.

ROBERT O. BLOOM, M.D., *Chairman*
BENJAMIN P. BURPEE, M.D.
FREDERICK S. GRAY, M.D.

Dr. Leonard, for the Committee on Officers' Reports moved that the report of the Committee on Maternity and Infancy be accepted.

This motion was duly seconded and was carried.

The report of the Committee on Medical Economics was then presented, as follows:

The principal development during the past year in the field of medical economics has been the inauguration of the American Medical Association's campaign of public education on the principles of voluntary medicine as opposed to compulsory insurance. Since this subject will be fully covered in other reports, it will not be considered further here.

As a result of the Campaign of the American Medical Association, the trustees of the National Physicians' Committee have concluded that their program is no longer necessary, and on April 10 of this year it was voted that the affairs of the Committee should be liquidated. This action brings to a close the activities of this Committee which has been the center of considerable controversy both within and without the profession, and it is undoubtedly best that the public relations of the American Medical Association should be in its own hands.

Schedule of Welfare Cases

In accordance with the instructions of the House of Delegates your committee met with the State Board of Public Welfare to discuss the fee schedule for patients receiving State aid. As a result of the discussion, the Board agreed to request an increased appropriation from the legislature in order to permit an increase in the fee schedule. To the present time, the legislature has taken no action on the budget.

Blue Shield

Growth in membership in the Blue Shield has been much slower in the past year than in the preceding twelve months. Surgical service now covers 175,000 persons

of whom 100,000 are also enrolled in medical service. This decrease in rate of growth is an expected development, since most of the available large employee groups had been enrolled previous to this year, and therefore later increase has been in small units. An important development in making the service more readily available to all citizens of New Hampshire and Vermont has been the vigorous campaign to organize community groups. All communities in New Hampshire now have such groups, and rapid progress is being made in Vermont. Another factor in the decreasing rate of growth has been the cancellation of contracts by some of the larger employers, with the inability of Blue Shield to write coverage outside our own territory as an important factor in these losses. With 20 per cent of the population covered, however, our plan now ranks second in the country in percentage of population enrolled.

Certain tendencies that have developed in the operation of our program require critical scrutiny and necessary corrective measures. A year ago your committee reported that the loss ratio of the surgical service was running in excess of 100 per cent, and made necessary an increase in premium rates. This increase was effective on July 1, 1948, and for the remainder of the year the experience was within reasonable limits. There has been a steady rise in the curve of utilization, however, and the rate at the present time, as indicated by hospital admissions, is at a level about 30 per cent above the expected rate as shown by the averages of the other New England states. It is difficult to determine the cause of this excessive utilization, but the question of abuse of the service by unnecessary use must be considered as one possible contributing factor.

The great majority of the members of the New Hampshire Medical Society have given full support to the Blue Shield program, but a small minority have obviously been guilty either through ignorance or design, of abusing the service for their own advantage. Such actions not only overburden the plan financially and unjustly penalize the co-operating physicians but also adversely affect the reputation of the program in the eyes of the public.

There has also been a generally increased tendency to charge fees in excess of the allowance in the schedule of benefits. Although this schedule was not intended to be a fee schedule, it was the understanding, when the plan was originally instituted, that in the low-income group, fees charged should not exceed the benefit allowed. At present, "low income" is generally considered to be any income up to \$3500 per year per family. For the protection of the policyholder it may be necessary to write a service contract for this group unless full voluntary co-operation can be obtained from the members of the sponsoring societies.

The excessive loss ratio can be met in one of three ways. First, the subscriber rates can be raised to the point necessary to cover the present cost. This step would be unfair to the subscribers until we as doctors are sure that we are all living up to our part of the agreement, and at this particular time, it would have an unfortunate effect from a public relations point of view. Secondly, payments to physicians may be prorated to cover the loss, and for the first time in the history of the plan, the Board of Directors considered this action to be necessary as affecting the May payments. Thirdly, any abuse by the minority must be controlled by the majority.

The action of the Cheshire County Medical Society furnishes an answer to some of these difficulties. In brief, the members have officially voted to accept the benefit allowance as full payment for services to the low-income group, and the staff of the Elliott Hospital in Keene has set up a committee to review all Blue Shield and Blue Cross admissions. The Board of Directors of the Blue Shield instructed its president to request each hospital staff to set up such a committee.

The New Hampshire and Vermont medical societies are the sponsors of our Blue Shield Plan and are responsible for its healthy growth. The promotion of voluntary sickness insurance is the cornerstone of the American Medical Association's educational campaign. It is therefore the obligation of each one of us to do everything in his power to make our own Blue Shield successful.

normal pregnancy until profuse vaginal bleeding occurred near term. She was taken to the hospital, where a transfusion was attempted. She was apparently in labor, but the uterus admitted only two fingers. A forceful manual dilatation was performed, and a stillborn infant delivered by forceps after the delivery of the placenta, which came down first. No rupture of the lower uterine segment was found. The patient died a few hours later. The Committee believed that consultation should have been sought and a more vigorous effort made to administer plasma and whole blood. It was the opinion that the patient might have had a better chance had a cesarean section been done, preceded and accompanied by adequate intravenous therapy with glucose and whole blood. This was especially considered a more desirable approach since the membranes had not ruptured and the cervix was not dilated to any degree.

The puerperal eclampsia reported and classified in Group II was a primipara, forty-three years of age, who had been given prenatal care from the earliest possible time

convulsions before a physician was called, 1 woman, who had had a kidney removed because of tuberculosis, and who had a history of hypertension over many years and became pregnant despite medical counsel to the contrary, died near term of complete failure of the remaining kidney despite every possible intensive medical treatment and delivery of a stillborn child by cesarean section when premature separation of the placenta was diagnosed, another case was in a woman with severe rheumatic heart disease who did not seek prenatal care and refused medical advice concerning pregnancy.

These cases point up the problem of attempting to inform the public of the necessity for adequate and early prenatal care. The Committee believes that physicians should seek and accept all available assistance from private and public agencies concerned with maternal health to the end that women seek a physician's services as early as possible in pregnancy.

In the group of unavoidable deaths there were the following ectopic pregnancy — acute rupture without vaginal bleeding, 1 case, puerperal nephritis with terminal pulmonary edema, 2 cases, inversion of the uterus, 1 case, placenta previa and pulmonary infarct, 1 case, and puerperal embolism and rheumatic heart disease, 1 case.

In the 1948 series of maternal deaths 5 autopsies were performed or recorded. This represents approximately a third of the number of cases and the Committee urges that more post-mortem examinations be performed as the years go on so that more accurate conclusions may be drawn concerning maternal mortality and morbidity.

COMMENTS AND RECOMMENDATIONS

In summary, the Committee attempts to emphasize by way of making recommendations and comments certain principles that may be of value in the deliberation of future conduct of comparable maternity cases. It is noted with gratitude that again almost half the total deaths reported were determined as unavoidable. This means that deaths from maternal causes occur chiefly through accidental or unavoidable circumstances. The decreasing maternal death rate of actually only 1 maternal death for every 1000 live births is indeed encouraging. The Committee would like to think that its efforts over the past fifteen years have contributed to this great decrease by the dissemination of information and the presentation of concrete and specific suggestions concerning accepted practices in obstetrics. It may be that a study of maternal morbidity should be undertaken by someone in accordance with requirements of the American College of Surgeons for hospital standards in obstetrics.

Since there has been evidence that treatment of toxemias and nephritic complications of pregnancy was indefinite or inadequate in this study, the Committee recommends that patients who show even the earliest symptoms or signs of suspected toxemia be seen prenatally at least once a week, or oftener if necessary. It cannot be repeated too often that treatment should be started at the earliest possible time. In toxemias (Grade III), this should be a regime of bed rest, sedation and intravenous injection of magnesium sulfate alternated every two hours with concentrated glucose, the dosage regulated according to the severity of the symptoms and adapted to the individual case. If convulsions develop or are threatened, rapid digitalization should be accomplished. Fluids should be limited early, with attention to a salt-free diet in the early stages. Interruption of the pregnancy should be considered with competent consultation with an obstetrician. The concern should be for planning the safest time and method of delivery weighed against all facts governing the individual case.

The Committee wishes to re-emphasize its continued stand on the practice of forceful manual dilatation of the cervix. There is no indication, in the Committee's opinion, for such a practice under any circumstances.

The Committee believes that all placenta previas in primiparas should be delivered by cesarean section, and that all complete previas, whether in multiparas or primiparas, should be delivered by section.

It should be stressed again that anesthesia is of the utmost importance in obstetrics. The goal of all should be that only well trained anesthetists be used if possible. One of the most important services of a hospital obstetric

and had not shown any symptoms or findings suggestive of a toxemia until about two weeks before the time when a planned cesarean section was to be performed. Indications for the section were fairly clear cut because of the woman's age and the possibility of renal failure in the face of the appearance of albumin. During the operation the patient's blood pressure suddenly rose and continued to remain high. Albumin was abundant in the urine. Treatment had consisted of a salt-free diet. No intravenous magnesium sulfate was given, nor was any regime aimed at combating the toxemia followed. Six hours after the cesarean section the patient had convulsions and died. The Committee believed that the patient should have been given earlier treatment for toxemia and vigorous post-operative intravenous therapy. Patients presenting even a suspicion of a toxemia should be seen once a week or oftener to check blood pressure and urine. In this case there was apparently a two-week period before hospitalization during which the patient was not seen.

In the other categories it seems sufficient to comment only on the causes as grouped. They are as follows in Group I, 1 case was a self-induced abortion, about which little could be determined. 1 patient neglected to seek prenatal care, had an uncontrolled diabetes and developed

department is the availability of a thoroughly trained anesthetist. Physicians should be encouraged to receive special training in this field so that the supply of much needed personnel will be ready to meet the demands.

The Committee believes that cesarean sections should not be performed without competent consultation with a qualified obstetrician.

The Committee wishes to point out that the third stage of labor is the most dangerous of all the stages. When the placenta is expelled great care should be taken that any exertion of pressure always be in the anteroposterior direction. An early Credé maneuver on the uterus should not be done unless it is done during contractions of the uterus and then in the anteroposterior plane. No placenta, it is urged again, should ever be delivered unless the fingers of one hand are between the fundus of the uterus and the symphysis pubis. If these things are observed the Committee believes that inversion of the uterus will be prevented. Although the incidence of inversions is small, the shock and sudden death of the patient developing this condition is so dramatic that a repeat performance would be disastrous so far as the physician is concerned. The Committee observes that inversions of the uterus are included as causes of maternal deaths in most past reports.

The Committee wishes to thank all physicians who reported maternal deaths for their co-operation in furnishing the necessary and detailed facts on each case. Thanks is also extended to hospitals for making records available and preparing copies of such records for use of the Committee. Any recommendations or comments from physicians throughout the State that would assist the Committee in submitting a more helpful report are welcome.

The Committee wishes to acknowledge with appreciation the co-operation of the Department of Health through its Divisions of Maternal and Child Health and Vital Statistics for assistance in furnishing data and personnel in the preparation of this report.

ROBERT O. BLOOD, M.D., *Chairman*
BENJAMIN P. BURPEE, M.D.
FREDERICK S. GRAY, M.D.

Dr. Leonard, for the Committee on Officers' Reports, moved that the report of the Committee on Maternity and Infancy be accepted.

This motion was duly seconded and was carried.

The report of the Committee on Medical Economics was then presented, as follows:

The principal development during the past year in the field of medical economics has been the inauguration of the American Medical Association's campaign of public education on the principles of voluntary medicine as opposed to compulsory insurance. Since this subject will be fully covered in other reports, it will not be considered further here.

As a result of the Campaign of the American Medical Association, the trustees of the National Physician's Committee have concluded that their program is no longer necessary, and on April 10 of this year it was voted that the affairs of the Committee should be liquidated. This action brings to a close the activities of this Committee which has been the center of considerable controversy both within and without the profession, and it is undoubtedly best that the public relations of the American Medical Association should be in its own hands.

Schedule on Welfare Cases

In accordance with the instructions of the House of Delegates, your committee met with the State Board of Public Welfare to discuss the fee schedule for patients receiving State aid. As a result of the discussion, the Board agreed to request an increased appropriation from the legislature in order to permit an increase in the fee schedule. To the present time, the legislature has taken no action on the budget.

Blue Shield

Growth in membership in the Blue Shield has been much slower in the past year than in the preceding twelve months. Surgical service now covers 175,000 persons

of whom 100,000 are also enrolled in medical service. This decrease in rate of growth is an expected development, since most of the available large employee groups had been enrolled previous to this year, and therefore later increase has been in small units. An important development in making the service more readily available to all citizens of New Hampshire and Vermont has been the vigorous campaign to organize community groups. All communities in New Hampshire now have such groups, and rapid progress is being made in Vermont. Another factor in the decreasing rate of growth has been the cancellation of contracts by some of the larger employers, with the inability of Blue Shield to write coverage outside our own territory as an important factor in these losses. With 20 per cent of the population covered, however, our plan now ranks second in the country in percentage of population enrolled.

Certain tendencies that have developed in the operation of our program require critical scrutiny and necessary corrective measures. A year ago your committee reported that the loss ratio of the surgical service was running in excess of 100 per cent, and made necessary an increase in premium rates. This increase was effective on July 1, 1948, and for the remainder of the year the experience was within reasonable limits. There has been a steady rise in the curve of utilization, however, and the rate at the present time, as indicated by hospital admissions, is at a level about 30 per cent above the expected rate as shown by the averages of the other New England states. It is difficult to determine the cause of this excessive utilization, but the question of abuse of the service by unnecessary use must be considered as one possible contributing factor.

The great majority of the members of the New Hampshire Medical Society have given full support to the Blue Shield program, but a small minority have obviously been guilty, either through ignorance or design, of abusing the service for their own advantage. Such actions not only overburden the plan financially and unjustly penalize the co-operating physicians but also adversely affect the reputation of the program in the eyes of the public.

There has also been a generally increased tendency to charge fees in excess of the allowance in the schedule of benefits. Although this schedule was not intended to be a fee schedule, it was the understanding, when the plan was originally instituted, that in the low-income group, fees charged should not exceed the benefit allowed. At present, "low income" is generally considered to be any income up to \$3500 per year per family. For the protection of the policyholder, it may be necessary to write a service contract for this group unless full voluntary co-operation can be obtained from the members of the sponsoring societies.

The excessive loss ratio can be met in one of three ways. First, the subscriber rates can be raised to the point necessary to cover the present cost. This step would be unfair to the subscribers until we as doctors are sure that we are all living up to our part of the agreement, and at this particular time, it would have an unfortunate effect from a public relations point of view. Secondly, payments to physicians may be prorated to cover the loss, and for the first time in the history of the plan, the Board of Directors considered this action to be necessary as affecting the May payments. Thirdly, any abuse by the minority must be controlled by the majority.

The action of the Cheshire County Medical Society furnishes an answer to some of these difficulties. In brief, the members have officially voted to accept the benefit allowance as full payment for services to the low-income group, and the staff of the Elliott Hospital in Keene has set up a committee to review all Blue Shield and Blue Cross admissions. The Board of Directors of the Blue Shield instructed its president to request each hospital staff to set up such a committee.

The New Hampshire and Vermont medical societies are the sponsors of our Blue Shield Plan and are responsible for its healthy growth. The promotion of voluntary sickness insurance is the cornerstone of the American Medical Association's educational campaign. It is therefore the obligation of each one of us to do everything in his power to make our own Blue Shield successful.

The Committee therefore recommends that the House of Delegates urge all members of the New Hampshire Medical Society to give full support and co-operation to Blue Shield, that each county medical society be requested to take action similar to that taken by the Cheshire County Medical Society, that each hospital staff be urged to co-operate fully with Blue Shield by appointing an active review committee, and that each county committee of the educational campaign be instructed to contact each hospital in its county to obtain co-operation in this program.

LESLIE K SYCAMORE, *Chairman*
JOSEPH N FRIBORG, M D
FRANCIS J C DUBE, M D

Dr Leonard, for the Committee on Officers' Reports, moved that the report of the Committee on Medical Economics be accepted with the understanding that this motion, when carried, indicates that the Delegates, as representatives of the component parts of the New Hampshire Medical Society, pledge continued support and co-operation to the Blue Shield.

Dr Johnston stated that the Cheshire County Society operated differently from most of the societies. The members went to Mr Shea, who told them what he liked and what he did not like, and the Society had tried to introduce what it thought was right.

One point that was not stressed too well was the Public Relations Committee. It was really a grievance committee, to iron out these difficulties and be accessible to the public. When there are grievances, this committee should have some authority to take care of them. Furthermore, it should look into the question of unnecessary hospitalization and unnecessary surgery, which undoubtedly is present throughout the State, so that there might be some action to stop such things, in order to bolster Blue Shield and Blue Cross coverage. People, for a small fee, would have a guarantee that their medical care would be taken care of.

Mr Russell S Spaulding, for Blue Cross and Blue Shield, stated that in February, 1948, total benefits per thousand participants were high but that was only one month. In general, the figure averaged out through the year. In January and February, 1948, it came up rapidly. It settled back a little bit seasonably in September and October, and then it went sky-high, way out of sight. Although x-ray services and operating room, medication and laboratory room showed a steady increase, the principal and the notable increase was in room and board. The two possibilities, to account for that increase, were the increased rate of hospital stay and increased utilization. Obviously, the great percentage of increase is because of the increase in cases. The only thing that the increase could be charged to was unemployment. Hospital admissions and unemployment claims closely corresponded. Prior to 1947, they continued on a seasonable up and down level. In 1948 jobs were harder to get, and people were out of work longer. When em-

ployment started down, hospital admissions also started down. But in September and October, 1948, the normal seasonable decline in unemployment leveled off, and hospital admissions immediately started to climb and went way out of sight. It appeared that unemployment and hospital admissions were tied in together and that the current increase was probably due to elective surgery. Mr Spaulding continued with the statement that an increase in rates might be necessary in the near future.

In reply to a question he stated that the increase would probably have to be higher than 10 per cent.

Dr Penhale stated that the subscribers needed surgery and were finding that they could have it done at very little expense to themselves. He believed that the fee schedule would have to be changed, so that Blue Shield would not have to pay so much for that surgery. Perhaps that did not answer the problem of how to lower the hospital costs, but it did answer the problem of Blue Shield.

Dr Sycamore observed that the Trustees of the Blue Shield Plan did not believe that the doctors were responsible for all this excessive utilization. They knew that the great majority of the members of the two medical societies were co-operating fully with the program. A certain small minority were definitely not co-operating, utilizing the service to their own and their patients' advantages. Before the rates to the public are raised the medical profession should be very sure that they are fulfilling their part of the bargain, otherwise, they would be sabotaging the whole program of the American Medical Association and of the New Hampshire Medical Society, admitting to the public that organized medicine cannot meet this challenge.

Secretary Metcalf pointed out that, in the beginning, there was a ruling that if they did not break even, the doctors would take a pro rata break on it. He asked what the delegates would think of paying the doctors less instead of soaking the public more — taking \$70.00 for an appendectomy instead of \$75.00.

Mr Spaulding said that his personal opinion was that Blue Shield could probably struggle along until this trend reverses, as it should sometime. If it happened in a month, there would be no problem. But it might not happen for a year. If Blue Shield could struggle along, by withholding a small percentage from the doctors' payments and not changing the fee schedules and the rates, they could get by with the two commissioners, New Hampshire and Vermont. But that would not help the Blue Cross.

Secretary Metcalf asked if the same thing could not be done with the hospitals.

Mr Spaulding replied that, unfortunately, the hospitals had to have money to run them.

Dr Montgomery asked if it would not obviate much of the difficulty and also take away the

charges of unco-operation if the Society adopted for one year the County Welfare Schedule, which pays the doctors \$50.00 for a major operation and \$10.00 for a minor one. That would cut down the hospital admissions, giving the Blue Shield and Blue Cross a chance to build up.

Dr. Feiner stated that if the fee for a major operation were cut down to \$50.00 Blue Shield patients would be placed in the ranks of the indigent patient. As Mr. Spaulding had pointed out, the fault was not with the doctors — it was with the hospital admissions. Since Blue Shield called for semi-private rooms, was there a breakdown on the admissions, showing whether all hospitals were charging semi-private rates for most of the rooms, he also inquired if there was a breakdown of utilization of laboratory and x-ray services.

Mr. Spaulding replied that the hospitals were being paid their established and published rates. It was possible, of course, that the hospitals were putting the patients in the wards and charging Blue Shield semi-private room rates but he did not believe that any of the hospitals were doing that. He demonstrated that operating room, medication and dressings showed a general increase in utilization, but nothing that matched this peak.

The length of stay in the hospital was decreasing and the number of operations had increased.

Dr. Johnston asked whether comparison with the other New England states showed that New Hampshire patients had more illnesses.

Mr. Spaulding replied that there was no question that there was a great deal more hospitalization in New Hampshire than in the other states.

President Dunbar read the following letter from the Portsmouth Hospital, dated May 18, 1949:

After considerable discussion by the staff last evening, we came to the following conclusions:

1. Doctors on our staff will try to cut down on hospital admissions by doing minor procedures outside.
2. To discourage patients from going to the hospital unless they are really sick.
3. Members of the staff have tried wherever possible, to make the admitting diagnosis conform to the regulations of the Blue Cross.

The hospital had further stated that the doctors had cut down considerably, and that they were watching the outpatient work, because the Blue Cross did not pay for that or for x-ray charges.

Mr. Spaulding read the following list of payments for hospital costs: in January, \$170,000, in February, \$175,000, in March, \$176,000, and in April, \$177,000.

Dr. Dye asked if that were not due to increased hospital costs.

Mr. Spaulding stated that it was for nonsurgical illness. There were many reports of people with colds and the like.

Speaker Dube inquired if Mr. Spaulding had any recommendations to make to the House of Delegates or any suggestions concerning the best means available to solve this problem.

Mr. Spaulding answered that his personal opinion was that the Keene Plan should be effectively tried: let the Committee look the cases over, and let the doctors decide whether anybody is abusing it, and if so, let the doctors take it up with the doctors. The only alternative was an increased rate on Blue Cross, there was no question about that. And it would take some help from the new president or the Committee to convince the Insurance Commissioner that there should be a delay of another month.

Dr. Leonard pointed out that there was a motion that the report of the Committee on Medical Economics be accepted, with the understanding that this motion, when carried, would indicate that the delegates as representatives of the component parts of the New Hampshire Medical Society, pledged continued support and co-operation with the Blue Cross and Blue Shield.

Speaker Dube stated that the motion had been seconded before all the questions had come up. He asked all those in favor of the motion to signify assent by saying "aye." There was a chorus of "ayes," and the motion was carried.

CASE 35431

PRESENTATION OF CASE

First admission A thirty-six-year-old machinist was admitted to the hospital for diagnosis

Four months before admission the patient had a roentgenogram of his chest taken by a mobile unit at his place of work. Several weeks later he was recalled for further x-ray studies and was subse-

FIGURE 1

quently referred to this hospital after being told that he had an abnormal shadow in the right lung. The patient felt well and was completely free of complaints. There was no history of cough, dyspnea, chest pain or weight loss.

A review of the systems and the past history were noncontributory.

Physical examination revealed a well developed and well nourished man. The chest was clear, and the remaining physical examination was negative. There was no cyanosis or clubbing.

The temperature was 99.0°F, and the pulse and respirations were normal. The blood pressure was 120 systolic, 75 diastolic.

The urine was normal. The blood hemoglobin was 13.3 gm, the white-cell count was 10,300, with 54 per cent neutrophils. A stool specimen gave a negative guaiac reaction.

In the hospital the patient remained free of complaints. A roentgenogram of the chest disclosed a rounded area of increased density, measuring 2 or 3 cm in size, in the lower medial portion of the right lower lobe (Fig. 1). Subsequent studies, including an intravenous pyelogram, barium enema and upper gastrointestinal series were negative. On the sixth day a bronchoscopy was entirely negative.

It was believed that in view of the negative studies the patient should be followed in the Out-patient Clinic. He was discharged on the seventh hospital day.

Second admission (three weeks later) In the interval the patient remained completely asymptomatic, and an additional roentgenogram of the chest during one of his two clinic visits was unchanged. Cytologic examination of the bronchoscopy washings taken the day before discharge from the hospital was subsequently reported as "doubtful," and the patient was therefore readmitted.

Physical examination and laboratory studies were essentially the same as at the previous admission.

On the fourth hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. J. GORDON SCANNELL The diagnostic and therapeutic problem of the entirely asymptomatic chest lesion that is the by-product of tuberculosis control is a very real one. The present case is an example, for the decision to explore was, according to the protocol at least, made upon an equivocal basis, namely, a "doubtful" cytologic smear. Once the suspicion of cancer was raised, there was no alternative course but to allay it by surgical exploration if necessary.

When we consider the x-ray films, I think it becomes apparent why there was some hesitancy on the part of the staff in electing to explore this patient, for the lesion is quite consistent with a small incidental inflammatory process that was so hidden away in the voluminous substance of the lungs as to be silent. By the same token, even a small carcinoma, located as centrally as this lesion appears, should have sufficiently encroached upon the bronchial tree to have given rise either to cough and expectoration or to the x-ray picture of segmental atelectasis or localized emphysema.

Before going farther may we see the x-ray films?

DR JAMES J McCORT The round area of increased density is in the posterior basal segment of the right lower lobe. It is smooth in outline and shows no calcification. There is no evidence of segmental collapse or obstructive emphysema in the involved segment. No lymph-node enlargement is apparent in the right peribronchial region. The remaining lung fields are clear, and the heart and vessels are within normal limits. I do not see any evidence of involvement of the bones of the thoracic cage.

DR SCANNELL Am I right in saying that the x-ray picture is not that of a benign tumor of the lung with the exception of adenoma? Chondroma is the most common of these benign lesions, fibroma and hamartoma are not rare and yet these tumors usually have a sharply defined border and are quite round, or at the most somewhat lobulated. Similarly, a bronchiogenic cyst should be either a well defined round or an oval lesion unless its outline was obscured by superimposed infection, which, in turn, should have been reflected in the clinical course of the patient.

The differential diagnosis here lies between some chronic, low-grade infectious process and neoplasm. Of the latter, metastatic tumor is for our purpose excluded by the failure to find a primary source. Of the former, tuberculosis comes to mind first, and secondly some localized nonspecific chronic pneumonitis or residuum thereof for which we have not the slightest indication in the record, not even the smallest red herring. Coccidioidomycosis and histoplasmosis are mentioned in passing. As for tuberculosis, I do not see how we can exclude it even if sputum specimens were negative—a finding not reported in the protocol. In the absence of any statement to the contrary, we can assume that there was no unusual exposure to tuberculosis, and there is certainly no evidence of active infection, but there need be none. This could well represent the parenchymal lesion of a primary infection complex and could therefore quite reasonably be treated expectantly. I cannot make out enlarged satellite hilar nodes.

The manifestly disturbing feature of the case is the "doubtful" report of the cytologic washings taken during an otherwise negative bronchoscopy. I understand that "doubtful" indicates a real degree of suspicion on the part of the interpreter of the slide, and not a synonym for unsatisfactory sampling, poor preservation of cells and so forth, which would call for a diagnosis of "unsatisfactory" and a request for another sample. The examination of bronchial washings has been an effective measure in extending the range of the bronchoscope in making the diagnosis of cancer, particularly if an unequivocal diagnosis of carcinoma cells in the sputum is made. It seems reasonable to suppose that irrigation of the suspected limbs of the bronchial

tree should yield a high percentage of positive diagnoses, although it is my impression that the results in our laboratory have differed little from examinations of fresh sputum carefully obtained and sent straightway to the laboratory.

Except for the suspicious cytologic smear there is little upon which to base a diagnosis of carcinoma. Ordinarily a bronchial lesion of this size will give rise to symptoms of pressure, obstruction or irritation. A truly peripheral tumor will not, and is likely to be discovered in a routine chest film, or, if the tumor has involved a pleural surface and caused pain, a film of a nearby joint to discover the cause of the arthritis is apt to demonstrate mischief in the lung. Therefore, although the number of incidental lesions picked up in chest surveys is great, the number of central bronchiogenic carcinomas must be very small. I am aware that this lesion is not central enough to be within the range of the bronchoscope, and therefore my premise that it is large enough to lead to symptoms may be incorrect.

What of bronchial adenoma? Here, again, the lesions are usually central enough to give rise to symptoms—notably hemoptysis or expectoration. An occasional adenoma may be peripheral, but, if so, it has no business producing even a doubtful smear since these are essentially lesions of the bronchial wall and not the mucous membrane.

One tumor that has aroused great interest recently is alveolar adenomatosis probably a multicentric alveolar-cell carcinoma. Although these lesions are multicentric in development, they may be first seen just as this case was seen, with the first of their lesions established. The relation of this type of carcinoma in man to a similar histologic picture of a virus disease in sheep—jagziekte—leads to interesting speculation concerning the genesis of malignant tumors. I do not believe enough of these cases have been seen to make a cytologic diagnosis on the sputum certain, and therefore "doubtful" is the interpretation I would expect.

We are left, then with three likely diagnostic choices. If we did not have the disturbing cytologic report, my vote would be for tuberculosis. Since we have it, we must consider carcinoma. If the cancer is of the usual variety however, it should give an unequivocal smear. I interpret the "doubtful," therefore, to mean malignant cells that the cytologist had not seen in the lung before or were at least unfamiliar enough to shake his confidence. I will therefore choose alveolar-cell carcinoma as the preoperative diagnosis, meaning by that the initial lesion of pulmonary alveolar adenomatosis.

DR JACOB LERMAN Does Dr Scannell mean diffuse tuberculosis or a tuberculoma?

DR SCANNELL I suppose I mean localized tuberculous infection rather than diffuse tuberculosis. I think this is a localized area of infection.

DR HELEN S PITTMAN We are getting a tremendous number of people referred to the Pulmonary Clinic because of the results of industrial survey studies. This is one of them. We are confused by it and do not know what to do about it. This man came in soon after a patient with a fairly similar finding had been operated on and been found to have bronchiogenic carcinoma. So, we took his lesion seriously from the start and decided that he had to be explored. He was sent to the hospital to

be explored. Very recently, we explored a man with, again, a very similar lesion and no symptoms, and found that he had extensive mediastinal metastases so that resection was not considered advisable. In this case our preoperative diagnosis was a combination of two questions, the same ones that Dr Scannell has brought up: tuberculoma and carcinoma. It seemed that this case would probably be suitable for a lobectomy, even though it proved to be carcinoma, granting no mediastinal involvement or hilar-lymph-node involvement was found. Consequently, we went ahead to determine just what this tumor was anatomically and found, as shown by x-ray studies, that it was in the basal portion of the right lower lobe, and as a biopsy procedure we elected to do a segmental resection of that portion of the lung. When the pathologist who was in the operating room reported his finding, I contented myself with that and did no further operation.

FIGURE 2

be worked up as stated in the record and was discharged at the end of a few days because everything appeared to be normal. He turned up in the Pulmonary Clinic a couple of weeks later. At that time we had this doubtful report from the bronchoscopic washing on the smear of the sputum. Dr Lamar Soutter and I discussed it and decided that we should consider this a bronchiogenic carcinoma until it was proved otherwise. The patient accordingly was sent back to the hospital from the Pulmonary Clinic with that diagnosis.

DR CARROLL MILLER From the surgical point of view I would emphasize the implications and statements already made — that this patient should

CLINICAL DIAGNOSIS

Tuberculoma?
Carcinoma?

DR SCANNELL'S DIAGNOSIS

Pulmonary alveolar adenomatosis, localized

ANATOMICAL DIAGNOSIS

Bronchial adenoma

PATHOLOGICAL DISCUSSION

DR TRACY B MALLORY The tumor was very well circumscribed (Fig 2) and proved to be entirely endobronchial. It arose in a small branch of the primary bronchus to the lobe, about 2.5 cm distal to the point of resection — in other words, much farther out in the lung tissue than we commonly see bronchial adenomas, and yet histologically that is what it turned out to be.

There are two fairly well characterized types of bronchial adenoma. In one, the tumor resembles very much the appearance of basal-cell tumor of the skin. In the other type the tumor is very suggestive of the carcinoid tumor seen in the appendix and small bowel. This tumor was of carcinoid type. In the vast majority of the tumor, the cells were very small and uniform, and in the section stained with hematoxylin and eosin, I think it would be impossible to distinguish it from carcinoid of the bowel. In one very small area there was a large, atypical mononucleated cell, which is an unusual finding in adenoma. However, I do not believe it would alter my diagnosis. It might possibly explain the fact that a few atypical cells reached the sputum.

DR SCANNELL Did the cytologist explain the basis of the doubtful report?

DR MALLORY No. I cannot find any further information on that.

DR SCANNELL I wish to emphasize that because it is a constantly recurring problem. We must accept "doubtful" as a real finding. Dr Maier* reported a series of four or five bronchial adenomas beyond the range of the bronchoscope. I believe they are quite uncommon.

DR PITTMAN It was on the basis of the doubtful tumor cells that we sent the patient back into the hospital, even though he had been discharged fairly recently after adequate study.

CASE 35432

PRESENTATION OF CASE

A forty-seven-year-old housewife, a para III, gravida V was admitted to the hospital because of dyspnea, ascites and peripheral edema.

The patient had been well until one year before entry, when she noted the onset of shortness of breath on climbing stairs. During the following three months, dyspnea on exertion became progressively more severe, and the patient then noted that her legs and ankles became swollen after prolonged standing. These symptoms became increasingly more marked until eight months prior to admission, when she could no longer climb one flight of stairs or do minor household tasks without becoming very tired. She noticed on waking that the lower portion of her face was swollen and that the swelling of ankles and legs no longer cleared overnight. Slight cyanosis appeared at about this time and persisted. A roentgenogram of the chest taken by her physician had shown an enlarged heart. Six months before admission abdominal swelling occurred, and since that time the patient had been almost completely bed ridden. The patient was seen in the Out Patient Department of this hospital, following which numerous studies were performed. Initially the patient responded to treatment with digitalis, diuretics and other cardiac therapy, however, six weeks before admission symptoms returned, and she seemed to have become refractory to treatment. She did not have orthopnea or hemoptyses.

The past history was significant in that prior to one year before admission the patient had never had any symptoms referable to the chest. The patient's mother had no known illnesses during the pregnancy, and the patient was born following a normal, full-term delivery without cyanosis or other neonatal difficulty. Growth and development progressed normally, and as a child she was well and active without dyspnea or other limitations. The patient had rather frequent attacks of tonsillitis until fourteen years of age, when a tonsillectomy and adenoidectomy were performed. She recalled severe epistaxes during childhood and one episode of abdominal pain and fever at eight or ten years of age, but no other symptoms suggestive

of rheumatic fever. At the age of fourteen a "heart condition" was diagnosed, following which she was told not to exert herself too much. She was asymptomatic, however, and took part in all the usual activities of a girl of her age. Subsequently she had married and during the last seventeen years before admission she had five pregnancies, two of which ended prematurely, the cause was unknown. Through all these pregnancies she had remained symptom-free. The patient recalled that during several of the pregnancies a "heart condition" was again mentioned. One of the physicians stated that there was no murmur but that the heart rate was rapid. There was no history of asthma or other chronic pulmonary disease, pleurisy, hemoptysis or dyspnea, although she had had rather frequent winter colds associated with a dry cough. The patient denied ever having had scarlet fever, diphtheria or influenza.

Physical examination revealed a moderately well developed, thin woman who appeared chronically ill and who was slightly cyanotic but in no acute discomfort. There was no clubbing of the fingers. The veins of the forehead, arms and upper chest were distended, as well as the superficial and deep neck veins, where a deep jugular systolic pulse was present. The chest was clear. The heart was enlarged to the left anterior axillary line, with a diffuse apical pulse. There was a Grade IV harsh systolic murmur best heard at the lower left sternal border and apex in addition to a thrill. The murmur was not transmitted to the neck or back and was poorly transmitted to the left axilla, and was not well heard at the base of the heart. The pulmonic second sound was four times greater than the aortic second sound. There were no diastolic murmurs. The pulse was regular. There was marked ascites and liver dullness extended 3 or 4 cm below the costal margin although the liver edge was not palpable. There was a ++ edema of the legs.

The blood pressure reading on the right arm was 115 systolic, 100 diastolic, and on the left, 110 systolic, 95 diastolic. The temperature and pulse were normal, the respiratory rate was 20.

The urine had a specific gravity of 1.016 and gave a ++ test for albumin. The sediment was normal. The blood hemoglobin was 16.0 gm, and the white-cell count 9400 with 68 per cent neutrophils. The total protein was 5.15 gm per 100 cc, with an albumin of 3.66 gm and a globulin of 1.49 gm. The albumin-globulin ratio was 2.5. The blood sodium was 136.4 milliequiv, the chloride 100 milliequiv per liter. The nonprotein nitrogen was 36 mg per 100 cc and the vital capacity 2.1 liters (63 per cent).

A roentgenogram of the chest showed the lung fields to be clear. The diaphragm particularly on the left, was rather low in position and somewhat

limited in excursion fluoroscopically. The heart shadow was increased in size, the cardiothoracic ratio measuring 16.5 to 28 cm., and the enlargement appeared to be in the region of the ventricles. The main-pulmonary-artery shadow and the hilar vessels were somewhat more prominent than usual, but the peripheral vessels in the lungs were not so prominent as usual. There was no substernal mass. An electrocardiogram showed a probably normal rhythm at a rate of 80. No definite P waves were made out. There was moderate right-axis deviation, the T waves were low and upright in Lead 1 and 3, upright in Lead 2, essentially flat in Lead VL and upright in VF. The R waves were high in Lead V₁ and V₄, and the T waves were diphasic in Lead V₂ and upright in Lead V₄ and V₆. This reading showed no significant change over a record taken about two months earlier, except that the P waves were now not clearly present. Five days later another electrocardiogram showed a regular rhythm at a rate of 95 with absent P waves. The special auricular leads also failed to reveal definite P waves. The T waves were low in Lead 1 and diphasic in Lead 2 and 3. The chest leads showed upward deflection in V₂ and downward deflection in V₄ and V₆.

On the sixth hospital day an abdominal paracentesis was performed, with the removal of 3900 cc of slightly cloudy, straw-colored fluid. The specific gravity was 1.010, and the protein 2.20 mg per 100 cc, with 314 red cells and 89 white cells per cubic millimeter. A culture was subsequently reported as showing no growth.

Repeated vital-capacity studies ranged from 60 per cent to 66 per cent. The sedimentation rate was 1 mm in sixty minutes and a prothrombin time 19 seconds (normal, 15 seconds), or 63 per cent. There was little change in the patient's course except for a short period of weakness at which time the serum sodium was found to be 121.7 milliequiv and the chloride 96 milliequiv per liter. This deficiency was corrected by the addition of 10 gm of salt to her diet, following which the patient felt somewhat better. Another electrocardiogram taken on the twenty-sixth hospital day showed no significant changes from the previous readings except for the presence of definite P waves. Several days before discharge the patient complained of tenderness in the legs. Examination, however, was negative for thrombophlebitis. An examination of the chest one day before discharge showed little change in findings. The heart was much as before, with the apical impulse at the left anterior axillary line. There was a slight thrill palpable at the apex and also over the second and third left intercostal spaces.

A Grade III systolic murmur was loudest between the apex and lower left sternal border. The pulmonary second sound was much accentuated, and there was a loud third heart sound along the left sternal border and at the apex, now followed by a questionable slight diastolic rumble.

Since the patient's morale was low and she wanted to go home and since it was believed that little more could be done for her in the hospital, she was discharged on a cardiac regime on the thirty-fourth hospital day.

Three days after discharge she suddenly died at home.

DIFFERENTIAL DIAGNOSIS

DR EDWARD F. BLAND: This patient had been remarkably well until the last year of her life, and the history gives us various but vague information concerning the background for her final decline and death. There are two features that are definite—namely, extreme pulmonary hypertension and subsequent heart failure. As is often true under these circumstances, she went inexorably downhill and died of pure right-sided failure, with clear lungs. She had never had pulmonary edema or hemoptysis.

There are several likely possibilities to explain this clinical picture, but at this point we need help from the X-Ray Department. I have not seen the films, and they may influence considerably the direction of the discussion. What we would like to know, Dr McCort, is the size and shape of the heart, the degree and type of pulsation of the hilar vessels, the character of the lung tissue beyond as to vascularity, and whether or not there is evidence of pulmonary infarction—either old or recent.

DR JAMES J. MCCORT: Examination of the chest shows marked enlargement of the heart to the left side of the chest. There is fullness anteriorly suggesting that the enlargement is mainly in the region of the right ventricle. There is also widening of the pulmonary artery, seen in the right anterior oblique film and enlargement of the right branch of the pulmonary artery. We do not see the left branch well. A paucity of the vascular markings in the peripheral lung fields is noted. There is no evidence of scars from previous infarction. Slight blunting of the right costophrenic sinus is present. We have no information of the character of the pulsation of the right pulmonary artery.

DR BLAND: Do you see any linear scars in the lung parenchyma? Can you say that the auricles are enlarged?

DR MCCORT: I do not believe they are enlarged. There is no posterior or lateral displacement of the barium-filled esophagus.

DR. BLAND Is the aorta normal, is it too small or too big?

DR. MCCORT It is within normal limits I should say.

DR. BLAND The heart is not quite as large as I expected to find it. The pulmonary arteries are moderately enlarged, not huge. The aorta does not appear unusually small. Huge pulmonary trunks and a small aorta would suggest interauricular defect, but that seems unlikely in this patient. We can be reasonably sure however that she had a serious obstruction to the pulmonary circulation. Can we be certain that she did not have rheumatic heart disease and mitral stenosis as a background for this pulmonary hypertension? I do not think so, for several reasons. The history is neither helpful nor the reverse because many people have no rheumatic history and yet develop mitral stenosis of high degree.

The physical signs do not suggest mitral-valve disease, and furthermore the heart rhythm remained normal throughout the twelve months of failure. Most patients under these circumstances would develop auricular fibrillation if mitral stenosis were present. And, finally, with back pressure from mitral stenosis, the lungs suffer. In this patient there is no history or x-ray evidence of lung congestion. Therefore, I do not believe rheumatic heart disease played any part in this picture.

Next we have to consider some congenital lesion that might lead to this situation in the pulmonary circuit. If we take the physical signs as described — the loud systolic murmur and the thrill near the lower sternum — the commonest cause on a congenital basis would be interventricular septal defect. In this condition, however, signs are usually characteristic and are present throughout a person's life, at least from early childhood. If present, such a lesion is not likely to escape comment during three pregnancies. So I am willing to throw out interventricular septal defect.

What else could cause this murmur and thrill? Congenital stenosis of the pulmonary valve might be responsible, but this patient lived too long without symptoms, and the degree of right-axis deviation in the electrocardiogram was hardly extreme enough to warrant serious discussion of this possibility.

How about interauricular septal defect complicating the situation? It would be most unusual to have a murmur and a thrill of this degree from auricular septal defect, and murmurs that exist are related to the tremendous amount of blood flowing through the pulmonary circuit with a relative pulmonary stenosis. So I shall have to put aside for the moment the systolic murmur and

thrill because I cannot logically account for them other than on the basis of pulmonary-artery dilatation.

We have still left unexplained the obstruction in the pulmonary circuit. There are two likely possibilities. First, embolization of the lung can do this, and the cardiac difficulty need not come at the time of embolization. Such cases have been recorded and we have had one here in a patient who following pregnancy had widespread embolization of the lung, presumably from amniotic material. She succumbed four years later from right-sided heart failure under circumstances somewhat similar to those in the case under discussion. Another possibility is embolization of the lung from clinically undetectable thrombophlebitis. There is nothing in the history to point in this direction although terminally there was slight tenderness in the legs. We would like in this connection a clue from the history such as spells of breathlessness in the past, or perhaps pleurisy or hemoptysis — although none of these are essential. Hence, I do not find suggestive evidence for embolization of the lungs as a cause of the ultimate right-sided failure in this case. Secondly, and finally by exclusion we are left with primary endarteritis of the pulmonary arterioles. I know of no way short of lung biopsy to establish this diagnosis clinically, although cardiac catheterization is helpful in puzzling cases. The derangement here, as with widespread embolization of the lung, is pulmonary ischemia. These patients usually are dyspneic before they become cyanotic. In fact, the degree of cyanosis may vary from a barely detectable degree of dusiness to the extremely black appearance of the cardiac patients first described by Auerza. But once right-sided heart failure appears their course is progressively and unremittingly downhill.

Therefore, in summary, it is clear that this patient had a serious obstruction to the pulmonary arterial supply to the lungs sufficient to produce right-sided heart failure. I do not believe mitral stenosis or the Lutembacher combination had any part in this picture, nor is there convincing evidence for a congenital defect. I am left with either widespread embolism of the lungs or a primary pulmonary arteritis as the most likely cause — I prefer the latter.

DR. MCCORT The X-Ray Department suggested the possibility of massive thrombosis of the pulmonary artery to account for the dilated main pulmonary artery and relative avascularity peripheral to the major branches of the pulmonary artery.

DR BLAND The X-Ray Department has become very expert in spotting an obstructing thrombus in a main pulmonary trunk. They have repeatedly—well, perhaps twice—pointed them out to us, and they have been correct. In this x-ray film two main vessels can be seen, one stops abruptly with avascular lung beyond, and the other does not. This is suggestive of thrombosis locally. Perhaps there is one here. But it would be difficult to assume that such an event occurred a year before the patient died and was the explanation for the total illness. It may have been a later complication. It is an interesting speculation, but I do not think a large local thrombus existed here.

DR HOWARD B SPRAGUE I think I recognize this patient as being one over whom we agonized considerably from the standpoint of diagnosis for several months and arrived at about the same conclusion that Dr Bland has, by a method of exclusion. When she was presented at cardiac grand rounds, the question of the left main pulmonary artery came up, and it was reported as being not visible. Later, after fluoroscopy, a pulmonary artery was seen on the left side.

DR BLAND It is hard to see, is it not?

DR McCORT Yes it is.

DR BLAND Because it is obscured by the heart? What did you think she had, Dr Sprague?

DR SPRAGUE We came to the conclusion that cor pulmonale was the most likely diagnosis. I would like to say once more that the rule now seems to be when in doubt, say cor pulmonale. That opinion could well be spread through the country, I think, because it is not too well recognized. In the last case that I saw, in North Carolina, the patient had a tremendous main pulmonary artery and clear lungs—no one made the diagnosis.

DR DONALD S KING What do you mean by cor pulmonale?

DR SPRAGUE I mean primary endarteritis.

DR BLAND It is also worth emphasizing that patients with cor pulmonale rarely fibrillate, in contrast to those with rheumatic heart disease.

CLINICAL DIAGNOSIS

Cor pulmonale

DR BLAND'S DIAGNOSES

Primary pulmonary endarteritis

Embolization of lungs?

Cor pulmonale, with right-sided heart failure

ANATOMICAL DIAGNOSES

Pulmonary emboli, multiple, recent and old, with recanalization

Cor pulmonale

Hydrothorax

Ascites

Peripheral edema

Chronic passive congestion of liver

PATHOLOGICAL DISCUSSION

DR TRACY B MALLORY This patient was found at autopsy to have an enlarged heart, the enlargement being almost entirely confined to the right ventricle. The right ventricular wall measured 7 mm in thickness, with a dilated pulmonary conus. This photograph is from the heart and shows the right ventricle with tremendous thickening of the columnae carneae and considerable thickening of the ventricular wall itself (Fig 1). The left ventricle was of normal size. The main branches of the pulmonary artery contained some adherent thrombi or emboli, which showed traces of organization that looked as if they had been present for a week, possibly longer, but certainly not long enough to explain the enlargement of the right side of the heart. When the pulmonary artery was opened further, it was found that, although the main pulmonary artery and its primary branches were free from atheroma, the secondary and tertiary branches had numerous atheromatous plaques. At the next smaller division a point was suddenly reached where the scissors could no longer open the vessels, and it was evident that perhaps the fourth-division vessels were uniformly, almost completely, occluded by fibrous bands that were clearly the result of old organized, recanalized emboli. The case is almost identical with one that Dr Castleman and Dr Bland reported* a short time ago. The microscopical pictures from their case could be superimposed upon pictures from this case. Microscopically small pulmonary-artery branches showed athero-

*Castleman B and Bland E F. Organized emboli of tertiary pulmonary arteries: unusual case of cor pulmonale. *Arch Pathol.* 42:581-589, 1947.

matous plaques, and farther out in the vessels one came upon a point where there were thrombotic plugs and the lumen of the arteries had been divided into five or six small lumens (Fig 2)

DR GORDON MYERS Does Dr Bland think that the systolic murmur and thrill could have been caused by tricuspid regurgitation?

DR BLAND Thrills usually mean stenosis rather than regurgitation, either real or relative. I favor

to have been of the same size and uniformly scattered throughout both lungs, so that embolization must have been a major episode but we could not clearly identify it from the history. We were sus-

FIGURE 1

dilatation of the pulmonary artery immediately beyond the orifice as the most likely explanation.

DR MYERS The thrill was low, between the apex and the left sternal border.

DR MALLORY The tricuspid valve measured 14 cm in circumference. The pulmonary valve was normal in circumference, 8 cm.

DR BLAND I still favor the pulmonary orifice as the origin of the murmur and thrill. In the case Dr Mallory referred to, all the emboli appeared

FIGURE 2

picious of amniotic material at the time of her last pregnancy.

DR BENJAMIN CASTLEMAN Amniotic emboli are much smaller and get out even farther in the pulmonary circuit.

DR BLAND What is your explanation in today's case, Dr Castleman?

DR CASTLEMAN Multiple emboli, probably from the pelvic or deep leg veins.

DR MALLORY The pelvic veins were examined carefully, and no evidence of thrombus was found. The deep leg veins were not examined. The pulmonary vessels at the point of occlusion measured around 3 mm in diameter.

DR JAMES A. CURRENS The presence of pulsation in the jugular vessels might be in favor of tricuspid insufficiency.

DR BLAND Yes.

BOOMERANG

THE executive branch of the federal Government has given the appearance of getting down to business in a rather shocking manner in its intention to dictate the conditions under which medicine shall be practiced in this democracy. As long ago as February a United Press dispatch from Washington announced plans of the Government "to crack down on alleged antitrust practices of 'several' state medical associations," with the prediction that the action might come soon after President Truman sent to Congress his compulsory national health insurance program.

It would be unworthy of the dignity of American medicine to make capital of the publicized fact that also in February, during the session of the Board of Trustees of the American Medical Association, the Board room was broken into at night and the records of the Board and the brief cases of the trustees were thoroughly searched.

In August the secretary of the American Medical Association received the following letter, emanating from the Department of Justice:

Dear Sir:

In connection with an investigation by this Department of alleged violations of the federal antitrust laws in the medical field, it is requested that you make available for examination by the bearer, an agent of the Federal Bureau of Investigation, such of your files as he may request.

Your co-operation in this investigation will be very much appreciated.

Sincerely yours,

HERBERT A. BERGSON

Assistant Attorney General

September was an active month for the Department of Justice, for during that period of thirty days investigations of the following organizations were launched: American Medical Association, New York State Medical Society, Utah State Medical Association, Washington State Medical Society, Arkansas State Medical Society, Oklahoma State Medical Association, Michigan Medical Service (a Blue Shield prepaid medical-care plan), Arkansas Blue Cross-Blue Shield Medical Care Plan, Los Angeles County Medical Society, Beckham County Medical Society (Oklahoma), Wayne County Medical Society (Michigan), Nassau County Medical Society (New York), Queens County Medical Society (New York), New York County Medical Society, Harris County Medical Society (Texas), and King County Medical Society (Washington).

This is the September list only, during recent months a number of other medical societies also have been asked to open their records to investigation by Antitrust Division agents.

It is, on the whole, better to believe that the current activities of the Department of Justice are purely fortuitous, that they have no connection with the Government's proposed excursion into socialized medicine or the activities of the medical profession in opposing such compulsion. Under the circumstances it is exceedingly unfortunate that the Department of Justice should have chosen this particular time for its investigations. In so doing it lays the Government open to the suspicion of using methods that follow a pattern familiar in certain other countries but are still repugnant in its own.

Astute public officials are hardly likely to employ tactics that may recoil upon themselves.

POSTGRADUATE ASSEMBLY

THE Central Committee in charge of the New England Postgraduate Assembly announces that the eighth annual meeting will be held on November 9, 10 and 11 at the Copley Plaza Hotel, Boston. As usual an interesting and instructive program has been arranged, and as usual an impressive attendance of physicians from the six New England states is expected. Four papers will be presented on each of the three mornings, and six on each afternoon of the first two days. A jamboree — defined by Webster as (1) a noisy carousal or merrymaking and (2) an international or intersectional gathering of boy scouts — will be held on the evening of November 9. As doctors and their wives are urged to participate, the first definition is assumed to be the correct one. Since lusty joy should not be entirely unrestrained, however, in the land of the Puritans, the carousing will be preceded by a short lecture to put the merry-makers in a properly subdued frame of mind.

A feature of the Assembly will be the introduction of television programs in addition to the announced speakers on the mornings of November 10 and 11. These programs, arranged through the generosity of E. R. Squibb and Company, will emanate from the New England Medical Center, drawn by lot from among the various Boston hospitals. Part of the first morning's program will be presented by the staff of the Massachusetts Infantile Paralysis Clinic of the Children's Hospital.

Fifty-six commercial exhibits will occupy the usual booths.

The medical organizations of America have today much of their interest directed toward politics and public relations. Except for these two urgent demands the accent has always been and always should be on mutual improvement and the postgraduate education of physicians. It is one of the important and perpetual reasons for the existence of medical societies.

The New England Postgraduate Assembly is a thoroughly praiseworthy co-operative undertaking of a sectional group of societies. To say that it supplements such activities as the postgraduate lecture course offered each spring by the Massachu-

setts Medical Society to all physicians in the Commonwealth, and the program of postdoctorate medical education for practicing Connecticut physicians currently in operation under the sponsorship of the Yale University School of Medicine and the Connecticut State Medical Society is not enough.

The Postgraduate Assembly in its own right, with its outstanding list of speakers and the other features that it offers takes high rank among such gatherings.

DR ALAN R. MORITZ

RECENTLY, a signal tribute was paid to a distinguished leader in legal medicine. On the occasion of his departure from Massachusetts, Dr. Alan R. Moritz, formerly head of the Department of Legal Medicine at Harvard Medical School and pathologist to the Commonwealth, was honored by a bronze plaque, which was presented with a sum of money to Harvard Medical School in commemoration of Dr. Moritz's ten years of service. In addition he received from his associates in the Massachusetts Medico-Legal Society a scroll in recognition of his achievements in his field.

The *Journal* joins his confreres in wishing Dr. Moritz the best of fortune in his new duties as professor of pathology and director of the Institute of Pathology at Western Reserve University. Regret that the Commonwealth is losing an outstanding figure in legal medicine is tempered only by the conviction that further accomplishments are in store.

NATIONAL GASTROENTEROLOGICAL ASSOCIATION

THE *Journal* congratulates the National Gastroenterological Association and its president, Dr. William Reid Morrison, on the fourteenth annual convention of the Association that has just come to a close in Boston.

Many prominent speakers were on the three-day program, they included, in addition to leading American physicians and surgeons, the Rt. Hon. the Lord Alfred Webb-Johnson, president of the Royal College of Surgeons of London, the subject of whose paper was "Experientia Docet." Lord

Webb-Johnson spoke again at the annual banquet, and is addressing the Postgraduate Course in Gastrointestinal Surgery that follows immediately on the meeting of the Association, on the subject "Some Surgical Adventures"

The Most Reverend Richard J. Cushing, D.D., archbishop of Boston, and James H. Rand, Jr., president and chairman of the board of Remington Rand, Inc., were the other dinner speakers. For the first time in Boston a program of abdominal surgery was presented over television.

Mr. Lacoupey states that, as yet, therapeutics do not teach how to arrest the progress of pulmonary tubercularization, he thinks that he has supplied the desideratum. He has administered, in a multitude of cases, the pharmaceutical preparation pommade mercurielle (mercurial ointment), in pills, a dose from five to forty centigrammes daily, half in the morning, half in the evening. Under this treatment the morbid phenomena soon lessened, and then ceased altogether.

Boston M & S J, October 24, 1849

MASSACHUSETTS MEDICAL SOCIETY

DEATHS

BURBECK — Edward K. Burbeck, M.D., of Marblehead, died on July 1. He was in his seventieth year.

Dr. Burbeck received his degree from Johns Hopkins University School of Medicine in 1907. He was affiliated with the Mary A. Alley Emergency Hospital and was a fellow of the American Medical Association.

His widow survives.

GREENE — Ransom A. Greene, M.D., of Wayland, died on October 4. He was in his sixty-ninth year.

Dr. Greene received his degree from Baltimore Medical College in 1902. He was superintendent of the Walter E. Fernald State School in Waverley and was formerly superintendent of the Taunton State Hospital. He was a member of the American Psychiatric Association and New England Society of Psychiatry and a fellow of the American Medical Association.

His widow, a son and two grandchildren survive.

MISCELLANY

FORMATION OF MASSACHUSETTS HEART ASSOCIATION AND NEW ENGLAND CARDIOVASCULAR SOCIETY

At a meeting of the members of the New England Heart Association held on September 19, 1949, the name of the New England Heart Association was changed to the Massachusetts Heart Association. The present officers and Executive Committee officers will continue until the annual meeting in the spring. In addition, steps were taken to form the New England Cardiovascular Society.

The purpose of this change in name to the Massachusetts Heart Association is to promote greater efficiency of operation in the work of the organization as an affiliate of the American Heart Association, in the development and implementation of a program and in fund-raising activities. Similar state heart associations have been formed in Maine, New Hampshire, Connecticut and Rhode Island, and it is expected that Vermont will soon have its organization. Membership in the New England Heart Association will automatically be transferred to the Massachusetts Heart Association unless a member desires to be transferred to another state heart association.

To avoid too much centralization and yet to prevent diversion into too small and ineffective units, it is planned to organize the State into regional areas, to be known as chapters. Already Worcester County has been so organized, and the other divisions will be Western Massachusetts, North Shore and Merrimac Valley, Southeastern Massachusetts and Greater Boston. Within these areas heart committees will be formed to serve smaller areas.

Each area chapter and committee will be organized with lay and professional representation. The Board of Directors of the Massachusetts Heart Association will provide representation both lay and medical from each of the five area chapters.

The New England Heart Association has been in operation for some twenty-eight years, and its principal function has been to provide a meeting place for physicians throughout New England who wish to report and discuss new work in cardiovascular research. The Executive Committee of the New England Heart Association believes that this function is valuable and should be continued and has recommended that the New England Cardiovascular Society be formed to provide this meeting place for physicians throughout New England interested in cardiovascular disease. The membership will consist of physicians and other persons professionally concerned with cardiovascular research or program development. All present physician members of the New England Heart Association are eligible for election to the New England Cardiovascular Society. There will be no dues in this Association. Members of other New England state heart associations affiliated with the American Heart Association may be elected to membership.

The New England Cardiovascular Society will conduct the hospital meetings, print the *Proceedings* and, in general, represent purely professional interests in this field. The expenses of the Cardiovascular Society will be borne by the Massachusetts Heart Association as part of its function to advance the standards of professional practice and knowledge in the cardiovascular diseases.

The following important committee appointments have been made by the Massachusetts Heart Association:

Research Allocations Committee

C. Sidney Burwell, M.D., *Chairman*
Robert E. Gross, M.D.
Samuel H. Proger, M.D.
Robert W. Wilkins, M.D.
Burton E. Hamilton, M.D.

Boston Chest X-Ray Program for the Study of the Screening of Cardiac Patients

Benedict F. Massell, M.D., *Chairman*
C. Sidney Burwell, M.D.
David D. Rutstein, M.D.

Rheumatic Fever Service Committee

George P. Sturgis, M.D., *Chairman*

Committee for Home Care of the Ambulatory Cardiac

Paul M. Zoll, M.D., *Chairman*
Andrew W. Contratto, M.D.
A. F. Foster, M.D.
Sylvester McGinn, M.D.
Elizabeth Howland, R.N.

Committee on Professional Education

Eugene C. Eppinger, M.D., *Acting Chairman*

Committee for Free Penicillin

Edward F. Bland, M.D., *Chairman*
Maxwell Finland, M.D.
Samuel A. Levine, M.D.
Edwin O. Wheeler, M.D.

Committee on Rehabilitation

Howard B. Sprague, M.D., *Chairman*

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Bone Marrow Biopsy. Haematology in the light of sternal puncture. By S J Leitner, M D, reader in internal medicine University of Berne (Switzerland), and deputy medical superintendent, Sanatorium for Tuberculosis Herligenschwendli, Berne. English translation revised and edited by C J C Britton M D, Ch B, DPH, consulting haematologist to the Prince of Wales's General Hospital, Tottenham, London, and Queen Mary's Hospital, Roehampton and E Neumarck M B, B S (Lond), M R C S, L R C P, lecturer in pathology, St Mary's Hospital Medical School London 8°, cloth 433 pp, with 194 illustrations and 7 color plates. New York: Grune and Stratton, 1949. \$8.50.

Dr Leitner first published his researches in the *Folia Haematologica* in 1941. This material was thoroughly revised and published in the German edition, from which this translation into English has been made. The monograph is intended primarily for clinical use but necessarily contains some technical material. The work is based on investigations carried out at the medical clinic of the University of Berne, where more than 2700 sternal punctures were made on more than 920 patients. The author is convinced that bone-marrow biopsy is of immense practical value in the diagnosis of blood disorders and many other diseases. The larger part of the text is devoted to disorders of the blood, but there are chapters on tumors, liver disease, endocrine disorders and the effects of radium and x-rays on bone marrow. The concluding chapters discuss the metabolism of bone marrow and blood cells, the defense reaction of marrow cells and tissue culture of marrow cells. Extensive bibliographies are appended to the various chapters, and there is a good index. The type and printing are good, and the color plates excellent. The printing was done in Great Britain. The monograph should be in all medical libraries.

Oral Anatomy. By Harry Sicher, M D, professor of anatomy and histology, Loyola University School of Dentistry, Chicago College of Dental Surgery. 4°, cloth, 529 pp with 310 illustrations. St. Louis: C V Mosby Company, 1949. \$15.00.

The textbook is written primarily for dental students but should prove valuable to surgeons interested in the head and neck. It is not intended to supplant textbooks on human or dental anatomy, but to supplement them. The text is divided into two parts—descriptive and regional and applied anatomy—and deals with the head and neck. In the second part, among other topics, the anatomy of local anesthesia, arterial hemorrhages and ligation of arteries, the propagation of dental infections, tracheotomy and laryngotomy and the temporomandibular articulation are discussed. There is an extensive, comprehensive index. The type, printing and illustrations are excellent. The book is recommended for all medical libraries and should prove valuable to surgeons.

An Elementary Atlas of Cardiology. An introduction to electrocardiography and x-ray examination of the heart. By H Wallace-Jones, M D, M Sc, F R C P, honorary consulting physician, Royal Liverpool United Hospital. E Noble Chamberlain, M D, M Sc, F R C P, honorary physician, Royal Liverpool United Hospital and E L Rubin, M D, F F R, D M R E, honorary radiologist, Royal Liverpool United Hospital. 8°, cloth, 108 pp with 99 illustrations. Bristol, England: John Wright and Sons, Ltd., 1948. Incorporating the third edition of *Electrocardiograms*.

This elementary atlas was first published in 1939 as an *Atlas of Electrocardiography*. In this edition it has been enlarged to include a section on cardiac radiology. Some revision of the original text has been made including the addition of records showing Lead CR₁ in normal and abnormal rhythms. The section on auricular fibrillation has been rewritten in the light of the knowledge gained from this lead. The text is divided into two parts: electrocardiography com-

prising fifty pages, and radiography of the heart and large vessels, with forty-eight pages. The small atlas has been written primarily for medical students. The type printing and illustrations are excellent. The lack of an index is regretted.

Nursing Care of Neurosurgical Patients. By Roland M Klemme, M D, professor of surgery, Saint Louis University School of Medicine. 8°, cloth 117 pp with 61 illustrations. Springfield, Illinois: Charles C Thomas, 1949. \$3.00.

This manual for nurses incorporates the lectures of the author and is based on years of experience in the care of neurosurgical patients. There are chapters on anatomy of the brain and spinal cord and on clinical signs and symptoms, neuralgia, traumatic head injuries, the spine and spinal cord and miscellaneous neurosurgical procedures. The chapters on the scrub nurses table, materials and supplies and on instruments for operative procedures, give in detail the layouts for the different operations. An appendix provides special information of a general character. There is a good index. The volume is a fine example of good book making and should be included in all collections on neurology and should be in all medical libraries.

Aviation Medicine in Its Preventive Aspects. An historical survey. By John F Fulton, O B E, M D, D Sc, Sterling professor of physiology, Yale University. 8°, cloth, 174 pp, with 43 illustrations. New York: Oxford University Press, 1948. \$3.50.

Dr Fulton, in 1947, delivered the Heath Clark lectures at the London School of Hygiene and Tropical Medicine. These lectures are now printed in this small volume and constitute a valuable contribution to aviation medicine. The five lectures considered altitude sickness and acclimatization (the history of oxygen), decompression sickness (the genesis of the tissue bubble), pressure cabins and explosive decompression (the spring of the air), effects of acceleration (dim-out and black-out protective measures) and man and the machine (problems of safety in flight). In these various lectures Dr Fulton has outlined the history of the topics from the time of Robert Boyle to the present. Each chapter is well documented with a long list of pertinent references. The publishing is of the highest type. The book should be in all public and medical libraries.

Symptoms in Diagnosis. By Jonathan C Meakins, C B E, M D, D Sc, LL D, F R S (Edinburgh), F R S (Canada), F R C P (London), F R C P (Edinburgh), Hon F R C S (Edinburgh) and F R C P (Canada). Second edition. 8°, cloth, 542 pp. Baltimore: Williams and Wilkins Company, 1948. \$7.50.

This standard monograph, first published in 1941, has been rewritten for this second edition. More than a third of the chapters were written by colleagues of the author. The material is arranged according to the organs and systems of the body and concludes with a chapter on psychiatry. There is a good index and the publishing is excellent. The book should be available to all clinicians and should be in all medical libraries.

An Atlas of Bone-Marrow Pathology. By M C G Isaacs, M Sc, M D, M R C P, lecturer and deputy director, Department of Haematology, The University and Royal Infirmary, Manchester. 8°, cloth, 79 pp, with 3 illustrations and 12 plates. Illustrations by D Davison, medical artist to the University of Manchester. New York: Grune and Stratton, 1948. \$6.50.

This special atlas consists of fifty-two pages of text and twelve excellent color plates. It seeks to provide an accurately illustrated account of the bone marrow in health and disease. The material is well arranged and deals with the nomenclature and development of the blood cells, the technic of sternal puncture, the morphology of the marrow cells, the normal bone-marrow puncture, bone-marrow changes in disease, the bone-marrow in infants and children and differential diagnosis and indications for sternal puncture. There is a bibliography of seventy-seven titles and also a combined index to the text and plates. The printing of text and plates was done in Great Britain.

The Hospital in Contemporary Life Edited by Nathaniel W. Faxon, M.D., director, Massachusetts General Hospital 8°, cloth, 288 pp. Cambridge Harvard University Press, 1949 \$5.00

This symposium by eight Boston authorities comprises the following topics: the development of the hospital, the relief of suffering, human nature and the understanding of disease, the care of the patient, the education of the doctor, how medicine grows and its relation to science, unsolved problems and the place of the hospital in the social order. There is a good index. The book is well published and should be in all medical and social libraries.

Social Medicine: Its derivations and objectives The New York Academy of Medicine Institute on Social Medicine, 1947. Edited by Iago Galdston, M.D. 8°, cloth, 294 pp. New York Commonwealth Fund, 1949 \$2.75

This small volume contains the papers read by twenty-six persons at the Institute. The material is divided into seven parts: changing concepts of the relation of medicine to society, the history of social medicine, social medicine—its differentiation from and relation to clinical and preventive medicine, epidemiology in social medicine, the place of nutrition in social medicine, social psychiatry and social medicine, social applications of psychiatry, and social medicine—the appeal to the common man by Lord Horder. The publishing is excellent. The lack of an index in a Commonwealth Fund publication is surprising. The book should be in all medical and social libraries.

The Physiology of the Eye By Hugh Davson, D.Sc. (London). With a foreword by Sir Stewart Duke-Elder, K.C.V.O., M.A., D.Sc., Ph.D., M.D., F.R.C.S. 8°, cloth, 451 pp., with 301 illustrations. Philadelphia: Blakiston Company, 1949 \$7.50

This textbook provides in a compact form the information on the physiology of the eye and on optics needed by the student and optician. The text was printed in Great Britain and bound in the United States. The material is well arranged, and the printing well done with a good type. The volume should prove useful to the persons for whom it was written.

Flight from Reality By Norman Taylor 8°, cloth, 237 pp. New York: Duell, Sloan and Pearce, 1949 \$3.50

This popular book relates the story of the misuse of the narcotics, as well as of alcohol, coffee, chocolate and tea.

NOTICES

ANNOUNCEMENTS

Dr. G. Marshall Crawford announces the association of Dr. Robert F. Tilley in the practice of dermatology and syphilology at 1180 Beacon Street, Brookline.

Dr. Frank M. Heifetz announces the opening of his office for the practice of otolaryngology at 174 Central Street, Lowell.

Dr. Edward J. Twigg announces his association with Dr. Philip S. Marcus for the practice of anesthesiology and diagnostic and therapeutic nerve blocks at 270 Commonwealth Avenue, Boston.

WOMAN'S AUXILIARY TO SUFFOLK DISTRICT MEDICAL SOCIETY

The November meeting of the Woman's Auxiliary to the Suffolk District Medical Society will be held in Sprague Hall, Boston Medical Library, on Thursday, November 3, at 2:30 p.m. The speaker for the afternoon will be Dr. Arthur W. Allen, president of the Massachusetts Medical Society. Tea will be served after the meeting.

NEW ENGLAND HOSPITAL FOR WOMEN AND CHILDREN

The monthly clinical conference and meeting of the staff of the New England Hospital for Women and Children will be held in the classroom of the Nurses' Residence on Thursday, November 3, at 7:15 p.m. Dr. Langdon Parsons will speak on the subject "Present-Day Concept of Carcinoma of the Cervix." Dr. Rosemary Nelson will be chairman.

NEW ENGLAND CARDIOVASCULAR SOCIETY

A meeting of the New England Cardiovascular Society will be held at the Massachusetts General Hospital, Boston, on Monday, November 7, at 8:15 p.m., Dr. Edward F. Bland presiding.

PROGRAM

The Blood and Interstitial Fluid Volumes after Sympathectomy for Hypertension. Dr. Fiorindo A. Simone.

A Study of the Castrate Male: Its contribution to cardiovascular research. Dr. Menard M. Gertler and Stanley M. Garn, Ph.D.

The Clinical Response of Rheumatic Fever and Acute Carditis to ACTH. Drs. Benedict F. Massell, Joseph E. Warren, George P. Sturgis, Buford Hall and Ernest Craige.

Further Experience with a Venous Shunt for Advanced Mitral Stenosis. Drs. Edward F. Bland and Richard H. Sweet.

Electronic Mapping of the Heart. Drs. Conger Williams and Fred Alexander and Stanford Goldman, Ph.D.

The National Heart Program: A progress report. Dr. Paul D. White.

Interested physicians and medical students are cordially invited to attend.

NATIONAL TUBERCULOSIS ASSOCIATION

The forty-sixth annual meeting of the National Tuberculosis Association will be held April 24-28, 1950, at the Hotel Statler, Washington, D.C. The American Trudeau Society, the Medical Section of the Association, and the National Conference of Tuberculosis Secretaries, an organization of public-health workers, will meet concurrently with the Association.

The medical sessions will be devoted to four major fields: the chemotherapy of tuberculosis, surgical aspects of tuberculosis, laboratory investigations and nontuberculous diseases of the chest. Tentative plans for the public-health sessions include discussion of the nonhospitalized patient, evaluation of community-wide programs, elements in a community health program and new developments in community health organization.

Both scientific and public-health exhibits will be displayed throughout the meeting.

Further information may be obtained from the National Tuberculosis Association, 1790 Broadway, New York 19, New York.

EDWARD K. DUNHAM LECTURES

Christopher Howard Andrewes, F.R.S., head of the Department of Bacteriology and Virus Research at the National Institute for Medical Research, Hampstead, London, will deliver three lectures in the amphitheater of Building D, Harvard Medical School, at 5 p.m., on the general subject "Adventures among Viruses," under the Edward K. Dunham Lectureship for the Promotion of the Medical Sciences. The dates and subjects of the lectures are as follows:

Thursday, November 3 Some Properties of Viruses
Tuesday, November 8 Epidemic Influenza
Thursday, November 10 The Puzzle of the Common Cold

(Notices concluded on page xv)

PULMONARY EMBOLISM*

A Statistical Study of Post-Mortem Material at the Massachusetts General Hospital

BENSON B. ROE, M.D.,† AND JOEL C. GOLDTHWAIT, M.D.‡

BOSTON

CONSIDERABLE interest has been manifested in the subject of thromboembolism during the past few years, and numerous reports have appeared in the literature on the various preventive measures. As far as we know, however, no long-range mortality statistics following an extended trial of one method of treatment have been reported, and it is our purpose here to analyze the possible effects of femoral-vein interruption on the mortality of pulmonary embolism at the Massachusetts General Hospital.

Interruption of the femoral veins was introduced in this hospital in 1939 as a measure hoped to be of value in the prevention of fatal pulmonary embolism. The procedure was employed in selected cases during the four-year period from 1939 to 1942, and the results¹ from this small group were sufficiently encouraging that a large-scale program was undertaken in the attempt to obliterate or to reduce the mortality from this distressing complication. Special attention was given to the problem, and more careful vigilance for the manifestations of pulmonary infarction and thrombophlebitis in the deep leg veins was maintained on both general surgical services and later to a large extent throughout the hospital. Bilateral interruptions of the femoral veins were done in large numbers for minimal indications and later (see Table 1) on an even greater scale with the addition of prophylactic interruptions in older age groups. Earlier reports²⁻⁶ have attempted evaluation of this immense effort from a clinical standpoint. It is the purpose of this paper merely to report the autopsy statistics for the five-year period 1943 through 1947, during which 1929 bilateral femoral-vein interruptions were done, as compared with similar earlier periods before the advent of specific preventive measures. Our two control series are taken prior to 1941, and

the period between 1941 and 1943 is omitted because vein interruptions were done on such a small scale as to have no significant effect on the whole hospital mortality rate.

The material for this study was obtained from the autopsy protocols from 1930 through 1947 and from the hospital records of patients. No case that did not come to autopsy was used, and every case with the autopsy finding of pulmonary embolism was reviewed. Classification of the data was difficult and necessarily arbitrary, but similar criteria were used in the comparative series. We were impressed with the large personal element in evaluat-

TABLE 1 *Incidence of Therapeutic and Prophylactic Femoral-Vein Interruption in 1929 Cases at the Massachusetts General Hospital*⁶

YEAR	THERAPEUTIC OPERATIONS	PROPHYLACTIC OPERATIONS	TOTALS

1944	208	72	280
1945	214	178	392
1946	259	289	548
1947	227	317	544
Totals	1058	871	1929

ing the records and protocols, as well as the variability of details within them, and, therefore, must urge caution in the use of these figures in comparison with other series.

To eliminate the cases of doubtful significance and the question of incomplete autopsy dissection, we have listed separately all cases in which the embolus or emboli were small and improbable as the cause of death. The remaining cases of fatal embolism were further divided into two groups: the first with massive emboli unquestionably lethal, and the second with large emboli considered to be of fatal magnitude (labeled "Large ? Fatal") but open to some challenge as the actual cause of death because of an atypical terminal clinical course or the presence of other fatal disease of equal or greater magnitude.

*From the Department of Pathology and Bacteriology, Massachusetts General Hospital.

†Assistant resident surgeon, Massachusetts General Hospital.

‡Assistant resident in medicine, Veterans Administration Hospital, West Roxbury, formerly assistant resident in pathology, Massachusetts General Hospital.

The findings of the three five-year periods — 1931 through 1935, 1936 through 1940 and 1943 through 1947 — are tabulated below. The total number of autopsies in each period was about the same, and it seems reasonable to assume that these are equally representative major samples of total deaths. The sharp increment of small emboli from 2.2 per cent in the first period to 5.4 per cent in the second, as pointed out in the third column of Table 2, is undoubtedly attributable to the focus of attention in the pathology laboratory on this problem and consequent emphasis on more complete routine

emboli, and hence the totals, showed a steady and appreciable increase, which was exactly the same (2.7 to 3.5 per cent) in the recent period as that between the first and second control periods (1.9 to 2.7 per cent), as shown in the fourth column of Table 2.

The steady increase of deaths from pulmonary embolism in spite of venous interruptions can perhaps be explained on the basis of the relative decline of other diseases and complications with the advent of chemotherapy, blood banks, improved technics and so forth, as well as the rising number

TABLE 2 *Incidence of Pulmonary Embolism in Total Autopsies (Massachusetts General Hospital)*

DATE	NO OF AUTOPSIES	CASES WITH SMALL, INCIDENTAL EMBOLI		CASES WITH FATAL EMBOLI					
		no	percentage	no	percentage	no	percentage	no	percentage
1931 1935	1,991	43	2.16	37	1.86	15	0.75	52	2.16
1936 1940	1,832	99	5.40	49	2.67	18	0.98	67	3.66
1943 1947	2,083	111	5.33	73	3.50	19	0.91	92	4.42

dissection of the pulmonary vascular tree. It is our impression, however, that these figures are still unreliable because of the variability of this routine and the difficulty of standardizing the pathologist's interpretation. For this reason we have included under "small" all emboli described as lodging in secondary or smaller branches of the pulmonary artery even though some of them were

of older patients in the hospital census. In addition, it has been suggested that the increasing number of cancer patients and the greater magnitude of surgery are responsible for this increase although it is notable that thromboembolism appears through a wide range of age, primary disease, and operative procedure (see Tables 5, 6 and 7). Statistical evaluation of these changing factors is impractical if

TABLE 3 *Analysis of Deaths from Pulmonary Embolism*

PERIOD	TOTAL ADMISSIONS	TOTAL AUTOPSIES	TOTAL DEATHS FROM PULMONARY EMBOLISM		CASES OF ADVANCED INCURABLE CANCER		DEATHS THAT SHOULD HAVE BEEN PREVENTED	
			MASSIVE FATAL EMBOLISM	LARGE ?FATAL EMBOLISM	MASSIVE FATAL EMBOLISM	LARGE ?FATAL EMBOLISM	MASSIVE FATAL EMBOLISM	LARGE ?FATAL EMBOLISM
1931-1935	67,038	1,991	37	15	3	2	34	13
1936-1940	78,065	1,832	49	18	5	1	44	17
1943-1947	79,951	2,083	73	19	13	4	60	15

extensive enough to suggest at least a precipitating cause of death. The ones considered to be probably or definitely fatal were described as organized clots lying in and occluding no less than two primary branches of the right or left pulmonary artery so as to block a major portion of the pulmonary circulation. Subdivision of the large emboli as described above was more or less arbitrary but where there was any reasonable doubt they were listed under "Large ? Fatal." It is interesting that these disputable cases remained very constant between the three periods and probably are a source of less inaccuracy than we feared. The massive

not impossible, and we can but recognize their influence on the net result.

Further to analyze the comparative statistics between the preligation era and the recent series, we were obliged to introduce corrective factors as much as possible. It must be taken into account that during the recent period of venous interruptions the procedure was considered but not done in many cases in which advanced incurable malignant lesions seemed to contraindicate strenuous preventive measures. We therefore separated these cases from both series (see Table 3) to arrive at a figure of deaths from pulmonary embolism that

it would be desirable to prevent. This figure in the last series, however, can further be challenged as not representing the failures of the whole program of venous interruption since the doctrines of such a program could hardly receive universal acceptance in an institution of this size. It is pointed out that deaths from pulmonary embolism occurred in patients on private services and specialty services who had indications for venous interruption under the precepts of the more vigorous policy. It was therefore necessary to review all the clinical records in the cases of fatal embolism and separate from the previous figure the cases in which, in retrospect, there had been signs suggestive of warning pulmonary infarction or venous thrombosis in the legs according to the criteria used by the peripheral vascular service*. We were also obliged to rule out the autopsies on patients whose embolic episode occurred outside the hospital, where early diagnosis may have been overlooked and prompt venous interruption was impossible. The remaining number of deaths from pulmonary embolism after the "corrections" represents the failures of the over-all program, assuming it to have been properly executed throughout the hospital.

It is evident, then, that all the autopsy percentages fall within the same range, and the lower figure of 2.54 per cent for the recent period is not significantly smaller than the preceding one.

It must be pointed out that these figures demonstrate not only the effect of so-called "therapeutic" venous interruption on thromboembolic mortality but also the sum total effect of all preventive

singly. Not only has the total figure for this period been unchanged but figures for individual years† have remained surprisingly constant despite the recent — during the past two years — increased use of prophylactic interruptions and anticoagulants‡.

It has not been our purpose to evaluate so-called "prophylactic" venous interruption but as a corollary to Table 3 it is interesting to point out that of the 53 total net deaths in the last period 14 fell into the category that, in retrospect, would have received prophylactic interruption according to the proponents of this more recent measure§. Application of this figure to the above data has not been made and would hardly be judicious except in the most theoretical sense because of the narrower scope of the procedure, but if one accepted this added correction, as well as the assumption that venous interruption would prevent all emboli the net total deaths would be reduced from 53 to 39, which would drop the incidence to a significantly lower figure 1.87 per cent.

FATAL PULMONARY EMBOLI FOLLOWING FEMORAL-VEIN INTERRUPTION

In the course of this study a group of patients was collected in the recent five-year period who had received bilateral femoral-vein interruption, either superficial or common, and who also had an anatomic diagnosis of pulmonary embolism at autopsy. This group was included in the above series, but we believe that further analysis of these cases is warranted. The group included a total of

TABLE 3 (Continued)

CASES WITHOUT VENOUS INTERRUPTION BUT WITH INDICATIONS IN RETROSPECT		CASES WITH ONSET OF SIGNS OUTSIDE HOSPITAL		NET DEATHS			PERCENTAGE OF AUTOPSIES	PERCENTAGE OF ADMISSIONS

*Calculated standard error of percentage

measures exercised. Early ambulation, prophylactic interruptions and anticoagulants unquestionably play an important role, but they obviously cannot be separately evaluated from this material. However, since there had been no significant change in the mortality figures in the presence of all factors, it seems reasonable to assume that there would have been no significant change had these factors acted

26 cases. Of these 16 were discarded for the following reasons: in 1 case the emboli were composed of tumor from a renal-cell carcinoma, in 6 cases the emboli were considered small enough to be incidental as a cause of death, in 5 cases the embolus might have been the immediate cause of death, but was not classified as such because of its size

*Bilateral interruptions of the superficial femoral veins were done as an emergency procedure on any patient with otherwise unexplained signs of deep-calf or popliteal tenderness, measurable calf or ankle swelling, localized pulmonary consolidation by x-ray study unless interpretation could rule out infarct, sudden chest pain or hemoptysis or both (even with negative x-ray examination) and in many cases when simultaneous rise of temperature, pulse and respiration was accompanied by minimal or equivocal evidence of one or more of the above.

†Total deaths from thromboembolism by years were 1943 15 1944 25 1945 12 1946 15 and 1947 2.

‡In all over 800 patients received Dicumarol in some dosage through 1947.

§Prophylactic bilateral interruptions of the superficial femoral veins were done on patients over sixty years of age preceding or within forty-eight hours of a major surgical procedure and in certain younger patients such as those with peritonitis who were to be immobilized in Fowler's position.

or the importance of other diseases (uremia, peritonitis and so forth), and in 4 cases the clinical course suggested that massive embolism had occurred

significance, that the group contained no cases of congestive heart failure. The fatal embolism in Case 3, which followed an eye operation, suggested

TABLE 4 Data in Clear-Cut Cases of Massive Fatal Embolism following Femoral-Vein Interruption

PATIENT	AGE	PRIMARY DISEASE	REASON FOR INTERRUPTION	CLOTS FOUND AT OPERATION	INTERVAL FROM INTERRUPTION TO DEATH	SOURCE OF FATAL EMBOLUS
M McD	75	Thrombophlebitis deep veins of legs	Leg signs	Yes	11 days	Unknown (restricted autopsy)
C S	74	Carcinoma of colon with metastases	Pulmonary infarct 3 days after pentoneoscopy	No	8 days	Left deep femoral vein occluded at junction of middle and lower thirds
C B	70	Cataracts	Pulmonary infarct 3 days after eye operation	No	2 days	Thrombi in left common femoral, internal and common iliac and right common iliac veins
L B	62	Incisional hernia in scar of hysterectomy obesity	Prophylactic interruption 2 days after hernia repair	No	13 days	'Currant jelly clot' in 3-cm. stump of superficial femoral on left attached to this 8 cm. of red gray laminated thrombus in common femoral vein otherwise clear
E M	74	Diabetes mellitus gangrene of toes	Prophylactic interruption 2 days after low thigh amputation*	No	2 days	Thrombus in 1-cm. stump of right superficial femoral vein continuous with 7-cm. clot in common femoral vein otherwise clear
W D	42	Subarachnoid hemorrhage	Interruption on 2nd hospital day because of calf tenderness	Yes (right side only)	13 days	Right common femoral vein ligated this and iliac vessels thrombosed to mouth of vena cava left side clear
J P	78	Arteriosclerotic gangrene of foot	Prophylactic interruption at time of low thigh amputation	No	2 hr	No thrombus found in common femoral veins or deep femoral veins 8 cm. below sites of operation
G C	68	Carcinoma of colon	Prophylactic interruption on 5th hospital day 5 days after oostomy	No	17 days (8 days after resection)	Iliac common and deep femoral veins clear as far as examined—8 cm. below operative sites
F B	77	Thrombophlebitis with pulmonary infarct 1 day prior to admission	Pulmonary infarct interruption on day of admission	No	13 days	Thrombosis of left external iliac common and deep femoral veins thrombus 0.5 cm in diameter at ligation site on right.
D S	54	Carcinoma of stomach	Prophylactic interruption 2 days after total gastrectomy	No	32 days	Thrombi 2 cm. long extending into common femoral vein from each interruption site

*Because at autopsy the clot in the common femoral vein was considered to be several days old and thus probably antedating interruption the procedure was classified as 'inadequate therapy' in retrospect

prior to the venous interruption. The remaining 10 cases in which there was a clear-cut picture of massive fatal pulmonary embolism following venous interruption are discussed in Table 4.

It is apparent that there is nothing remarkable about the age and sex distribution in these cases, all but 2 patients were over sixty years of age. The

that the operative procedure itself was probably of little significance.

Five patients in this group had venous interruptions for prophylactic reasons, but one of these cases was later reclassified under therapeutic (see footnote in Table 4), 3 were done after a warning pulmonary infarct, and 2 because of thrombophle-

primary disease seemed to represent a fair random sample of that found in the whole group of fatal pulmonary emboli. It is of interest, but of doubtful

bitis in the deep venous system of the legs. Clots were found in the veins at operation only in the last 2 cases. In the 4 cases classified as prophylactic

interruptions, 1 patient was found at autopsy to have a blind stump of the superficial femoral vein in which a clot had developed and propagated into the common femoral vein. One patient had both superficial femoral veins tied flush with no pouches

FATAL PULMONARY EMBOLISM WITHOUT WARNING

It is of interest that a breakdown of the 92 deaths from pulmonary embolism in the recent five-year period reveals that 49 or 53 per cent occurred with-

*These were all operations on the esophagus or stomach and are included under the heading "Resection or Exteriorization of Gastrointestinal Tract."

lateral femoral-vein interruptions. The 4 prophylactic interruptions in this group represent a 0.5 per cent mortality among the 871 prophylactic interruptions done during that period.

that the entire house staff was aware of the problem during this period, and most of the records contained periodic notes about leg and chest examinations. Of the remaining 43 patients 25, or

27 per cent, were known to have had one or more warnings, either in the legs or by pulmonary infarct, but the records on the ante-mortem course of the other 18 cases are incomplete or absent

the Lahey Clinic, reported premonitory signs in 85 per cent of their fatal cases. One can only speculate over this discrepancy. Perhaps its cause is the successful surgical treatment of patients with warning infarcts or thrombophlebitis. However, there is apparently considerable variation in the criteria used for "warning," and this should be considered seriously as the principal cause. We did not believe that a review of the hospital records in the period before venous interruption would provide a suitable comparison because so little attention was focused on the problem that the signs were probably more often missed than recorded.

DISTRIBUTION OF FATAL EMBOLISM

Table 5, 6 and 7 are presented as supplementary information gathered during the course of this study and do not have any direct bearing on the more pertinent over-all figures. However, the distribution of fatal pulmonary embolism is of considerable interest, and although our figures in each group are too small for individual analysis the material may prove useful in the compilation of more extensive data.

Age

That pulmonary embolism is a disease more common in the older age groups is demonstrated in Table 5. It is significant, however, that approximately 20 per cent of all fatal emboli occurred in ages below fifty, in which total deaths were less numerous. Thus, if the ratio of deaths from pulmonary embolism is plotted in relation to total deaths, or autopsies (Fig 1), there is a more slowly rising curve, which supports the initial statement but which also emphasizes the wide age distribution of the disease.

It is interesting that comparison between these curves for the different periods studied shows no dramatic shift that could be interpreted as an effect of preventive measures. In fact, if anything, there is a shift toward the higher age groups in the recent period despite concentration of preventive efforts on this group. This is probably due to the constant increase in the average age of patients admitted (a sample study from 1930 and 1943 [thirteen years] showed an increase of eight years).

Primary Disease

The deaths from pulmonary embolism have been further analyzed in Table 6 and 7 with regard to the primary disease and operative procedure with which they were associated.

It should be made clear that comparison between any two figures in these tables cannot be considered valid since there is no statistically significant difference between them according to sample statistical analysis. However, Table 6 shows that massive fatal pulmonary embolism occurs in a

FIGURE 1 Distribution of Autopsies and Pulmonary Emboli by Age Groups

This figure of unheralded fatal emboli is somewhat higher than that given in other reports. DeTakats⁷ states that one fifth to one fourth of emboli are fatal at first occurrence, and Evans and Dee,⁸ of

wide variety of diseases and that although a few are found in medical conditions, the majority of emboli complicate surgical disease and occur during the postoperative period. Comparison of the totals in Table 6 and 7 demonstrates this fact.

The decline of pulmonary embolism as a complication of benign conditions of the gastrointestinal and biliary tracts is more apparent than real, being exaggerated by a combination of many different types of disease under one heading. The same reservation can be made for benign conditions of the genitourinary system, although in both these categories it is undoubtedly true that operative procedures are not so formidable and convalescence not so prolonged as they were fifteen years ago. The increasing number of patients with pulmonary embolism complicating malignant lesions of the gastrointestinal and biliary systems is probably a reflection of the increased number of patients with cancer in the hospital population. We have not analyzed this in more detail because, considering the questionable significance of the figures as they stand, nothing would be contributed by such a study.

Also of interest is the fact that diseases in which the treatment has been fairly standardized for many years (uterine fibroids, hernias and lesions of the breast) show an apparently constant incidence of embolism.

It should be noted that the absence of fracture cases in this list is due to the fact that all such deaths came under the jurisdiction of the medical examiner and do not appear in our autopsy files.

Operative Procedure

In similar fashion it is seen that fatal pulmonary emboli follow a wide variety of operative procedures. The chief point to be made in Table 7 is the fairly constant number of deaths from pulmonary emboli with the different procedures throughout the three periods. The increased number of fatal emboli following gastrointestinal-tract resection is probably accounted for by the increased number of patients in the hospital population subjected to operation for gastrointestinal cancer. The decrease following operations on the bladder and prostate has been attributed to femoral-vein interruption.*

In Table 5, 6 and 7 the obvious question arises over what these figures represent in terms of ratio to total hospital population by age group, total patients treated in each disease category and total operations performed in each category. These data, however, were not readily available and are essentially beyond the scope of this paper, which is an analysis of autopsy figures only.

Discussion

In an evaluation of this study it becomes evident that the incidence of pulmonary embolism is affected by a complex interplay of factors. The introduction of femoral-vein interruption is only one of many

considerations, and the impossibility of evaluating separately the other factors makes it equally impossible to evaluate the effect of one method in terms of the sum total.

It can be said, however, that a five-year, large-scale program of femoral-vein interruption has failed to alter significantly the mortality figures for pulmonary embolism as compared with earlier, similar periods.

The problem is further confused by the introduction of conflicting factors, which have tended to increase the incidence of thromboembolism during the same period of preventive efforts. Some of these are technical and therapeutic advances that have reduced other fatal complications and kept sick patients alive for a longer period in which to develop venous thrombi, an increasing number of geriatric patients, in whom pulmonary embolism is more common, an increasing proportion of cancer patients in this hospital, also with a somewhat higher incidence, and more heroic surgical procedures from which convalescence is often prolonged and complicated. The extent to which these factors have actually promoted thromboembolic disease cannot be accurately determined*, however, if their effect has been appreciable it might be postulated that a higher expected mortality rate has been kept down by the preventive program. It is regrettable that our controls had to be taken from a virtually different era rather than a comparable set of circumstances, but no group sufficiently large for comparison was deprived of some preventive measure.

Mortality statistics alone are not a satisfactory criterion for evaluating a procedure, and it should be pointed out that clinical analysis of selected patients demonstrates more favorable results from femoral-vein interruption in preventing fatal pulmonary embolism. The continued high incidence of the disease at the autopsy table, however, suggests that the problem remains unsolved.

SUMMARY

At the completion of a five-year program of femoral-vein interruption, autopsy statistics of pulmonary embolism are reviewed for this period and compared with those for two previous five-year periods.

These figures are analyzed and corrected in an attempt to demonstrate more accurately the effect of the program.

Analysis is made of the pulmonary embolic deaths that followed femoral-vein interruption.

Data are presented on the distribution of fatal emboli by age group, primary disease and operative procedure.

*To demonstrate the magnitude of these changes a sample analysis was made from reports of the general surgical service for the contrasting two year periods: 1930-31 and 1946-47. In brief it was found that the average age at death has risen from 49.3 to 57.6 years; surgical admissions for malignant lesions have risen from 28 to 44 per cent, whereas admissions for inflammatory disease have decreased relatively from 28 to 14 per cent and sepsis as a fatal complication on surgical patients has declined from 63 to 37 per cent (of all deaths).

No significant improvement in the mortality figures for pulmonary embolism in the hospital as a whole could be demonstrated in the period of venous interruption

Because of the many considerations that defied statistical analysis and the inadequacy of control data, no conclusions can be drawn either to support or to negate the value of the program

PLASTIC OPERATION ON THE FALLOPIAN TUBE

FRANCIS M INGERSOLL, M D *

BOSTON

DURING the past fifteen years there has been an increasing interest in the problem of sterility. One of the more difficult obstacles in this field has been occlusion of the oviducts. Rubin's¹ establishment of a diagnostic method for determining tubal patency enabled gynecologists to make a diagnosis of occlusion while hysterosalpingography accurately localized the point of obstruction. From 1932 to 1936 Solomons,² Bonney³ and Holden and Sovak⁴ presented encouraging reports concerning operative relief of sterility due to occluded tubes. As Solomons put it, "an occasional good golf shot impels the worst player to persist with the game, so occasional successes impel me and others to try further." However, enthusiasm for the tubal plastics lessened since results were poor, and some authors even discouraged further attempts.

Recently those interested in the problem have stated that even though only 5 to 10 per cent of these women become pregnant postoperatively, an operation is well worth while, after conservative therapy by repeated carbon dioxide insufflation, heat by diathermy or Elliot bag or estrogenic hormone stimulation has been tried. The discovery of nonpatent tubes during a sterility study on many of my own patients stimulated me to look up the results obtained by operative procedures. Twenty-three patients were operated upon at the Massachusetts General and Palmer Memorial hospitals during the years 1932-1947, either on the ward service or in the private practices of Dr Joe V Meigs or Dr Langdon Parsons or myself. Of these, 5 had uterotubal implantations for bilateral cornual obstruction, after which 3 had a normal pregnancy and delivery. Eighteen patients had salpingostomies for occlusion of the fimbriated ends of the

tubes, and in these cases no pregnancies have occurred.

The first tubal implantation was performed and recorded by Watkins⁵ in 1896, and the patient had a subsequent pregnancy and miscarriage. In 1921 Shaw⁷ described a successful tubal implantation performed by Cullen. Solomons² reported 6 pregnancies following this procedure. Holden and Sovak⁴ discussed 3 cases of tubal implantation with 1 subsequent normal pregnancy, and Sovak⁴ later reported another of their cases in which an ectopic pregnancy occurred with rupture of the tube. The accepted technic employed has been a division of the tubes at the point of occlusion, after which patency of the remainder of the tube is demonstrated by air and saline solution injection. The occluded cornual portion is reamed out with a special instrument or by sharp dissection. The patent tube is then pulled into the uterus and held there by stitches (Fig 1). Patency is again proved by air or water insufflation from the fimbriated end. The serious complications following this operation include exacerbation of pelvic inflammatory disease, and there is the possibility of uterine rupture during pregnancy at the site of implantation of the tube.

The first salpingostomy was reported by Martin⁶ in 1885. Nine years later Mackenrodt¹⁰ described the first 2 successful cases. The largest series in the literature is that of Solomons,² who in 1936 reported on 366 tubal operations—cornual, isthmic and fimbrial. Two tubal and 28 normal pregnancies occurred—that is, pregnancy was obtained in 8.2 per cent. Bonney reported 70 cases, with follow-up study in 37, in which 7, or 18 per cent, of patients conceived. The results of these operations have varied from 100 cases without a pregnancy¹¹ to 8 full-term pregnancies after 7 operations.¹²

*Instructor in gynecology Harvard Medical School assistant in surgery Massachusetts General Hospital

The technic of salpingostomy generally recommended is that of Holden and Sovak⁵—a modification of the circumcision operation devised by Bonney (Fig 2)⁴. The advantage of this operation is that bringing the mucosa back to the serosa for a distance of 1.5 to 2.5 cm closes the raw edge and the chances of adhesions and secondary closure are thereby lessened. The technic is as follows: the tube is handled without instruments and the fimbriated end is opened if possible by gentle, blunt dissection—or a small section of the dilated tube is resected. Patency is tested for with a glass syringe. A urethral catheter, No 5 Fr or a piece of polyethylene tubing, is threaded into the tube and a Bonney clamp applied to the tube 1.5 to 2.5 cm from the amputated end. A circular incision is made through the serosa and muscularis at the end of the Bonney clamp. Then, with two fine Allis clamps, the amputated end of the tube is gently pulled backward while the Bonney clamp is slowly

FIGURE 1 Implantation of the Outer End of the Fallopian Tube into the Uterine Cavity. (Reproduced from Shatz,¹ with the Permission of the Publisher.)

pushed forward. The tubal cuff so formed is held in place with fine catgut. Tubal patency is again established by the use of the syringe. The tube and ovary are then suspended by a stitch through the hilus of the ovary attached to the pelvic peritoneum. In the 18 salpingostomies reported here a simpler procedure of amputating the end of the hydrosalpinx and then suturing the mucosa to the serosa was employed. None of these patients became pregnant, although in 33 per cent of cases tubal patency was proved by the Rubin test or by hysterosalpingography postoperatively. The small diameter of the tube, the friable, infected

tissue and the tendency to bleed make it difficult to maintain an adequate lumen.

The serious complication after this operation has been an exacerbation of pelvic inflammatory disease. This occurred once in the 18 cases discussed here. If pregnancy results abortion sometimes occurs, and ectopic pregnancies have been reported. However, successful pregnancies do occur, and the risks are too slight to contraindicate the operation.

In the patients who had tubal operation three different pathologic conditions seemed to be con-

FIGURE 2 Technic of Salpingostomy. (Reproduced from Siegler,¹² with the Permission of the Publisher.)

cerned infection involving the endosalpinx, such as gonorrhea or tuberculosis, infections spreading through lymphatics and into the muscularis such as that after septic abortion, and infections around the tube—that is, perisalpingitis similar to that after a ruptured appendix.

In the 3 patients who became pregnant the infection was limited to the cornual segment of the tube. Success followed implantation because the diseased portion was easily resected. For example in Case 1 the infection started as endometritis occurring after abortion. At operation it was found that bilaterally only 2.5 cm of tube near the uterus was scarred and completely blocked. The remainder of the tube seemed to be of normal size, and the fimbriated ends were entirely free. In Case 3 the same cornual scarring was found. The left tube was otherwise normal. The right tube was also blocked at the fimbria. In the third successful case the block was limited to the cornua, as in Case 1.

In the other 2 cases with implantation into the uterus in which no pregnancy resulted, the cornua and the fimbriated ends of both tubes were involved, and according to the history the patients had had a much more severe post-partum infection. In the other 18 cases the fimbrial end of the tube was blocked by either gonorrheal infection or a pelvic peritonitis due to a ruptured appendix

the original infection the tube is abnormal and pregnancy impossible or, if pregnancy occurs, ectopic pregnancy is common.

The findings on the 23 patients operated upon are given in Table 1. In the 3 successful cases that resulted in living infants cornual resection and tubal implantation were performed. These cases are briefly presented below.

TABLE 1 *Results of Operation in 23 Cases*

20	L. T.	26	10	Pelvic inflammatory disease after miscarriage	Pregnancy in right tube left hydrosalpinx	—
21	J. C.	33	5	Post partum pelvic inflammatory disease	Right hydrosalpinx left tubo-ovarian abscess	—
22	A. C.	34	13	Post-appendectomy peritonitis	Right tube and ovary previously removed left hydrosalpinx	Tube opened with air
23	A. T.	31	11	Post appendectomy peritonitis	Right tubo-ovarian abscess left hydrosalpinx	Tubes closed

*Three years later a total hysterectomy and bilateral salpingectomy were performed.

These tubes were difficult to operate upon, and patency was obtained in only 6 of this group. Such a poor result is probably due to the fact that gonorrheal infection has been shown to travel across the endometrium and endosalpinx and then to invade the deeper layers. Microscopical examination of the acutely inflamed tube shows why the damage is so extensive and why even years after

CASE REPORTS

CASE 1. V. K., a 31-year-old woman who had been married 8 years, had 2 living children — aged 7 and 5. She had lost 2 children at the ages of 3 and 8 months, and had had a miscarriage at 3 months. Severe puerperal fever developed 2½ years before the studies began. The infection subsided after 2 months' hospitalization and 3 months' rest at home. Conception failed to occur thereafter. Physical examination was negative except for a cervical laceration and a retroversion. Over an interval of months

three Rubin tests were done, and the tubes were found to be completely blocked. A uterosalpingogram showed the occlusion to be at the cornua. The husband had a normal physical examination and semen specimen. At operation the uterus was retrocessed, and there were numerous fibrous adhesions about both tubes. The tubes were patent and normal except for a fibrous, densely scarred portion at the junction of the tubes and the uterus. Resection of the cornua and implantation of the distal tube was done. A Rubin test 4 weeks postoperatively demonstrated the tubes to be wide open. The patient conceived 2 months postoperatively and

normal uterine cavity, but no filling of the tubes. The husband had a normal semen specimen. At operation she had many adhesions, and there was obliteration of both tubes at the cornua. The right tube was closed at the fimbriated end. This was opened. The cornua were excised bilaterally, and the tubes implanted into the uterus. Four weeks postoperatively the Rubin test demonstrated patency. A repeat test was equivocal, and a uterosalpingogram was unsatisfactory. The patient adopted a baby 18 months after operation and 1 month later conceived. She was delivered 9 months later by cesarean section.

TABLE 1 (Continued)

has been delivered. This patient obviously had an excellent prognosis since the cause of the block was definitely known and both she and her husband had previously been very fertile.

CASE 2 F G, a 30-year-old woman who had been married 2½ years had had no pregnancies. She had had pelvic peritonitis before her marriage, and a uterosalpingogram showed blocked tubes prior to the studies under consideration. Physical examination was negative. The Rubin test failed to demonstrate patency. Repeat x-ray studies showed a

CASE 3 R U, a 33-year-old woman, had been married 9 years, had had no pregnancies and had no history of pelvic inflammation. Her menstrual cycle was regular. Biopsy showed a secretory endometrium. Rubin tests failed to demonstrate tubal patency on repeated examinations. A uterosalpingogram showed both tubes blocked at the cornua by nodules suggestive of salpingitis isthmica nodosa. The husband had an excellent semen examination. At operation both tubes were blocked 19 cm from the fundus. The obstructed tubes were resected into the endometrial cavity, and the remaining patent tubes sutured into the uterus.

A Rubin test postoperatively demonstrated patency, and the patient experienced shoulder pain. A uterosalpingogram showed the right tube open and the left tube blocked. Four years later she conceived and had a normal delivery.

DISCUSSION

Before surgery is contemplated for treatment of tubal occlusion both husband and wife must be completely studied. The diagnosis of occlusion must be well established, preferably by both a Rubin test and a uterosalpingogram. There should be no history of tuberculosis, and the pelvic inflammatory disease, if present, should be in a chronic, quiescent stage, with no fever or leukocytosis. Observation over several months is indicated, during which conservative treatment is carried out. The woman should be otherwise in good health, with a negative physical examination. The husband must have been studied and must be fertile. After these studies operation for tubal occlusion can be recommended with full realization that success does not crown every effort. The gratitude of the patient who does become pregnant, however, affords impetus for further attempts.

STREPTOMYCIN IN THE TREATMENT OF SUBACUTE BACTERIAL ENDOCARDITIS*

Review of the Literature and Report of a Case Caused by Bacteroides

ROBERT WALLACH, M.D.,† AND NORMAN POMERANTZ, M.D.‡

NEW YORK CITY

UP TO the present there have been scattered reports on the use of streptomycin in the treatment of subacute bacterial endocarditis. No individual series of cases has been large enough from which to draw conclusions. It is the purpose of this paper to present another unusual case of subacute bacterial endocarditis successfully treated with streptomycin, and to summarize the literature on the subject to May, 1949.

After several unencouraging reports, Loewe et al.,¹ 1944, showed that subacute bacterial endocarditis could be cured by penicillin given in sufficiently high doses for adequate lengths of time. Prior to this the prognosis in subacute bacterial endocarditis had been almost hopeless, subsequently the recovery rate has become approximately 80 per cent. In an effort to reduce further the 20 per cent failure rate other antibiotics have been sought for and tested. Since most of the failures are due to penicillin-resistant streptococci and to

gram-negative bacilli, both of which are often sensitive to streptomycin, this agent, next to penicillin, has proved most useful in the treatment of the disease. The first reports of streptomycin-treated subacute bacterial endocarditis appeared in 1946. In the ensuing three years and up until May, 1949, 49 cases treated wholly or partly with streptomycin have been reported in the literature.

REVIEW OF THE LITERATURE

Of the 49 cases, 28 were treated successfully. In the great majority of cases both penicillin and streptomycin were used. It was often difficult to attribute the successful outcome to either of the drugs or to a combination of both. In some cases it was possible to say that streptomycin was the decisive factor because of the progressively downhill course that had preceded its use.

Seventeen different organisms were encountered. There were 33 gram-positive organisms, of which 18 responded to treatment, and 18 gram-negative organisms, of which 12 responded to treatment. (In 2 cases² there were mixed infections.) In vitro

sensitivity tests, although not completely dependable, can give a fair estimate of the prognosis but are not helpful in determining the dosage necessary for treatment. Thirty-eight organisms were tested for streptomycin sensitivity, 31 were found to be sensitive to 9 units or less per cubic centimeter, and of these, 21 were treated successfully. Seven were found to be sensitive to more than 9 units per cubic centimeter, and of these only 1 was treated successfully.

The range of streptomycin dosage varied widely. In some of the earlier cases small dosages for short periods were used because of the scarcity of the drug, and, remarkably enough, some of these patients recovered. In general the dosage used and the

that followed an unfavorable response to large doses of penicillin.

CASE REPORT

P. R., a 53-year-old waiter, was admitted to the New York Polyclinic Medical School and Hospital on December 2, 1947, because of increasing fatigue of 6 months' duration. Except for an occasional sore throat or pain in the knees he had been well until the previous July, when his remaining upper teeth had been extracted for replacement by a denture. Shortly after this he noticed increasing fatigue and weakness. Three weeks before admission he started to have fever, night sweats and chilly sensations, however, he continued to work. One week before admission he was forced to discontinue work because of weakness. He received seven daily injections of 300,000 units of penicillin in oil and wax without any appreciable effect on the fever, fatigue or night sweats.

Although he does not remember ever having had rheumatic fever, he knew that he had "murmurs of the heart" since

FIGURE 1 Effect of Streptomycin Therapy in a Case of Subacute Bacterial Endocarditis

length of time treatment was continued were less than that advocated for penicillin. This is fortunate because of the uniformity of appearance of toxic symptoms. In all the cases in which this was alluded to it was noted that such symptoms did appear and were frequently permanent. The decision when to discontinue streptomycin in the face of a favorable response and the appearance of toxic symptoms remains a difficult one. This is even more so because bacterial sensitivity to streptomycin decreases rapidly, unlike that to penicillin.

The pertinent features of these cases are summarized in Table 1.

An unusual case of subacute bacterial endocarditis is presented below because the causative organism, a bacteroid, is rare in endocarditis, and because of the favorable response to streptomycin

childhood. He had had malaria at the age of 12, a tonsilectomy at 49 and a submucous resection at 51 years of age.

Physical examination disclosed a well developed, fairly well nourished man of asthenic habitus. He appeared acutely ill. Close scrutiny of the skin and mucous membranes revealed no petechiae. The eyes, ears, nose, mouth and throat were normal except for the presence of an upper denture. The lungs were clear. The heart was enlarged, and the rhythm regular, and presystolic and systolic murmurs were heard at the apex. The liver and spleen were not palpable. The extremities were normal.

Examination of the blood showed a red-cell count of 3,650,000, with a hemoglobin of 72 per cent, and a white-cell count of 8000, with 65 per cent neutrophils, 34 per cent lymphocytes and 1 per cent eosinophils. Urinalysis was normal except for a faint trace of albumin, the sediment contained no red blood cells. The sedimentation rate (Westergren method) was 30 mm in 1 hour, and the icteric index was 10. Blood cultures taken on the 2nd, 3rd and 9th hospital days were negative. Urinalysis repeated on the 29th and 31st days demonstrated no red blood cells in the sediment. A roentgenogram of the chest showed emphysema of the lungs and a globular-shaped heart whose borders extended to the right and the left.

*Total.

The effect of streptomycin therapy is shown in Figure 1. On the 3rd hospital day two petechiae were found on the left buccal mucous membrane. On the 5th day penicillin, 500,000 units daily in divided doses every 3 hours, was begun. During the next 11 days the swinging temperature, night sweats and fatigue remained unchanged. New petechiae were found on three occasions, whereas the older ones faded. All were on the buccal mucosa. On the 16th day penicillin was increased to 800,000 units daily. For a few days the patient felt better and his appetite improved, but then he lapsed back to his previous state. On the 25th day the penicillin was increased to 2,400,000 units daily. On the next day two new petechiae appeared in the right conjunctiva, and one on the lower lip. Because it was believed that he was not making any progress, penicillin was discontinued on the 28th day.

Blood cultures were taken on the 32nd, 33rd and 34th days. After all therapy had been stopped the daily temperature spikes reached higher levels, and his general condition seemed to deteriorate more rapidly. On the 37th day it was believed that further delay might cause irreparable damage, and penicillin therapy was resumed, massive doses (5,000,000 units daily) being used. Although the temperature fell somewhat he remained otherwise unchanged and on the 41st day new petechiae appeared in the left conjunctiva. On the 42nd day the blood culture taken on the 32nd day was reported positive for bacteroids. Streptomycin, 4 gm daily in divided doses every 3 hours, was then started and continued for 28 days. Four days later, on the 46th day, the penicillin was discontinued. From the 45th day (3 days after the start of streptomycin therapy) clinical improvement was marked. His appetite improved, and he became more alert. From the 49th day the temperature remained below 100°F. No new petechiae appeared after streptomycin had been started. Two blood cultures taken after the beginning of streptomycin therapy (47th and 53rd days) and two after its termination (69th and 76th days) were negative. During the 3rd week of therapy symptoms of streptomycin toxicity appeared. The patient complained of dizziness, but his hearing remained unimpaired. The dizziness persisted for 6 months. When last seen in May, 1949, 14 months after discharge, he was in excellent health and working although he still had a slight gait disturbance.

DISCUSSION

The genus *Bacteroides*²⁶ is made up of gram-negative, obligate anaerobes, which are motile or nonmotile rods without endospores. They may or may not require enriched culture mediums. Until recently they comprised an amorphous unclassified group. They are normally inhabitants of the mucous membranes of the intestinal tract and may be found in the apical abscesses of teeth. They are rarely the cause of endocarditis. Four cases have appeared in the literature since 1945. Three²⁷ were treated with penicillin—2 successfully. The fourth²⁸ was treated with penicillin and streptomycin successfully, and the result attributed to streptomycin.

The organism isolated in the case reported above was found on three successive daily cultures. It was a minute gram-negative bacillus, which grew slowly and poorly on Kracke's blood culture medium. It also grew on Brewer's thioglycollate medium. It did not grow on blood agar under ordinary conditions but did grow sparsely on blood agar under 10 per cent carbon dioxide. Unfortunately, the organism died off before further bacteriologic studies or sensitivity tests could be done.

This man's illness most likely started with the extraction of his teeth six months before his admission. Penicillin in the amounts used inhibited

the organism (as evidenced by the persistently negative blood cultures during its administration) but could not effect a cure. After five days of penicillin in massive doses (5,000,000 units per day) the temperature receded somewhat, but new petechiae continued to appear and clinical improvement was not evident. It was not until seven days after streptomycin therapy that the temperature remained persistently below 100°F by rectum and clinical improvement was noted. Symptoms of streptomycin toxicity (vertigo) appeared during the third week and were very annoying for six months. The decision to continue streptomycin after the appearance of toxic symptoms was made because it was thought that this drug offered the only chance for recovery and because of the known loss of sensitivity that ensues when sublethal doses of streptomycin are used. When seen for follow-up examination fourteen months after discharge the patient had completely recovered and was able to work although he still had a mild gait disturbance.

SUMMARY

The literature relating to subacute bacterial endocarditis treated with streptomycin is reviewed.

A case of subacute bacterial endocarditis caused by *Bacteroides* and successfully treated with streptomycin is reported.

EVALUATION OF TOLSEROL IN THE TREATMENT OF CHILDREN WITH CEREBRAL PALSY*

ERIC DENHOFF, M.D.,† RAYMOND H. HOLDEN, M.A.,‡ AND CAROLL M. SILVER, M.D.§

PROVIDENCE, RHODE ISLAND

THE basic concept of the treatment of cerebral palsy is re-education in the form of physical and occupational therapy. This treatment might be enhanced if a drug were found that would favorably influence the disabilities peculiar to this syndrome. This drug should have a relaxing effect on spastic and athetoid states and should facilitate the correction of resulting deformities. Since such a therapeutic program cannot be successful without the co-operation of the patient, the drug would be even more valuable if it were to alter favorably the child's attitude and behavior.

Tolserol (3-o-toloxv 1,2-propanediol) has been reported to effect relaxation¹ and to act favorably upon behavior.² Although its action is more dramatic when the drug is administered intravenously, Berger and Schwartz¹ have reported a beneficial relaxant effect on muscle spasm, spasticity and rigidity and an ameliorating effect on tremor and involuntary movement of extrapyramidal origin when the drug is given in adequate oral dosage.¹ Since the drug is relatively nontoxic in this form and is palatable, it makes an attractive pharmacologic approach to the treatment of cerebral palsy in children.

Any new drug proposed as an adjunct to such treatment should be rigidly evaluated prior to its release for general use. Therefore, a study of young children with cerebral palsy was initiated in the hope that this drug might help improve their condition.[†]

The purpose of this study is to evaluate the effect of tolserol on the child as a whole, as well as its specific action on the neuromuscular system. Inasmuch as many children with cerebral palsy fre-

quently make slow but steady developmental progress in their early years, a legitimate criterion for benefit from the drug should be a more marked quantifiable improvement over a relatively short period.

MATERIALS AND METHODS

Subjects

Sixteen children with ages ranging from three to eight years who had been attending the Meeting Street School for Cerebral Palsy from four to ten months were selected for study. Fourteen cases were diagnosed as spastic, 1 as athetoid, and 1 as ataxic. In classification of neuromuscular dysfunction, 2 were considered severe, 11 moderate, and 3 mild.||

Experimental Procedure

All the children had been attending the school for at least three months before the beginning of the drug evaluation. In the period prior to the beginning of the study, all the subjects were given complete pediatric, neurologic, orthopedic and psychologic examinations, as well as personality ratings by experienced nursery-school teachers.

The subjects were divided into two groups. Those in Group I received the drug for three weeks, followed by a placebo mixture for another six weeks, and then the drug was readministered for another three-week period. In Group II, the procedure was reversed: a placebo mixture was given for the first three weeks, after which the drug was substituted for six weeks, and the placebo was given again for the last three weeks. This procedure provided both a three-week and a six-week period of evaluation, and was of great convenience in statistical evaluation.

||A severe case was one in which the patient could not walk or utilize his hands with any degree of skill. A patient with a moderate case was one whose gait was decidedly deviant from normal and whose manual dexterity was impaired so that nursery school tasks were performed with difficulty. A mild case was one in which gait and manual dexterity were functionally good although lack of smoothness of movement was apparent.

¶Tolserol was supplied through the courtesy of Dr. E. Sidney Newcomer, E. R. Squibb and Sons, New York City.

Medication

Tolserol was prepared with aqueous propylene glycol and syrup of cherry* so that 30 cc of the solution contained 10 gm of the drug¹. The dosage for each child was computed by Fried's rule based on a proportional amount according to body weight. The suggested adult dose was 10 gm three to five times daily¹. In this study the average dose was 33 mg per pound of body weight per twenty-four hours. The tolserol mixture was administered to each child six times a day. The group that was serving as a control (that is, patients receiving the placebo) in each period was given a menstruum that was similar to the liquid tolserol in ingredients, color, taste and smell but did not contain the drug. The medications were coded so that none of the staff or the parents knew in which drug period each child was actually receiving myanesin. Since each child attended school only three days each week, the medication had to be administered mainly at home. The parents of each child recorded each dose in a notebook. Occasional lapses in dosage were due to illness.

Methods of Evaluation

Neurologic examination consisted of evaluation of cranial nerves (third, fourth, sixth, seventh and eleventh), reflexes and tests for co-ordination (Romberg, diadokokinesis, gait and movements). Reflexes were graded on a nine-point scale from +4 (markedly hyperactive) through 0 (normal) to -4 (absent).

Orthopedic examination consisted of evaluation of the following points: ability to stand or walk, or both, deformities of gait, grasping functions of upper extremities and absence or presence (and degree) of spasticity and contractures of extremities and trunk. A physical therapist and an occupational therapist supplemented the orthopedic examination by weekly progress reports.

Psychomotor tests evaluated performance in fine manipulation and gross movement. Wallin pegboards A and B and the speed of placing ten marbles in a cup measured fine manipulation, whereas walking a measured distance (2½ yards) and up and down a flight of five stairs represented measures of gross bodily movement.

Personal-social rating scales were utilized to obtain objective measures of any behavioral changes. The records were completed by nursery-school teachers twice during each testing period. The nine items used rated sociability, activity control, noise-disturbance control, self-entertainment, co-operation in routine, work capacity, willingness to follow directions and mood swings. A similar rating scale was distributed to parents so that quantifiable data could be obtained of changes

observed in the home surroundings. In addition, a daily behavior chart was maintained by the nursery-school teachers to record any outstanding behavior not included in the rating scales.

Laboratory studies were performed to determine possible toxic effects on the hematopoietic and genitourinary systems, before and after each drug period. These tests consisted of blood counts and urine examinations.

Criteria of Improvement

The criteria of improvement due to drug action were considered to be a primary relaxing effect as shown by improvement in neuromuscular status and greater ease in motor performance, and a secondary effect on behavior because of neuromuscular relaxation, which might well be shown by lessened hyperactivity, greater concentration and more facile social relationships — characteristics that children with cerebral palsy frequently lack. Ratings of "improved" were judged as follows: neurologic — improved co-ordination, less hyperactive reflexes and improved function of areas innervated by the third, fourth, sixth, seventh and eleventh cranial nerves, orthopedic — decrease in deformity or improved function, or both, psychomotor — improved performance on five tests, and behavior — decreased irritability and hyperactivity, or increased sociability, or both. Ratings of "worse" were judged as follows: neurologic — poorer co-ordination, more hyperactive reflexes and greater cranial-nerve impairment, orthopedic — increased degree of deformity or increased impairment of function, or both, psychomotor — less accurate test performance, and behavior — increased irritability and hyperactivity or decreased sociability, or both.

RESULTS

There was no consistent outstanding, observable, over-all improvement in the children studied. One child improved in three of the methods of evaluation used, 7 improved in two, and 5 improved in one. On the other hand, 3 children showed no improvement or got worse in at least one category (Table 1).

Neurologic

Nine children (56.25 per cent) showed improvement. At the completion of the study, superficial and deep tendon reflexes were nearer normal, the Babinski reflex was lessened, and there was improvement in the Romberg sign and tests of co-ordination. Cranial-nerve action did not seem to be affected. Six children (37.5 per cent) became worse, and 1 (6.25 per cent) showed no change.

Orthopedic

Five children (31.25 per cent) showed slight improvement. In no case was a striking improvement

*Tolserol 80 propylene glycol 480 camphor water 720 distilled water 720 and syrup of cherry as needed 2400

noted Two patients (12.5 per cent) became worse, and in 9 (56.25 per cent) there was no change

Psychomotor

Five children (31.25 per cent) improved, 2 (12.5 per cent) became worse, and 9 (56.25 per cent) showed no change. Statistical analysis of group results demonstrated no significant difference between the group while the drug was being given and the group while the placebo was being given. All tests for fine motor co-ordination showed a slightly longer mean performance time, whereas tests for gross

or later. Whether this was because insufficient dosage of the drug was given or because the clinical methods of testing behavior were not sufficiently sensitive to reflect minimal degree of improvement is difficult to state.

It has been the experience with curare, which has also been used to facilitate relaxation in cerebral palsy, that the degree of orthopedic improvement, when it occurs, is measurable, even though the effect may be transient.³ With tolserol, this grossly relaxant effect was observed neither by the orthopedic surgeon in his examinations nor by

bodily movement showed a slightly faster mean performance time — neither significantly so, however.

Behavior

Three children (18.75 per cent) improved, 3 (18.75 per cent) became worse, and the remainder showed no changes in over-all behavior. More specifically, 7 children showed improvement in one but not more than two of the personal-social behavior items, whereas 6 were reported as worse in one or two items, and 3 showed no change. The behavior items affected were usually sociability, self-entertainment, elation and depression.

Laboratory Studies

There were no significant deviations from the normal in urine or blood counts either during administration of the drug or after the cessation of tolserol therapy.

DISCUSSION

The results of this study proved interesting in several respects. Although there were no outstanding general improvements, there was evidence that the drug caused a diminution of exaggerated reflexes and some improvement in co-ordination. These results are in accord with those reported by Berger and Schwartz¹ and Gammon and Churchill.² However, this change in neurologic status did not seem to be reflected in improved over-all performance or in improved relaxation either immediately

the physical therapist in her tri-weekly therapeutic periods. Thus, although in 5 cases there was improvement from the orthopedic standpoint, the improvement was invariably slight and not of appreciable degree in any case. It is also of note that in 2 cases (12.5 per cent) the patients became definitely worse orthopedically while on tolserol therapy.

Performance time on tests of fine manipulation tended to be slightly slower on the drug, whereas in tests for gross bodily movement the time was somewhat faster. However, in neither case were the results statistically different from those of the control group.

Since it is recognized that parents and workers tend to be overly enthusiastic when they know a new drug is being administered, this study was designed to evaluate behavioral results of tolserol as objectively as possible and to minimize unwarranted conclusions based on subjective opinion alone. Nevertheless, great leeway was given both parents and nursery-school observers to report noticeable behavior changes in any way, and at the same time reports on objective behavior scales were required. In spite of the natural inclination for enthusiasm, in only 3 children could improved behavior be noted in the drug periods. Favorable behavioral changes might be expected, since one might assume that when a spastic child is relaxed he would feel happier or "lighter," a result obtained with a comparable group studied with curare.⁴

Three children who had been reluctant to participate in group activities for several months prior to administration did seem happier during the drug administration. On the other hand, a similar number of children became gloomy or withdrawn when they received the drug.

A liquid vehicle for administration is preferred since it has been shown experimentally that a higher drug concentration is obtained by this method and that absorption is much more uniform than by tablets.⁵ The drug was given six times a day at two-hour intervals to ensure maximum concentration in the blood for at least twelve hours a day during each entire three-week period of administration. There were no observable toxic effects, although for the first few days a few children complained of nausea and abdominal pain. This effect was transient.

It is believed that the drug did not have a primary or secondary relaxing effect. It did have a specific beneficial relaxant effect on some children as shown by improved reflexes only, but improved behavior and performance were negligible. The methods utilized in this study were considered sufficiently sensitive to demonstrate any improvements had they been present. It is possible that the dosage was not sufficient to achieve adequate relaxation although the dosages employed were of the same relative magnitude as those recommended in the literature.¹ If this is so, further study should be

initiated to ascertain the maximum dosage that can be tolerated in children of this age.

SUMMARY

Sixteen children with cerebral palsy received tolserol in two three-week periods. No definite over-all improvement was noted.

Improvement was primarily in the neurologic category. 56.25 per cent of the children showed diminution of exaggerated reflexes, and 12.5 per cent became worse.

Orthopedic improvements were slight. Five patients (31.25 per cent) showed improvement, not marked, and 2 (12.5 per cent) became worse, 9 (56.25 per cent) showing no change.

Locomotion was improved somewhat in 6 cases (37.5 per cent).

Behavior changes were not appreciable.

The drug did not produce any noticeable toxic effects.

We are indebted to the staff and consultants of the Meeting Street School for their invaluable assistance in this research.

ORAL ADMINISTRATION OF AUREOMYCIN IN THE TREATMENT OF URINARY INFECTIONS*

ALEXANDER M. RUTENBURG, M.D.,† AND FRITZ B. SCHWEINBURG, M.D.‡

BOSTON

IN A previous communication¹ intramuscular injection of aureomycin hydrochloride was reported to be not only a highly effective antibiotic in a variety of urinary infections but also, in many cases, curative after other antibiotics had failed. Owing to the pain caused by the intramuscular injections, even when the drug is given in a 1 or 2 per cent procaine solution, a subsequent series of 26 patients were treated by aureomycin given orally.

OBSERVATIONS

These cases comprised an unselected group of 26 acute and chronic urinary infections and included 5 with chronic renal insufficiency. Seventeen patients had had prior treatment with other anti-

*From the Kirstein Laboratory for Surgical Research, Beth Israel Hospital and the Department of Surgery, Harvard Medical School. Aided by a grant from Lederle Laboratories Division of American Cyanamid Company, New York City.

†Kirstein Fellow in Surgery, Beth Israel Hospital, assistant resident in surgery, Beth Israel Hospital.

‡Research associate, Harvard Medical School, research bacteriologist, Beth Israel Hospital.

biotics without clinical or bacteriologic improvement. Twenty had one or more of the following complications: hydronephrosis, calculi, ureteral stricture and prostatic obstruction. Obstructive disease, if present, was treated during aureomycin therapy.

Twenty-one of the infections were due to a single organism, and 5 to more than one. The organisms involved were *Escherichia coli* (8 cases), *Aerobacter aerogenes* (12 cases), *Pseudomonas aeruginosa* (11 cases), *Proteus vulgaris* (1 case), hemolytic *Staphylococcus aureus* (1 case) and *Streptococcus faecalis* (1 case).

Two grams of aureomycin was given daily in divided doses for four to six days, or longer, so long as bacteria were present. If cure did not result in two weeks, the drug was discontinued.

Oral administration of aureomycin was generally well tolerated. In 3 patients with nausea and another with diarrhea, the reactions were mild, and the therapy was not interrupted. In 2 other patients

vomiting prevented oral therapy, and the drug was given parenterally. The reactions varied with different lots of the drug. With the more recent lots, no gastrointestinal symptoms occurred. Renal injury was not observed during treatment. The nonprotein nitrogen was not increased in patients with renal insufficiency. Shortly after the drug had been started the urinary pH dropped to 4.5 to 6.0 and remained within this range as long as the drug was administered. Catheter specimens were cultured every second day, and treatment was continued for two or three days after the first sterile specimen. The patients were followed for ten to thirty days and were considered cured only when two to five specimens of urine were found to be sterile after cessation of treatment. Anemia, leukopenia or thrombopenia did not develop. The white-cell counts, which had been elevated before treatment, dropped to normal values within one or two days when treatment was successful.

RESULTS

The clinical symptoms disappeared in all patients in a surprisingly short period—usually within twenty-four to forty-eight hours. It is noteworthy that the clinical improvement occurred whether the urine had or had not become sterile. In cases in which bacteria persisted, the clinical symptoms usually recurred when the drug was discontinued. The urine became sterile in 16 cases and remained so after the drug was discontinued.

A close correlation was observed between the clinical result and the *in vitro* sensitivity of the organism to aureomycin. Thus, a rapid cure of the infection was obtained in every case in which the strain was sensitive, whereas partial or total therapeutic failure resulted when the strain was resistant.

The sensitivity of bacteria to a given antibiotic varies considerably, not only from species to species but also from strain to strain within a species. One hundred and thirty strains of various species, including many of those encountered in the present group of cases, were tested for sensitivity *in vitro* to aureomycin by the serial tube-dilution method.¹ This method tests the response of a twenty-four-hour broth culture inoculated with some 20,000 organisms of a particular strain to graded dilutions of the antibiotic. The lowest concentration of an antibiotic, in microgm per cubic centimeter, that produces no macroscopically visible growth after incubation for twenty-four hours at 37°C is considered the bactericidal titer. This titer for aureomycin was found to be as follows: the titer for thirty-five strains of *Ps aeruginosa* varied from more than 200 to 0.0125 microgm per cubic centimeter, over half the strains requiring more than 50 microgm per cubic centimeter. The titer for thirty strains of *P vulgaris* ranged from over 200 to 0.0125, a third of the strains requiring more than

50 microgm per cubic centimeter. The titer of twenty-five strains of *Esch coli* and of twenty strains of *A aerogenes* ranged from 6.25 to 0.0125 microgm per cubic centimeter, but with an occasional strain requiring more than 200. The titer of ten strains of hemolytic *Staph aureus* and of ten strains of beta-hemolytic streptococcus were inhibited by 0.4 to 0.0125 microgm per cubic centimeter. If the growth of a strain was completely inhibited by a concentration of less than 50 microgm of aureomycin per cubic centimeter of culture, the strain was considered sensitive. If the growth was completely inhibited by a concentration of 50 microgm or higher per cubic centimeter of culture, the strain was considered resistant.

There was recurrence of infection in 2 patients. The first had chronic urinary retention and acute pyelonephritis due to *A aerogenes* that was very sensitive to aureomycin *in vitro*. He responded rapidly to aureomycin therapy, but twice at intervals of three weeks the infection recurred. Both relapses yielded promptly to the drug.

The second patient, with severe cardiovascular disease, renal tumor and a hypertrophied obstructing prostate, had an infection due to *Ps aeruginosa* that was very sensitive to aureomycin *in vitro*. Twenty days after the drug had been discontinued the infection recurred and again responded rapidly to the drug.

In a third patient with chronic cystitis and pyelonephritis due to *Esch coli*, as well as renal insufficiency and a blood nonprotein nitrogen varying from 80 to 120 mg per 100 cc, the infection was cured within forty-eight hours. The urine remained sterile for twenty-eight days. Reinfection occurred with *A aerogenes*. A second course of therapy promptly sterilized the urine, which remained sterile for the next fourteen weeks, when observation was discontinued.

In these 3 patients, bacterial resistance to aureomycin did not develop.

A fourth patient, with a vesicovaginal fistula and a mixed urinary infection due to *A aerogenes*, *Str faecalis* and *Ps aeruginosa*, improved clinically, but only the first two of these organisms were cleared from the urine. *Ps aeruginosa* remained. In a fifth patient with mixed infection, one organism (*A aerogenes*) was cleared, but the other (*Ps aeruginosa*) was not. This patient also showed clinical improvement.

There were 5 bacteriologic failures in monovalent infections, 1 due to *Esch coli* and 4 to *Ps aeruginosa*. In these cases the bacteria were resistant to aureomycin *in vitro*.

Of 34 strains of bacteria found in the urines of the 26 patients, all 12 strains of *A aerogenes*, 7 or 8 strains of *Esch coli* and 1 strain each of *P vulgaris*, hemolytic *Staph aureus* and *Str faecalis*, were eliminated from the urine. Of 11 strains of *Ps aeruginosa*, 5 that were sensitive to the drug

Three children who had been reluctant to participate in group activities for several months prior to administration did seem happier during the drug administration. On the other hand, a similar number of children became gloomy or withdrawn when they received the drug.

A liquid vehicle for administration is preferred since it has been shown experimentally that a higher drug concentration is obtained by this method and that absorption is much more uniform than by tablets.⁵ The drug was given six times a day at two-hour intervals to ensure maximum concentration in the blood for at least twelve hours a day during each entire three-week period of administration. There were no observable toxic effects, although for the first few days a few children complained of nausea and abdominal pain. This effect was transient.

It is believed that the drug did not have a primary or secondary relaxing effect. It did have a specific beneficial relaxant effect on some children as shown by improved reflexes only, but improved behavior and performance were negligible. The methods utilized in this study were considered sufficiently sensitive to demonstrate any improvements had they been present. It is possible that the dosage was not sufficient to achieve adequate relaxation although the dosages employed were of the same relative magnitude as those recommended in the literature.¹ If this is so, further study should be

initiated to ascertain the maximum dosage that can be tolerated in children of this age.

SUMMARY

Sixteen children with cerebral palsy received tolserol in two three-week periods. No definite over-all improvement was noted.

Improvement was primarily in the neurologic category. 56.25 per cent of the children showed diminution of exaggerated reflexes, and 12.5 per cent became worse.

Orthopedic improvements were slight. Five patients (31.25 per cent) showed improvement, not marked, and 2 (12.5 per cent) became worse, 9 (56.25 per cent) showing no change.

Locomotion was improved somewhat in 6 cases (37.5 per cent).

Behavior changes were not appreciable.

The drug did not produce any noticeable toxic effects.

in part in such conditions as hereditary hemorrhagic telangiectasia scurvy and hemophilia conditions associated with extreme thrombocytopenia hypoprothrombinemia and fibrinogenopenia and conditions associated with circulating anticoagulants and other abnormalities (Table 1)* In other cases it is possible to indicate the abnormal mechanism responsible for bleeding such as thrombocytopenia even though the biologic effect of the abnormality may not be completely understood and the cause of thrombocytopenia may not be evident Certain aspects of these tests are arbitrary nonspecific, crude, poorly defined and limited in significance by a lack of understanding of some features of their mechanism Also there may be a lack of true correlation of certain results obtained in vitro with the symptoms and signs observed in vivo For example there may be thrombocytopenia with or without hemorrhagic diathesis in hemophilia bleeding may continue in a serious degree when the clotting time, as measured in glass tubes has returned toward normal

HYPOTHESES CONCERNING HEMOSTASIS IN NORMAL SUBJECTS

Hemostasis is a term that by definition means halting the escape of blood Hemostasis probably results from a combined effect of extravascular factors, such as location of the vessel and tone of the surrounding tissue, vascular factors, such as size and structure of the vessels as well as vascular tone, and factors of clot formation such as the number of platelets and the amounts and state of the constituents of the blood required for proper blood coagulation A defect in any one of these three factors may result in an alteration of hemostasis In hemorrhagic diathesis, consideration is too often limited to the coagulation of blood itself All three of the factors listed above must be considered and critically scrutinized when bleeding is not halted spontaneously The critical reports of Quick,¹ Macfarlane,² Tocantins,³ Zucker⁴ and Zucker⁵ contain detailed discussions of the experimental evidence and the hypotheses concerning hemostasis in the normal person and the alterations observed in disease The theory of blood coagulation is discussed below

In the normal subject, hemostasis following injury occurs spontaneously, presumably because of the following series of mechanisms which are here outlined in an oversimplified manner More detail is given in the sections describing special tests

Extra-vascular Factors

When bleeding occurs from a vessel such as a capillary, the hydrostatic pressure within the vessel falls and that in the surrounding tissue rises as a

*Deficiency of calcium of sufficient degree to interfere with the clotting mechanism is not compatible with life Accordingly hypocalcemia is not observed clinically as a cause of hemorrhagic disease.

result of the outflow of blood from the ruptured vessel The increase in tissue pressure in combination with normal tissue tone tends to reduce the flow of blood through as well as from the ruptured vessel

Vascular Factors

After vascular rupture vasoconstriction and retraction of the vessel promptly occur Vasoconstriction lasts for a few minutes or a longer period tending thereby to occlude the lumen of the vessel Retraction also tends to occlude the lumen by mechanically blocking the opening of the vessel by means of the surrounding tissue

Factors of Clot Formation

Concomitantly with rupture of a vessel blood escapes into the surrounding tissue and may be mixed with tissue factors that enhance clot formation In the lumen of a ruptured vessel itself platelets agglutinate and adhere to the area of broken intima Fibrin is deposited about the platelets that disintegrate This apparently enhances the formation of a clot, with subsequent retraction, so as to form a plug in the lumen of the vessel If the clot formation is secure, hemostasis continues after the vessel is no longer constricted The clot will then be organized or resolved with recanalization of the vessel

DIAGNOSTIC PROCEDURES FOR THE STUDY OF PATIENTS WITH HEMORRHAGIC DISEASES

It is recommended that the physician study a patient with hemorrhagic disease by means of a systematic approach from the basic and screening examinations to the more specialized tests, certain of which are discussed below in detail

Basic and Screening Examinations

These include history physical examination, basic examination of the blood (determination of hemoglobin or hematocrit, white-cell count and differential count, estimation of the number of platelets from the stained smear and serologic test for syphilis), basic examination of the urine and basic examination of the stool From the initial study of the patient, a presumptive diagnosis can be made in certain cases of a disease complicated by hemorrhagic manifestations or of a primary hemorrhagic disease The vascular defense and the process of clot formation are usually studied to aid further in diagnosis

Special Tests Related to Vascular Defense and Clot Formation

Vascular defense and clot formation are determined by the following procedures measurement of capillary fragility, bleeding time, platelet count, clot retraction, coagulation time, clotting time of recalcified plasma, screening tests for abnormal

in vitro were eliminated, whereas 6 that were resistant in vitro were not

DISCUSSION

Sixteen of 26 patients were promptly cured by a single course of oral administration of aureomycin. Several courses were required in the 3 patients who had recurrence of infection. In these and in the patient with a vesicovaginal fistula, the underlying disease had not been dealt with successfully. Clinical improvement resulted in all the patients in this series, even in the 7 cases of failure to eradicate the bacteria (1 of *Esch coli* and 6 of *Ps aeruginosa*). There was exact correlation between bacterial sensitivity in vitro and the immediate bacteriologic response, regardless of whether the complicating disease was dealt with successfully. In the latter cases recurrences or reinfections were to be expected, and in fact occurred. Such patients cannot be permanently cured by any antibiotic. These results in *Ps aeruginosa* infections are better than those reported by others.^{2, 3} In 2 cases the strains that were resistant to aureomycin yielded to subsequent treatment with sulfamethazine⁴ to which they were very sensitive in vitro. We have

observed no case in which bacterial resistance to the drug developed during treatment.

SUMMARY

In 26 patients with a variety of urinary infections, due chiefly to gram-negative bacilli, aureomycin was as effective by oral as by intramuscular administration. Clinical improvement occurred in all cases. Bacteriologically, 19 patients, of whom 12 had failed to respond to other antibiotics and 13 had complicating disease in the urinary tract, were cured, 16 by a single course and 3 by repeated courses of therapy. *Pseudomonas aeruginosa* was the least susceptible of the bacteria encountered. Bacterial resistance did not develop.

We are indebted to Miss Annette Freedman for technical assistance.

WALTER B. FROMMEYER, M.D.,† AND ROBERT D. EPSTEIN, M.D.‡

BIRMINGHAM, ALABAMA, AND YONKERS, NEW YORK

THE subject of hemorrhagic disease is considered under the general headings of problem in diagnosis, hypotheses concerning hemostasis in normal subjects, diagnostic procedures, history, physical examination, basic examination of blood, urine and stool, measurement of capillary fragility, bleeding time, platelet count, clot retraction, measurement of coagulation and clotting times of venous blood, clotting time of recalcified plasma, screening tests for abnormal coagulation, determination of prothrombin activity, prothrombin consumption and determination of fibrinolysis.

PROBLEM IN DIAGNOSIS

The physician is called upon to diagnose and treat patients with signs and symptoms of an in-

creased tendency to bleed. The manifestations of hemorrhagic diathesis are extremely variable, since abnormal bleeding may be evidenced as purpura in the skin, subcutaneous hemorrhage, bleeding from any mucous surface or hemorrhage into any structure or organ of the body.

Since the prognosis and treatment for the patient with hemorrhagic diathesis vary widely, it is essential to establish, as well as possible, the diagnosis or mechanism for the bleeding. This is done by at least two approaches. In the first place the patient is studied, a series of basic and screening examinations being used, in an attempt to establish a diagnosis of the primary illness, which may or may not be that of a primary hemorrhagic disease. Secondly, a series of special examinations of a biologic nature are made to evaluate qualitatively and quantitatively abnormalities of the vascular defense of the body and of the process of clot formation.

With these data, the underlying disease and the mechanism causing hemorrhage can be defined.

TABLE 1 (Continued)

DISEASE	COMMENTS ON MECHANISM	BLEEDING TIME	COAGULATION TIME	CLOT RETRACTION	PLATELET COUNT	TOURNIQUET TEST	PROTHROMBIN CONCENTRATION	PROTHROMBIN CONSUMPTION
Hemorrhagic disease associated with <i>thrombocytopenia</i> <i>poor clot retraction and increased capillary fragility*</i>								
Purpura hemorrhagica idiopathic thrombocytopenic purpura (Werlhof's disease) thrombocytopenia with variable degrees of abnormality of capillaries	Mechanism of bleeding in this disease is known only in part. coagulation defect is associated with deficiency of 'platelet enzyme' there is poor clot retraction with decrease in adhesiveness rigidity and contractility and there is apparent failure to form platelet plug in severed vessel. The vascular defect is poorly understood. This disease occurs in children in adults it occurs largely in young women occasionally in men. It is of undetermined origin may be acute or chronic and is associated with variable degrees of thrombocytopenia, purpura and ecchymosis. Spontaneous recovery may occur in acute adolescent cases. In chronic type splenectomy may give symptomatic cure in about 70 per cent of cases in spite of continuing thrombocytopenia occurring in many cases. Diagnosis requires excluding causes of "secondary" thrombocytopenia.	Usually prolonged	Normal	Poor	Decreased	Marked increase in capillary fragility	Normal	Poor
Secondary' or symptomatic thrombocytopenic purpura (thrombocytopenia with variable degrees of abnormality of capillaries)	Mechanism of bleeding is the same as that in purpura hemorrhagica. It is acute or chronic hemorrhagic disease with symptoms and signs similar to those of idiopathic thrombocytopenia and may occur in children and adults of both sexes. Thrombocytopenia may be associated with such conditions as invasion of bone marrow (myelophthisis) aplastic marrow irradiation drug intoxication as with benzol allergic response as possibly illustrated by sensitivity to organic arsenical drugs. Sedormid and sulfonamides following thermal burns nutritional deficiency in pernicious anemia and occasionally with uremia.	Usually prolonged (may show great variation)	Normal	Poor	Decreased (may show great variation)	Marked increase in capillary fragility (may show great variation)	Normal	Poor (may show great variation)
Hemorrhagic diseases associated with manifest <i>abnormalities of clot formation</i>								
Hypoprothrombinemia	Mechanism of bleeding is impaired blood coagulation.	May be increased in severe cases	May be increased in severe cases	Normal†	Normal	Capillary fragility may be increased in severe cases	Decreased (usually only defect)	Normal
Lack of prothrombin or presence of antiprothrombin substance administered such as Dicumarol	Hypoprothrombinemia may be associated with severe hemorrhagic disease as evidenced by purpura ecchymoses and bleeding into any tissue. Hypoprothrombinemia may occur in such conditions as congenital absence (rare) faulty absorption of vitamin K as in absence of bile salts and in melena neonatorum steatorrhea or diarrhea defective formation by diseased liver and administration of Dicumarol and large doses of salicylates. Vitamin K, administered parenterally, usually restores prothrombin if there is adequate liver function. Massive doses may be needed after Dicumarol therapy.							
Circulating anti-coagulants (heparin and other anticoagulants)	Bleeding results from inhibition of coagulation by anticoagulants circulating in blood stream in such conditions as administration of heparin and ionizing doses of irradiation probably due to heparinemia. In other cases type of anticoagulant has not been classified.	Normal	Prolonged (patient's plasma may prolong clotting time of normal plasma or whole blood)	Normal	Normal	Normal	Normal	No studies reported

*Relation between thrombocytopenia and capillary fragility is not known

†Clotting time of whole blood not reliable index of degree of hypoprothrombinemia

TABLE 1 *Classification of Hemorrhagic Diseases, with Comments on Mechanism and Certain Laboratory Tests*

DISEASE	COMMENTS ON MECHANISM	BLEEDING TIME	COAGULATION TIME	CLOT RETRACTION	PLATELET COUNT	TOURNIQUET TEST	PRO-THROMBIN CONCENTRATION	PAO-THROMBIN CONSUMPTION
Hemorrhagic diseases associated with apparent abnormalities of vascular bed but with normal platelets and essentially normal blood coagulation								
Hereditary hemorrhagic telangiectasia (Rendu Osler, Weher disease)	Non sex-linked hereditary disease exhibiting telangiectatic lesions consisting of thin-walled dilated capillaries that are exposed and may bleed from slight trauma. Some capillaries show wall consisting of endothelium only with complete loss of supporting elastic tissue. Others reveal complete vascular wall with dilatation and exposure as only abnormalities. There are usually no symptoms in childhood; symptoms occur with increasing age in adults. Lesions may be located on skin or mucous membrane or in viscera. Patients may have no hemorrhage. Intermittent hemorrhage may occur externally or internally. There is no specific treatment.	Normal	Normal	Normal	Normal	Normal	Normal	Normal
Localized areas of exposed thin-walled capillaries								
"Thrombasthenia" hereditary hemorrhagic diathesis pseudohemophilia (von Willebrand and Glanzman)	Mechanism of bleeding is unknown but may be related to abnormal function of platelets or vascular malfunction such as poor vascular constriction following injury. Disorder may be familial and transmitted to either sex. There occurs persistent bleeding following minor trauma, bleeding gums, ecchymoses, melena, hematuria, epistaxis and in females menorrhagia and metrorrhagia. Hemarthroses have been reported but are rare. It is not known whether these cases represent disease entity or several diseases. There is no known treatment.	Markedly prolonged for normal	Prolonged in some cases	May be reduced	Normal	Increased capillary fragility in about 50% of cases	Normal	No studies reported
Scurvy (decreased intercellular collagen substance)	Hemorrhage appears to result from lack of intercellular collagen substance due to prolonged deficiency in ascorbic acid and may be associated with purpura that is perifollicular or there may be large ecchymoses.	Normal	Normal	Normal	Normal	Marked increase in capillary fragility, but test returns to normal promptly after administration of vitamin C	Normal	Normal
Senile purpura (lack of supporting structures)	Rupture of capillaries presumably results owing to loss of elasticity and atrophy of supporting tissues. In senility it is not uncommon for purpura and hematomas to develop especially in dependent parts of body with or without trauma.	May be slightly prolonged	Normal	Normal	Normal	Capillary fragility may be slightly increased	Normal	Normal
Sepsis (increased capillary fragility of toxic origin)	Although mechanism is unknown it is thought that purpura results from defect in capillary wall probably on toxic basis. Purpura may occur with or without septic emboli to capillaries of skin.	Normal	Normal	Normal	Normal	Capillary fragility may be increased	Normal	Normal
Allergic purpura (Henoch's and Schönlein's purpura) abnormal response of capillaries	Bleeding results from increased capillary permeability with resultant passage of plasma and blood cells through capillary wall. Such increased permeability is probably of allergic origin (drug intoxication, food idiosyncrasies and certain infections). Purpura joint symptoms and fever were described by Schönlein. Visceral lesions may occur including those of bowel (Henoch's purpura). Diagnosis usually made by exclusion of other causes for purpura and by associated symptoms and signs of primary abnormality.	Normal	Normal	Normal	Normal	May be normal or may show increased capillary fragility	Normal	Normal

Classification of Hemorrhagic Diseases

A brief classification of hemorrhagic diseases, based on known abnormalities and changes in certain tests for hemorrhagic diathesis, is presented in Table 1. Such a table is necessarily incomplete and oversimplified, more complete discussions of the diseases and their physiologic causes have been given elsewhere.^{1-3 6-67}

HISTORY

A complete and critical history is of first importance in the diagnosis of the cause of hemorrhagic diathesis. Often, the history alone provides adequate data on which to base a presumptive diagnosis. The history of abnormal bleeding occurring in alternate generations in male members of a family is presumptive evidence for the diagnosis of hemophilia. The history of familial bleeding that is not sex-linked suggests the possibility of "thrombasthenia." One may best obtain the *family history* by setting up a family tree on paper and, together with the patient and other members of the family, discussing and determining hemorrhagic diatheses in each member of the family as far ancestrally as is known. Often, it is necessary to question the patient and relatives to determine the onset and characteristics of bleeding. It is of importance to know the age of the patient at the *onset of bleeding*. An acute episode frequently brings the patient to the physician, but the past history will reveal many episodes of bleeding tendency reflected in such observations as frequent epistaxis, easy bruising, menorrhagia, metrorrhagia, hemarthrosis simulating arthritis, bleeding with eruption of deciduous and permanent teeth and severe hemorrhage with minor surgical procedures, such as circumcision, tonsillectomy and tooth extractions. The relation of bleeding at time of menses should be carefully investigated, since exaggeration of the normal menstrual bleeding may serve as an important index of a hemorrhagic diathesis. It is of importance to determine whether the patient has been exposed to potentially harmful drugs, chemicals or physical agents. The presence of infection, allergic symptoms or other diseases such as anemia is investigated historically in the patient. A dietary history may reveal an inadequate intake of vitamin C over a prolonged period and may thus suggest the diagnosis of scurvy.

PHYSICAL EXAMINATION

Usually, the physical signs occurring in hemorrhagic diseases do not permit a specific diagnosis to be made. The physical signs will depend on the site of hemorrhage. In *familial telangiectasia*, the lesions may be seen in the skin and mucous membranes.²⁴ In *purpura** petechiae may predominate

*Purpura is not a disease entity but a physical sign. Purpura means literally a purple effluvia from which a purple dye was extracted.

in dependent portions of the body and may be associated with bleeding of the mucous membranes. Intracranial hemorrhage may be manifested by signs of hemiplegia but there may be little evidence of hemorrhage elsewhere in the body. The follicular and perifollicular purpura of *scurvy* may be associated with massive hemorrhage into muscles and subcutaneous tissues without hemarthrosis.

In *hemophilia*, the occurrence of hemarthrosis is frequent enough to suggest the diagnosis. However, at any one time, there may be only one site of bleeding, such as hematuria, or there may be bleeding into more than one joint or into skin, muscle, mucous membranes or viscera.

The *complications of hemorrhage* may include the following: loss of large amounts of blood, pain and swelling, pressure from hematomas with obstruction of air passages and with atrophy of nerves or muscles and deformities of joints. If hemorrhagic diathesis is a complication of another disease, the physical signs of the primary disease may be manifest, such as those of infection, anemia, leukemia, lymphoma or cancer.

BASIC EXAMINATION OF BLOOD, URINE AND STOOL

In the basic examination of the blood, it may be possible at the time of capillary puncture and venipuncture to detect a prolonged bleeding time or an increase in capillary fragility. Anemia may or may not be present. The stained film of blood may permit the immediate detection of thrombocytopenia, leukemia, myeloid leukocytosis or other abnormalities that may serve as diagnostic aids. There may be hematuria or blood in the stool. There may be jaundice with choloria, acholic stools or variable evidence of disease of the liver.

MEASUREMENT OF CAPILLARY FRAGILITY

Principle

With rupture of capillaries the extravasation of blood into the skin forms a purple or purpuric spot. If there is a larger area of bleeding into the skin an ecchymotic area is formed that is dark red or blue, later changing to greenish or brown as the hemoglobin is converted, apparently, to biliverdin and bilirubin and subsequently removed.

Two terms are used to describe the susceptibility of capillaries to rupture and have resulted in some confusion. Both expressions have the same meaning, and thus it is correct to speak synonymously of *increased capillary fragility* or *decreased capillary resistance*. The ability of the capillary to withstand pressure is measured in two ways: by increase in the venous pressure by means of a blood-pressure cuff used as a tourniquet (tourniquet test), and by application of a known negative pressure to an area of the skin by the *Dalldorf*⁶⁵ method.

In the *Dalldorf method* a negative pressure equivalent to 200 mm of mercury is maintained for 1

TABLE 1 (Continued)

DISEASE	COMMENTS ON MECHANISM	BLEEDING TIME	COAGULATION TIME	CLOT RETRACTION	PLATELET COUNT	TOURNIQUET TEST	PROTHROMBIN CONCENTRATION	PROTHROMBIN CONSUMPTION
Hemophilia Deficiency in blood plasma of material required for normal coagulation	Bleeding results from deficiency of plasma factor probably thromboplastic in action. Hemophilia is sex-linked recessive hereditary disease occurring only in males and transmitted only by females. It is characterized by prolonged clotting time and marked susceptibility to hemorrhagic manifestations throughout life. Hemorrhages occur from trauma and appear 'spontaneously' affecting any tissue or organ. Hemarthroses are frequent. Administration of fresh whole blood, plasma or plasma fractions results in transient reduction of coagulation time toward normal with or without decrease in bleeding.	Initially normal, but puncture wound may subsequently bleed indefinitely	Prolonged in variable degree	Normal	Normal	Normal	Normal	Poor
Deficiency of fibrinogen fibrinogenopenia afibrinogenemia Deficiency or absence of fibrinogen	Abnormal bleeding is result of impaired blood coagulation. Deficiency or absence of plasma fibrinogen occurs rarely and may be associated with hemorrhagic symptoms and signs similar to those occurring in hemophilia but without hemarthroses. Absence of fibrinogen occurs as rare congenital anomaly. Acquired fibrinogenopenia may be complication of severe parenchymal disease of liver, or presence of plasma fibrinolysin.	Normal	Prolonged†	May be reduced	Normal	Normal	Normal‡	Normal
Parahemophilia (Owren's disease) Deficiency of Factor V of Owren	Disease has been reported only in females but males should be equally affected. It is probably hereditary and is characterized clinically, by epistaxis, ecchymoses following trauma, hematuria, menorrhagia and metrorrhagia. Hemarthrosis did not occur in Owren's patient. Congenital absence of factor in plasma required for conversion of prothrombin to thrombin results in prolongation of coagulation time and hemorrhagic manifestations. Addition of normal whole blood in vitro and in vivo corrects all laboratory and clinical abnormalities.	Normal	Characteristically prolonged	Normal	Normal	Normal	Normal§	Poor

†Coagulation of blood may be absent in afibrinogenemia. It may be quite normal until fibrinogen level is greatly reduced (levels of 50 to 75 mg per 100 cc).

‡Prothrombin concentration is normal but cannot be determined by one stage method since fibrinogen may be absent and must be added.

§Prothrombin time is prolonged by use of one stage Quick method but is normal if plasma-dilution technic is employed.

coagulation, determination of prothrombin activity and prothrombin consumption, all of which are described in detail below, and determination of fibrinolysins, determination of fibrinogen, vitamin C level of buffy coat, therapeutic trial with vitamin C and vitamin K and specific tests for circulating anticoagulants, which are discussed elsewhere.^{1, 6, 7-16}

It is frequently desirable or necessary to conduct other special examinations in patients with hemorrhagic diathesis to establish the diagnosis or response to treatment of the underlying disease process.

Special Tests for Hemorrhagic Disease

A partial list of special examinations that may be indicated in patients with hemorrhagic disease includes examinations of blood for leukemia, per-

nicious anemia and aplastic anemia, smear and biopsy* of bone marrow for morphology and number of platelets, and megakaryocytes, signs of neoplasia, aplasia and hyperplasia, biopsy* of lymph nodes or other structures, splenectomy as a therapeutic test in idiopathic thrombocytopenia or certain cases of secondary thrombocytopenia, examinations for the presence of infections, examinations of urine for drugs (sulfonamides, barbiturates and arsenic), x-ray examination of the gastrointestinal tract for bleeding, and study of the function of the liver as related to hypoprothrombinemia.

*All surgical procedures in a patient with hemorrhagic diathesis are done after consideration of possible complications of bleeding. In hemophilia, for example, surgical intervention may be hazardous even under carefully controlled conditions.

BLEEDING TIME

Principle

The bleeding time is the period required for effective hemostasis to occur after infliction of a standardized wound of the capillary bed. Bleeding time depends primarily on extravascular and vascular factors and to a lesser degree on factors of clot formation. It is an arbitrary biologic procedure with many limitations. Two methods are used at present: the Duke⁷⁰ method and the Ivy⁷¹ method. The former is employed most frequently.

Methods

Duke method A stab wound 2 mm in length and depth is made in the dependent portion of the lobe of the ear, a sharp-pointed scalpel blade, such as a Bard-Parker blade No 11, being used. The ear is not manipulated but must be warm. At intervals of half a minute, the blood accumulated on the skin is removed by gentle touching of the drop, but *not the skin*, with a blotter or piece of filter paper. The end point of this test is failure of blood to appear on the blotting paper when the drop is touched. The normal range for this method is from two to four and a half minutes. A needle should *not* be used for the capillary puncture, since the round hole does not bleed well enough to produce a sensitive test.

Ivy method A pressure equivalent to 40 mm of mercury is maintained on the arm with the use of a blood-pressure cuff. A puncture wound 2 mm in length and depth is made in a relatively avascular area of the forearm, just distal to the antecubital fossa. The escaping blood is absorbed on gauze pledgets and the bleeding time recorded to the nearest half minute. The normal range by this method has been reported⁶⁹ as 0 to six and four-tenths minutes, with a mean of three and two-tenths minutes.

Limitations and Interpretations

The difficulty of producing a standardized wound considerably limits this test as an aid in diagnosis. This limitation occurs also with the use of a mechanical lancet. Slight increases in bleeding time above the upper limit of normal always require that a series of such tests be made to control the variation in producing the wound and to determine the state of hemostasis. Under no circumstances should a needle be used for the puncture, since a significant increase in bleeding time may be missed that is readily demonstrable by a stab wound made by a scalpel blade.

An increase in the bleeding time does not permit a specific diagnosis to be made, nor does it signify an abnormality of a single mechanism. Prolongation of the bleeding time may be encountered in conditions in which the efficiency of the *extravascular factors of hemostasis* is decreased. Thus,

in *aged persons*, prolongation of the bleeding time due to poor tissue tone and atrophy of subcutaneous tissue may be encountered. As a result of these senile changes, the hydrostatic pressure in the surrounding tissue may not rise to effective levels when bleeding from the vessel occurs. In addition, flabby and sparse subcutaneous tissue is not conducive to proper mechanical plugging of the open end of the vessel as it retracts.

Abnormalities in the bleeding time may also result from changes in the *vascular factors of hemostasis*. Thus, in states in which there is altered capillary contraction the bleeding time may be prolonged. In senility, poor vascular contraction may be a factor, in conjunction with poor tissue tone and tissue atrophy, to account for the sporadic prolonged bleeding time that is observed. In "*thrombasthenia*" there may be extremely variable increases in the bleeding time, which are considered to be due to altered capillary contraction since the number of platelets is normal.^{2, 20-23, 25-27} A dogmatic conclusion that altered capillary contraction is the sole mechanism for prolongation of the bleeding time in this disease cannot be made since the platelet is of considerable importance in controlling the duration of the bleeding time. There is evidence that the platelets in "*thrombasthenia*" may not agglutinate normally,⁷² and it is possible that they do not form a stable plug in the open end of the vessel to aid in effective hemostasis.

Abnormalities in *factors of clot formation*, such as failure of formation of the platelet plug in thrombocytopenia, may be a contributing cause of a prolonged bleeding time.^{4, 5} Conversely, frank alterations in blood coagulation have little effect on the duration of the bleeding time. In *hemophilia* the bleeding time, as arbitrarily defined here, is "normal" in that bleeding stops within three minutes. This is explained on the basis that in hemophilia the initial vascular contraction is normal, and this, in conjunction with small amounts of tissue juice for partial coagulation, temporarily causes cessation of bleeding.² At a later time, such as an hour after the test, when vascular contraction has ceased, the stab wound may begin to "ooze" and bleed slowly and continuously, apparently owing to poor clot formation. The bleeding may continue until the wound is treated with thromboplastic material. Similarly, in *afibrinogenemia* the bleeding time is "normal" as a result of adequate initial vascular contraction and proper functioning of the extravascular factors concerned in hemostasis. As in hemophilia, oozing may occur later and continue unabated until fibrinogen is administered. A test of bleeding time in a known hemophilic patient or one with afibrinogenemia is to be *avoided* as an unnecessary *surgical* procedure. On the contrary, venipuncture with a 20-gauge needle is done whenever indicated and should *not* cause bleeding if

minute over a circular area 1 cm in diameter on the outer side of the upper arm, and the number of petechiae produced are counted. Fewer than 10 petechiae were observed by Aggeler, Howard and Lucia⁶⁹ in 92 per cent of 64 normal subjects tested, with a range of none to more than 30. Although the Daldorf method has certain advantages, such as reproducibility and ease of quantitative measurement, it requires specialized apparatus that is not usually available. The tourniquet test or positive-pressure method is most commonly used and is described below.

Tourniquet Test for Capillary Fragility

The forearm and hand are inspected in advance of the test for purpuric spots, nevi and hemangiomas that might be confused with petechiae produced by the test. These are marked with a ring of ink. A blood-pressure cuff is applied about the upper arm in the usual manner, and the *blood pressure accurately determined*. Although the usual procedure employs a pressure midway between systolic and diastolic pressure for five minutes, it is *recommended* that a pressure equivalent to 100 mm of mercury be employed for *ten minutes*. (If the patient's systolic blood pressure is 100 or less, a pressure is used that is midway between systolic and diastolic pressure.) After ten minutes the cuff is removed, and five minutes later the forearm, hand and fingers are examined on all sides for petechiae. One may devise a refinement by drawing a circle 5 cm in diameter, located on the flexor surface of the forearm, 2.5 cm below the antecubital fossa. The petechiae in this area are counted. It is recommended that a normal subject be examined as a control and as an aid in estimating the degree of abnormality of a positive test.

Limitations and interpretations. Normal subjects show no petechiae or a few scattered petechiae just below the margin of the cuff. In a circle 5 cm in diameter, the upper limit of normal is approximately 10 to 15 purpuric spots (adequate data for the range of normal are not available). In positive tests, the entire forearm and hand may show myriads of petechiae that may be separate or confluent.

The result on the whole arm is *graded* in a crude manner from + to ++++ as follows: +, slight increase over normal; ++, many petechiae over the anterior surface of forearm; +++, multiple petechiae over the whole arm and dorsum of the hand; and ++++ confluent petechiae in all areas of the arm and dorsum of the hand. *It is emphasized that a significant increase in capillary fragility may be missed by the use of a pressure below 100 mm of mercury for only five minutes or a pressure equivalent to 100 mm of mercury when the systolic blood pressure is less than 100.*

The tourniquet test is primarily a measurement of the integrity of the *vascular factors* in hemo-

stasis. The degree of positivity, however, is also a measure of the extravascular factors as well as the factors of clot formation, since blood must leave the vessel if a petechia is to be formed. Once blood escapes from the vessel lumen, factors in the surrounding tissue and within the blood itself come into play. Although an increase in capillary fragility does not permit a specific diagnosis to be made, certain facts are known.

In *scurvy*, there may be marked hemorrhagic diathesis characterized by an extreme increase in capillary fragility with formations of hematomas, apparently related to deficiency of intercellular collagen substance. There is no abnormality of the other special tests, as shown in Table 1. It is particularly noteworthy that the bleeding time is normal in scurvy and that the abnormal capillary fragility disappears in a few days after administration of vitamin C or orange juice.

In "*thrombasthenia*," a disease or group of diseases² of unknown origin, the capillaries have been reported to be abnormal in shape and in contractility; there is usually an increase in capillary fragility, but the number of platelets is normal.² The capillary fragility may be normal or abnormal (Table 1).

In severe *thrombocytopenia* of primary or secondary origin there usually occur bleeding from mucous membranes, purpura, increased capillary fragility, prolonged bleeding time and decreased clot retraction. There is considerable evidence from Macfarlane,² Bedson²⁹ and others that the abnormality of the capillary may result from poor contraction of the capillary, but the relation to thrombocytes is not defined. There is also evidence that the site of petechial hemorrhage is the arterial end of the capillary loop.⁶⁸ Although normally the platelets aid in "plugging" breaks in the capillary, it has been shown that there is a failure of this "plugging" in thrombocytopenic states^{4, 8} and that vasoconstriction of the severed and the adjacent vessels does occur. These observations do not agree with those of Macfarlane.² Although purpura and bleeding from mucous membranes occur in most cases of *severe thrombocytopenia*, there are well established exceptions. For example, after splenectomy there may be a prompt return to normal of the capillary fragility and bleeding time before there is a rise in platelets or during continued thrombocytopenia. In addition, there may be thrombocytopenia with normal capillary resistance and normal bleeding time.

In *allergic purpura* the tourniquet test may be extremely variable, presumably owing to abnormalities of the capillaries but of unknown mechanism. The same reservation is true of the purpura of sepsis.

to be normal or average in polycythemia. A case of hyperglobulinemia has been observed in which the fluid volume was greatly increased even though the level of platelets and amount of fibrinogen were normal.⁷² Thus, clot retraction may be affected not only by platelets but also by decreased fibrinogen, by the number of red blood cells and by elevated plasma proteins.

For the *qualitative method*, clot retraction occurs normally in an hour, forming a small, firm red elastic mass. In abnormal conditions clot retraction may not occur at all in twenty-four hours, or there may be variable degrees of retraction.

Classically in *thrombocytopenia*, with a platelet count below $100 \times 10^3/\text{mm}^3$, there is decreased clot retraction that is roughly proportional to the platelet count. In the semiquantitative method there may be no clot retraction, so that 100 per cent of the fluid volume is retained in the clot (no serum is expressed).

In "*thrombasthenia*" the platelet count is usually normal, but the clot retraction is frequently poor, suggesting abnormal function of the platelets.

In certain cases, as in medical and surgical shock, a so-called fibrinolysin,⁷³ which may obscure clot retraction by actual dissolution of the clot, develops.

Clot retraction is normal in the remaining hemorrhagic diseases (Table 1).

MEASUREMENT OF COAGULATION TIME OF VENOUS BLOOD IN GLASS TUBES — CLOTTING TIME

Theory of Blood Coagulation

Many of the factors concerned in clot formation are as yet poorly understood. Until recently the following fundamental equations of blood coagulation had remained unchanged:

This relatively simple schema was proposed by Morawitz¹⁸ in 1905, and it is recommended that it be used as a framework into which new factors can be fitted.

"*Prothrombin accelerators*" of plasma and serum. Almost simultaneously, from four different laboratories, there have recently appeared descriptions of a substance in plasma that is concerned with the speed of formation of thrombin from prothrombin. In Norway, Owren¹⁹ has designated the substance "Factor V", in Australia it was called "accelerator substance",²⁴ one group in the United States has designated it "plasma accelerator globulin",²⁵ another has called it "labile factor".²⁶ These various terms have led to confusion, and it is still uncertain whether they are designations of the same substance, for clarity in writing, however, they may be grouped into a single term,

"prothrombin accelerators" of plasma. In addition to these "prothrombin accelerators" of plasma, three "prothrombin accelerators" of serum have been described. Owren¹⁹ uses the term Factor VI, Ware and Seegers⁶¹ speak of serum accelerator globulin, and Alexander⁶⁴ terms his substance serum prothrombin conversion accelerator (SPCA). Again, it may be that these three terms designate the same substance, although conclusive evidence of this is lacking. Also, it is likely that the "prothrombin accelerators" of serum are derived from the "prothrombin accelerators" of plasma, much as thrombin of serum is elaborated from prothrombin of plasma. The serum "prothrombin accelerators" are considered to be the active substances accelerating the conversion of prothrombin into thrombin, whereas the plasma "prothrombin accelerators" are relatively inert.⁶¹

There is little doubt that these "prothrombin accelerators" exist, since deficiencies of these components have been described as parahemophilia by Owren²² and plasma accelerator globulin deficiency by Seegers and Craddock.⁵⁹ Although a clinical deficiency of labile factor has not been described as such, Quick and Stefanini⁶⁶ have suggested that the case described by Rhoads and Fitz-Hugh⁵⁷ probably represented such a deficiency.

Platelets in conversion of prothrombin to thrombin. It has been shown by Quick⁶⁵ and confirmed⁶⁰ that platelets are concerned with the total conversion of prothrombin to thrombin, and to a lesser degree with the speed of this reaction.⁶⁰ It has been demonstrated that the thromboplastin in platelets is not responsible for this activity,⁶⁰⁻⁶⁵ which has been described by Quick as "platelet enzyme" or thromboplastinogenase. It is Quick's concept that platelets are necessary for the activation (by an enzyme) of thromboplastinogen to thromboplastin, which in turn, in the presence of calcium, will convert (stoichiometrically) prothrombin to thrombin.⁶⁰

Hypothesis of blood coagulation. To build these new factors into the framework of Morawitz is as yet a theoretical and controversial problem. By a combination of the theories of blood coagulation of Quick⁶⁶ and Ware et al.⁶⁰ it is possible to make a *working hypothesis* for the location of all components.

It has been shown⁶¹ that the plasma "prothrombin accelerators" have essentially no effect on the yield of thrombin produced from a mixture of *purified* prothrombin, thromboplastin and calcium. It is established that the *serum* "prothrombin accelerators" cause a large evolution of thrombin in such a mixture.¹⁹⁻⁶⁰⁻⁶⁴ Therefore, it becomes necessary to show graphically the conversion of the "prothrombin accelerators" of plasma to those of the serum type. Although the mechanism for such conversion has not been clearly shown, it may be

gentle pressure is maintained over the site for five to fifteen minutes after the puncture

The bleeding time is normal in hemorrhagic states in which the only abnormality is increased capillary fragility. Thus, the bleeding time in *scurvy*, *allergic purpura* and *sepsis* is normal even though the tourniquet test is positive

PLATELET COUNT

The finding of thrombocytopenia does not permit an etiologic diagnosis to be made. The diagnosis of so-called idiopathic thrombocytopenia (purpura hemorrhagica) is made largely by the exclusion of conditions known to produce secondary thrombocytopenia. The role of thrombocytopenia in hemorrhagic diathesis can only be defined, in part, as pointed out above. Thrombocytopenia does not usually produce a prolongation of coagulation time as measured by the usual technic in glass, but definite prolongation of coagulation is easily demonstrable in glassware coated with silicone (Dri-film)⁷³

The blood platelet has also been shown to be an important factor in blood coagulation as indicated by its effect on the conversion of prothrombin to thrombin,*⁶⁶ since the lower the platelet count, the poorer this conversion. In addition to the disturbed coagulation (in silicone-coated glass) in thrombocytopenia, there is always associated *poor clot retraction*⁶⁶. The defects in coagulation (poor clot retraction, and decrease in adhesiveness, in rigidity and in contractility) may be factors, associated with the failure to form platelet plugs, that explain in part the bleeding tendency in thrombocytopenia

CLOT RETRACTION

Principle

Venous blood, containing all the factors necessary for coagulation and possessing no coagulation inhibitors, will clot spontaneously when placed in glass tubes. The clot when formed is usually a homogeneous suspension of red cells in plasma. Occasionally, if the red cells sediment rapidly or if coagulation is greatly prolonged, the clot will have an upper layer containing fibrin but no red cells and a lower layer of red clot. In either event, when the clot stands the fibrin contracts, expressing serum from the clot. This process is described as clot retraction or syneresis. In general, the correlation between poor clot retraction and thrombocytopenia is so close that an observed decrease in clot retraction may be a more reliable index of thrombocytopenia than the platelet count itself. As a corollary, a normal degree of clot retraction is good evidence that the platelet count is approximately $100 \times 10^3/\text{mm}^3$ or more. The relation of

platelet function to clot retraction is not well understood

Methods

Qualitative methods Clot retraction can be measured qualitatively by inspection as follows. 2 cc of blood is obtained by venipuncture during the coagulation test, as described below. The tube is placed in a water bath at 37.5°C and observed after half an hour and one, two, four and twenty-four hours for signs of retraction—namely, the separation of the clot with expression of serum. The clot may stick to the wall of the tube and require gentle separation if retraction has not occurred within an hour. This is done by gentle rimming of the top of the clot with a platinum wire or wooden applicator.

Semiquantitative method *Fluid volume of the clot* A semiquantitative method has been described by Macfarlane⁷⁴ and modified slightly by Aggeler, Lucia and Hamlin⁷⁵ and others^{76, 77}. In this method 5 cc of venous blood is introduced into a 15-cc graduated centrifuge tube. A cork fitted with a copper wire bent in the form of a hook is adjusted so that the hook is immersed in the upper layers of the blood. The tube is placed in a water bath at 37.5°C, and the coagulation time noted. One hour after coagulation the total volume (T) of the specimen is recorded and the retracted clot is removed by means of the hook. The residual volume of serum (S) is recorded, and the volume occupied by the clot (C) is taken to be $T - S$. The hematocrit is determined, in the usual manner on another portion of the blood sample, and the total corpuscular volume percentage (PCV) of formed elements is read, including the layers of white cells and of platelets. To calculate the fluid volume FV *occluded within the clot*, in percentage, the following expression is used: $\text{FV (percentage)} = [(C/T) \times 100] - \text{PCV}$. The normal range is reported as 6 to 20 per cent,⁶⁹ with a mean of 8 per cent.

Limitations and Interpretations

It is known that platelets are directly concerned with clot retraction so that good clot retraction is usually associated with normal platelet counts. However, there are various degrees of clot retraction as evidenced by moderate retraction of the clot with platelet counts of 35,000 to 40,000.⁶⁶ Other factors may influence the appearance of the clot in retraction. A reduction in fibrinogen results in the formation of a small clot that gives the false impression of normal clot retraction. Similarly, a reduction of erythrocytes, as in anemia, gives a false impression of normal clot retraction. Conversely, in polycythemia there appears to be poor clot retraction as shown by the qualitative method since the clot is large and the serum small in volume. By the use of the semiquantitative method, the volume percentage of entrapped serum is found

*Prothrombin consumption

introduction of tissue fluid from a traumatic venipuncture, agitation of the blood by rapid passage through the needle, introduction of air bubbles or traumatic transfer of blood to the test tubes and unclean or rough glassware. Prolongation of the coagulation time may occur as a result of the following variations in technic: unduly low or high pH, unduly low or high temperatures and the use of plastic tubes or tubes coated with paraffin or nonwetable plastics (silicone-Dri-film). In view of these facts it is quite important to carry out the test at controlled temperature, pH, and calcium concentration and with techniques that avoid trauma in the venipuncture, the introduction of air bubbles and unduly rough treatment of the blood obtained. The time for coagulation to occur is a purely relative test and does not indicate that complete coagulation has occurred for the whole column of blood. It is simply a measure of the time required for the formation of fibrin at the air interface in quantity sufficient to support the column of blood when the tube is inverted.

The coagulation time of whole blood is prolonged notably in *hemophilia* and after administration of *heparin*, varying from fifteen minutes to several hours. In general, the degree of elevation of the coagulation time is a function of the severity of the disease in hemophilia and of the effect of heparinemia. On the other hand, it has been noted that hemophilic patients with greatly prolonged coagulation times may have fewer hemorrhagic episodes than others with only slight prolongation of the coagulation time. The coagulation time of blood of a given hemophilic patient remains remarkably constant except when altered therapeutically.

In severe cases of *hypoprothrombinemia*, the coagulation time is also prolonged, but this test is unreliable as an index of prothrombin deficiency, since an increase in coagulation time is a late manifestation and indicates an extremely low and dangerous level of prothrombin, 5 per cent or less.⁴⁴ Only small amounts of prothrombin are necessary for the formation of thrombin and the subsequent fibrin formation that results in visible coagulation of blood. Accordingly, the coagulation time cannot be used with safety in following the course of hypoprothrombinemia resulting from Dicumarol therapy.

Prolongation of coagulation time is observed in *fibrinogenopenia* and completely incoagulable blood is encountered in absolute *afibrinogenemia*, whether congenital or acquired. The latter may be due to large amounts of fibrinolytic, as in shock.

Prolonged coagulation time is also encountered in *parahemophilia*⁵³ (Owren's disease), being due, in this instance, to a deficiency of the so-called "Factor V" of Owren.

The finding of prolongation of the clotting time is nonspecific information since it does not of itself indicate the presence of hemophilia, the absence

of fibrinogen, a deficiency of a "prothrombin accelerator" or the effect of heparinemia. As mentioned above, the coagulation time in hemophilia may be restored toward normal after treatment at a time when the patient is showing active hemorrhage.

If the test is carried out in glass tubes, a decrease in coagulation time below six minutes has no reliable clinical value as a measure of increased coagulability of blood, such as may occur in certain diseases with abnormal tendency to thrombosis. Strictly, the coagulation time should be used only in relation to plasma coagulation defects and coagulation inhibitors such as heparin.

(To be concluded)

as suggested by Ware and Seegers,⁶¹ that thrombin plays a part in this reaction as follows

Prothrombin + Thromboplastin + Calcium → Thrombin
 Thrombin (?) + Plasma "prothrombin accelerators" →
 Serum "prothrombin accelerators"
 Prothrombin + Serum "prothrombin accelerators" → Thrombin
 Thrombin + Fibrinogen → Fibrin

Since Quick⁶⁶ has shown *platelets* to be important in this reaction, it is possible to eliminate the one weak point of the foregoing theory — namely, that purified prothrombin, tissue thromboplastin and calcium form little or no thrombin.^{19 61} With the "platelet enzyme" activating plasma thromboplastinogen, there results augmentation of thrombin formation as follows

"Platelet enzyme" + Thromboplastinogen → Thromboplastin
 Prothrombin + Thromboplastin + Calcium → Thrombin

The next step then involves conversion of the plasma "prothrombin accelerators" to the active serum "prothrombin accelerators" by thrombin. Thus, the theoretical steps in the coagulation of blood can be combined into a *working hypothesis*, involving the following five steps

"Platelet enzyme" + Thromboplastinogen → Thromboplastin
 Thromboplastin + Prothrombin + Calcium → Thrombin
 Plasma "prothrombin accelerators" + Thrombin (?) →
 Serum "prothrombin accelerators"
 Prothrombin + Serum "prothrombin accelerators" → Thrombin
 Thrombin + Fibrinogen → Fibrin

With this concept one can endeavor to interpret abnormalities in the various laboratory tests that utilize the coagulation of blood or plasma as an end point

Coagulation Time of Venous Blood

Principle When unaltered venous blood, obtained by a nontraumatic venipuncture, is introduced into glass tubes the time required for clotting to occur is called the coagulation time or clotting time. This is a highly arbitrary biologic procedure since the glass surface and many other factors affect the coagulation time significantly. For example, normal blood collected in tubes made of a plastic, or tubes coated with paraffin or nonwetting agents such as silicone, requires a significantly longer time to clot (thirty to sixty minutes) than in glass tubes (six to twelve minutes). The temperature of shed blood profoundly affects the clotting time, as evidenced by the extreme prolongation (one to four hours) at a temperature of 3°C

as opposed to the relatively rapid clotting (six to twelve minutes) occurring at body temperature. Technically, the modified⁸ Lee-White method for measurement of blood coagulation time is probably as reliable a procedure as is available currently. It should be remembered, however, that coagulation times obtained by this method are purely relative, and that the method is of value primarily as a screening procedure in an effort to determine plasma coagulation defects and anticoagulant activity. *The method of measurement of the coagulation time by the use of capillary blood drawn into a capillary tube is so unreliable as to be valueless, it should not be used*

Method (modified Lee-White method) A sterile 5-cc syringe and sterile needle are rinsed twice with sterile physiologic saline solution, and all the solution is expelled. A venipuncture is performed with the least possible stasis and trauma. The tourniquet is applied just before the venipuncture is made. Traction on the plunger of the syringe — if used at all — should be gentle, to prevent agitation of the blood and to avoid the entry of air bubbles into the syringe as the sample is drawn. If the vein is not entered on the first attempt, the needle and syringe should be discarded,* and another sterile syringe and needle, rinsed twice with sterile saline solution, employed. A sample of 5 cc of blood is obtained, the needle is removed from the syringe, and 2-cc samples of blood are placed in each of two chemically clean test tubes (13 by 100 mm) that have been previously rinsed twice with physiologic saline solution. The blood should be made to run down the side of the tube *gently* to avoid agitation. The remaining 1 cc of blood in the syringe is discarded since it contains unavoidable traces of tissue juices.* The two tubes are placed in a water bath at 37.5°C, and at intervals of approximately a minute one of the tubes is observed for clotting by removal from the bath and gentle tilting. The end point of coagulation is reached when the tube can be inverted without loss of contents. When this occurs for the first tube, the second is observed in a similar manner, until coagulation occurs in it. The beginning of the test is the time when blood first enters the syringe. The average time, in minutes, required for blood to clot in the two tubes is reported as the coagulation or clotting time. If there is a difference of more than five minutes between the coagulation times of the two tubes, the longer time is reported. This is commonly found in hemophilia.

Limitations and interpretations The normal range (100 subjects) is from four to twelve minutes, with a mean of seven and seven-tenths minutes and a standard deviation of one and seven-tenths minutes.³⁹ Most errors in technic will tend to *shorten* the coagulation time, such errors include

*The tissue juices contaminating the needle and syringe from an unsuccessful venipuncture will decrease the coagulation time

CASE 35441

PRESENTATION OF CASE

A seventy-two-year-old Finnish-born married steel worker entered the hospital with a chief complaint of "severe" shortness of breath.

Two years before entry the patient was told that he had an "irregular" heart but successfully discharged his duties as a steel worker until eleven months before entry, when he tripped and fell 20 feet while on the job and injured the left seventh, eighth and ninth ribs anteriorly and his left hand. Radiograms of the chest were reported as not remarkable except for the rib fractures. After spending twelve days in two other hospitals he returned home but not to his job. The patient dated the beginning of his dyspnea as shortly after this accident. About nine months before admission vague precordial pain, described by the patient as "constriction" and "congestion," appeared especially after exertion but frequently at night. This discomfort lasted usually about five minutes but occasionally much longer and did not always disappear with rest. No radiation of pain to the shoulders or arms was ever present. The dyspnea temporarily improved three and a half months before entry so that he was content to take care of his flock of turkeys and do other small jobs. However, his dyspnea recurred in the next month, and he was denied even these minor pleasures, being unable to walk short distances without excessive fatigue. A slight cough productive of small amounts of whitish sputum appeared. About five weeks before entry he developed hay fever (which he had experienced in the past) and noted more difficulty sleeping at night, requiring two pillows to sleep comfortably. One month before entry he noted an increase in his anorexia, which he believed had been present since his accident. He further noted a weight loss of about 20 pounds in the last five or six months.

He visited the Medical Clinic of the Out Patient Department one month before admission, and an additional history was obtained of exposure to tuberculosis, a daughter had the disease several years previously and a sister-in-law was similarly afflicted thirty years before. Examination at this time revealed a blood pressure of 150 systolic, 90 diastolic, a pulse rate of 80, with 8 to 10 skipped beats at the wrist per minute, and a Grade II apical systolic murmur and auricular fibrillation, no definite cardiac enlargement was noted. The temperature was 97°F, and the respiratory rate 20. The lungs were resonant, and basilar rales cleared on coughing. A firm,

FIGURE 1

nontender right supraclavicular node (1.5 cm in diameter) was noted. Abdominal and rectal examinations were not remarkable. A blood Hinton test was negative. Urinalysis was negative. Radiograms of the chest revealed an enlarged heart (Fig 1) with a cardiothoracic ratio of 18/25, the enlargement appearing predominantly in the region of the left ventricle. The lung fields exhibited extensive, diffuse, linear and mottled densities, particularly in the middle and lower portions. The hilar vascular shadows were poorly seen but appeared somewhat enlarged. The patient was digitalized and given nitroglycerin.

Two weeks before entry he was again seen in the Medical Clinic, at which time his blood pressure was 130 systolic, 80 diastolic, and the pulse and breath

DR BRAILEY Could the shadows in the lung be tuberculosis?

DR McCORT There is no evidence of cavitation or calcification to indicate tuberculosis

DR BRAILEY Do you think the shadows are due to embolization?

DR McCORT Multiple small emboli could produce similar nodular densities, but there are strand-like densities in addition to nodules

DR BRAILEY Have you ever seen metastatic carcinoma present this kind of picture?

DR McCORT A small percentage of metastatic carcinomas show a lymphatic permeation that is compatible with this picture

DR BRAILEY There is no interference with the bronchi as far as you can see—no obstruction?

DR McCORT There is no narrowing or obstruction of the bronchi

DR BRAILEY This man was said to have an "irregular" heart for two years. We may assume that it was fibrillating for at least that long. The heart was really enlarged, he had a Grade II systolic murmur, and an abnormal electrocardiogram. The tracing was not inconsistent with infarction, nor was it inconsistent with left ventricular strain and digitalis effect. Would you agree with that, Dr Bland?

DR BLAND It sounds like an aging heart to me—a nonspecific electrocardiogram, showing the effect of digitalis, I would think.

DR BRAILEY What was the nature of the defect? Did he have rheumatic heart disease? Somewhat in favor of that diagnosis is the long-standing fibrillation. But patients with rheumatic heart disease rarely live to seventy-two years of age and no diastolic rumble was ever described. It does not seem reasonable to consider rheumatic heart disease here.

Did he have hypertensive and arteriosclerotic heart disease? The blood pressure was repeatedly reported as normal. If he had had hypertension in the past of sufficient degree and duration to result in a heart of this size, surely he would have been in severe congestive failure when the blood pressure fell to this level. But the evidence for congestive failure is not very impressive, even two weeks before he came into the hospital. He had marked dyspnea, to be sure, about which we will say more later, but he had no peripheral edema. The liver was not thought to be enlarged, and only transient rales were heard in the chest.

What else might reduce his hypertension other than heart failure? A failure of the adrenal cortex might do so. To be sure, little was said of fatigability, and there were no pigmentary changes recorded. But we wonder a bit about the adrenal glands because we are tantalized by the information that he was exposed to tuberculosis and the serum sodium was remarkably low, perhaps because he was on a low-sodium diet. He had not had it long, however.

Perhaps coronary-artery disease without a large infarct but with widespread microscopic scarring of the myocardium, was a factor here. The electrocardiogram would not be inconsistent with this possibility. He is said to have had ill described pain, which may have been angina and was probably considered as such since he was given nitroglycerin.

The dyspnea troubled him greatly and certainly troubles me. There are many causes for dyspnea, but if we confine ourselves to those that occur in the chest, they can be roughly divided into pulmonary and cardiovascular. Of the vascular causes, disease on the arterial side of the pulmonary circuit should have resulted in cor pulmonale. He had a tremendous heart, and the right ventricle and right auricle were enlarged. I am not at all sure that he did not have cor pulmonale. He had little evidence of peripheral right-sided heart failure until the last few days of life. Trouble on the venous side of the pulmonary circuit should have resulted in pulmonary edema, of which we have little or no evidence. We are struck by the curious lack of parallelism between his increasing dyspnea and his apparent cardiac performance as reported. It seems certain that he did not have enough cardiac failure per se to account for a vital capacity of 900 cc and that he must have had some pulmonary disease as well. He undoubtedly had some senile emphysema, but I think this picture presented by his x-ray films is very curious and I suspect that he had something else—either embolization with marked widespread fine scarring of the lungs, or an endarteritis.

The evidence for cancer consists of hard nodules, which may have been metastatic supraclavicular lymph nodes, and two gastric washings containing tumor cells. Where shall we put this malignant lesion, which must have been either exfoliating or ulcerating? Is it fair to ask if these cells were epithelial in type?

DR TRACY B MALLORY They were interpreted as that.

DR BRAILEY The obvious answer is carcinoma of the stomach, but if we plump for carcinoma of the stomach, we have to make the diagnosis in the face of normal gastric acidity, a not impossible situation but nevertheless rare. The sputum contained no tumor cells on one examination. That does not exclude tumor of the lung. The patient had a productive cough, and it was noted that he swallowed most of his sputum. I do not see why he might not have swallowed the cells for that matter although we do not usually look for carcinoma of the bronchus by doing gastric washings. Metastatic pituitary glands in the neck occur secondary to carcinoma of the stomach, but they are even more commonly found secondary to bronchial disease. It is possible that we shall find no explanation for the low serum sodium. It was probably the result of the low-sodium diet or the edema. But if he did have damage in the adrenal glands by any chance, it is possible that they were

sounds were essentially unchanged. Very shortly thereafter the dyspnea rapidly increased, three or four pillows being required at night. Five days preceding entry the dyspnea became so severe that virtually no sleep was obtainable, the patient having to sit in a chair or upright in bed to facilitate easy breathing. The next day he developed ankle edema, which gradually increased.

Physical examination on admission revealed a well developed, well nourished, somewhat apprehensive but co-operative man with extraordinary dyspnea, coughing frequently and usually swallowing the sputum. Cyanosis of the lips, fingers and mucous membranes was present. Bilateral distention of the neck veins, slightly more marked on the left, was evident in the upright position. A few small, hard nodes were present in each supraclavicular region. The chest was moderately emphysematous, and dullness was present on the right posteriorly and in the axilla to the angle of the scapula, with decreased breath and spoken voice sounds, dry rales were present in the right chest above the area of dullness, but no rales were noted on the left. The notable cardiac signs were a maximal impulse of the heart 11 cm. to the left of the midsternal line in the lower fifth interspace, auricular fibrillation with a 10-beat pulse deficit, some occasional bigeminy, and a short apical systolic murmur. Moderate ankle and slight to moderate sacral edema was present.

The temperature was 97°F, the pulse 80, and the respirations 32. The blood pressure was 135 systolic, 90 diastolic.

Investigative studies revealed a circulation time (Decholin) of 50 seconds, a venous pressure equivalent to 222 mm. of water and a vital capacity of 900 cc. Examination of the blood disclosed a red-cell count of 5,100,000, with a hemoglobin of 14.5 gm., and a white-cell count of 9550, with 80 per cent neutrophils. The prothrombin time was 19 seconds (normal, 15 seconds). The nonprotein nitrogen was 28 mg., the blood sugar 96 mg., and the total protein 5.9 gm. per 100 cc., and the sodium 127.8 milliequiv., the chloride 92 milliequiv. and the carbon dioxide 22.7 milliequiv. per liter, the alkaline phosphatase was 4.6 units per 100 cc. The phenol-sulfonephthalein test showed 62 per cent excretion of the dye, and the bromsulfalein test 64 per cent retention of the dye. The gastric acidity was in the normal range. Sputum smears were negative for acid-fast organisms and abnormal cells. Two separate gastric washings were positive for tumor cells and gave a ++++ guaiac reaction. The stools were consistently guaiac positive. Urinalysis was not remarkable, the urinary sodium chloride was 1 or 2 gm. per 24 hours. An electrocardiogram revealed auricular fibrillation, low voltage, sagging ST segments in Lead 1 and 2 and AVL and V₆, and inverted T waves in Lead 1 and 2 and AVL and V₆ and V₆.

Radiographic studies demonstrated very little change in the chest since the previous examination. A roentgenogram of the abdomen was marred by the dyspnea, the only discernible visceral outline being that of the liver, which was at the upper limits of normal, some air was present in the large bowel, and little or none in the small bowel. A gastrointestinal series was attempted but was incomplete and unsatisfactory because of the patient's extreme illness, however, the midportion of the posterior wall of the stomach appeared to be rather straight, and the duodenal bulb was deformed. X-ray films of the bones were normal.

The patient was placed on a cardiac regime, including digitoxin, ammonium chloride, Sodium Amytal, Mercuhydrin, a diet moderately low in sodium, and other supportive therapy. Despite these measures he continued to be critically ill and died on the sixth hospital day.

DIFFERENTIAL DIAGNOSIS

DR ALLEN G BRAILEY* It is hard to know what to take up first when one is confronted with this welter of signs and symptoms. We might begin by seeing the x-ray films.

DR JAMES J McCORT On the initial chest examination the strand-like and coarse and finely nodular increase in density in both lungs is well seen. These changes extend outward from the hilus to the periphery and involve the greater portion of both lungs. There is no fluid in either costophrenic sinus. The heart is markedly enlarged to the left and right (Fig 1), and there is definite fullness anteriorly, suggesting right ventricular enlargement. A widening of the hilar shadows is seen, suggesting dilatation of the main pulmonary arteries. A film of the chest made one month after the first examination shows very little change except possibly a small amount of fluid in the right costophrenic sinus.

Examination of the gastrointestinal tract was unsatisfactory because of the severe dyspnea. The esophagus was normal. On one film a flattening of the posterior wall of the stomach near the lesser curvature is demonstrated. There is also a slight constriction of the duodenal cap and a small diverticulum of the second portion of the duodenum.

DR EDWARD F BLAND Are the bones all right?

DR McCORT The skull and long bones were not abnormal.

DR BRAILEY What about the possibility of a pathologic fracture two years before admission?

DR McCORT I can see no evidence of it.

DR BRAILEY There is enlargement of the heart. Is it mostly right or left ventricle? The protocol says "left."

DR McCORT It is impossible to determine which ventricle is larger. There is definite right ventricular enlargement.

*Assistant physician, Massachusetts General Hospital.

chest, increasing on deep inspiration. The pain persisted for several weeks and then slowly subsided. There was no cough, sputum, hemoptysis, nausea, vomiting or weight loss. Three weeks before admission while in Canada on a vacation, she consulted a physician. After fluoroscopic examination she was told that she had pleurisy. She received pills for pain and returned home. Since then she was up and around doing housework. During the year before admission she noted a lump in the suprapubic region that swelled intermittently.

At the age of eighteen she had "wet pleurisy" on the right side and was treated at home by a homeopathic physician. Her father and mother were alive and well. Two of nine siblings had died of tuberculosis, but the patient had had no contact with them. An aunt and cousin had died of cancer.

Physical examination showed a well developed, well nourished woman who looked quite healthy. Her lungs were clear to percussion and auscultation. She took deep breaths without apparent difficulty. There was no pain over the ribs. The heart showed a normal sinus rhythm, and no murmurs were heard. Abdominal examination showed no spasm or tenderness. A large, irregular suprapubic mass was present. Pelvic examination confirmed this mass in the posterior cul-de-sac, which extended down to the posterior rim of the cervix. The cervix was not fixed but showed erosions about the external os.

The temperature, pulse and respirations were normal. The blood pressure was 128 systolic, 88 diastolic.

The white-cell count was 7800, and the hemoglobin 12.5 gm. The urine was normal. Cytologic examination of vaginal smears was negative. A chest x-ray film showed scars, a number of which were calcified, in the right upper lobe and to a lesser extent in the left upper lobe. The heart and aorta were not unusual. The nonprotein nitrogen was 19 mg, and the total protein 6.0 gm per 100 cc.

An operation was performed.

DIFFERENTIAL DIAGNOSIS

DR EDWARD HAMLIN JR * How long a period was there between the Out-Patient Department visit and the House admission? It is not clearly stated.

DR BENJAMIN CASTLEMAN A period of one week.

DR HAMLIN On receiving this protocol in the mail and after reading it over, I wondered what I was expected to say. It seemed that in all probability some information was being withheld because so little was being presented.

DR CASTLEMAN Nothing is supposed to be withheld.

DR HAMLIN That is what they always say.

The problem, it seems to me, and I may be wrong, but this is the way I looked at it is to try to correlate the large suprapubic mass, without any other

adjective attached, with the pain in the right chest. I think it is somewhat difficult. Dr Hanelin, can you help me?

DR JOSEPH HANELIN I doubt it very much.

DR HAMLIN You are my last hope.

DR HANELIN The chest film shows old areas of scarring in both upper lung fields. The left and right costophrenic sulci are clear. There is faint increased density at the right base, which may be due to old pleural thickening.

DR HAMLIN Is there any fluid?

DR HANELIN No.

DR HAMLIN We have to cling to straws. I do not think there is much value in discussing what a large irregular mass, felt suprapubically and in the posterior cul-de-sac, might be, because as far as I am concerned at the moment it could be anything. There is only one item that, if true, might be of some help (otherwise, fibroids would be far and away the most likely diagnosis) that is the statement made by the patient that the mass "swelled intermittently." It is not carefully stated what relation this had to the uterus.

DR CASTLEMAN Do you know, Dr Sturgis?

DR SOMERS STURGIS No.

DR HAMLIN Therefore, the field is wide open. We can guess about anything we want to. There is nothing outside the realm of possibility. It need not have anything to do with the pelvic organs. Let us look at it from the point of view of trying to correlate the pain in the chest with a mass in the pelvis. We immediately think of Meigs-Cass syndrome†. That, of course, involves ascites and pleural fluid, but neither, apparently, was present here.

The next thing one thinks of is a pulmonary infarct. Infarct could clear up in this period. It is possible that the patient would have had an infarct to account for the pain in the chest, but that does not help a bit.

DR CASTLEMAN Excuse me, Dr Hamlin, I have just found a little more information.

DR HAMLIN I thought there would be.

DR CASTLEMAN The record states "On bimanual pelvic examination the lesion seems to incorporate the uterus and movement of the mass is transmitted to the cervix."

DR HAMLIN Reward for being overcautious! We then think of metastases. There is no x-ray evidence of metastases. Metastases to lung or pleura, I think, we can ignore for lack of evidence. I want very much to work in perihepatitis. I took occasion to look up perihepatitis in relation to pelvic disease but could not find anything about it, although it certainly was taught when I was a house officer that it was common in association with salpingitis and we certainly do see many cases accompanied by a perihepatitis. It may simulate gall-bladder disease on occasion and produce the typical

knocked out by metastatic carcinoma — a rather frequent event in carcinoma of the bronchus

On the whole it seems to me that the odds are in favor of the tumor's being in the stomach, and I have not got the courage to put it anywhere else in the face of positive gastric washings. I have raised a number of questions that I cannot answer intelligently, but since I have to take a stand of some sort I will say that this man had arteriosclerotic heart disease and cor pulmonale, probably on the basis of many small emboli, and carcinoma of the stomach with metastases

DR ALFRED KRANES I wonder if the pulmonary metastases may not have been tumor emboli, and if that was so, I think it is not impossible that carcinoma of the pancreas might produce that picture

DR BRAILEY I should have mentioned that, but tumor emboli occur in carcinoma of the stomach too

DR KRANES But much less commonly, I believe

DR BRAILEY That is right

DR BLAND Does carcinoma of the bronchus frequently metastasize to the supraclavicular lymph nodes?

DR DONALD S KING Quite commonly

DR MALLORY Dr Warthin, I believe you were interested in this case

DR THOMAS WARTHIN I saw this patient in the Out Patient Department and was struck by the fact that he had heart disease basically. He definitely had abnormal lymph nodes, one of which was characteristic of the Virchow type associated with carcinoma of the stomach. Now seeing the x-ray films, which I had not seen before, I consider them typical of lymphogenous spread of carcinoma of the stomach, such as has been described by Mueller and Sniffen* from this hospital

DR BLAND Would sarcoid cause this picture in the lung?

DR KING It could, my opinion is that this was not sarcoid

Generalized thrombosis of small pulmonary arteries Cor pulmonale

PATHOLOGICAL DISCUSSION

DR MALLORY Autopsy showed that this man had a cor pulmonale. The wall of the right ventricle measured 7 mm in thickness, the left ventricle was normal. The lungs showed diffuse involvement of all the lymphatics with tumor. In a search for the source of the tumor an ulcerated lesion was found in the stomach. A large mass of tumor was found in the region of the pancreas, which at the time of autopsy was interpreted as lymph nodes surrounding the pancreas rather than a primary tumor of the pancreas itself. The subsequent microscopical examination showed that the acinar cells of the pancreas were totally replaced by tumor from end to end of the organ, and I believe that was the primary site. Invasion of the stomach was secondary, but since the secondary tumor had ulcerated into the lumen there is no reason why tumor cells should not be found in the gastric washings. On microscopical examination of the lungs it became evident that nearly all the arteries were surrounded by dilated lymphatics filled with tumor cells and that the majority of them also contained organized thrombi. In only a small number of vessels were tumor cells present within the intra-arterial thrombi, so that tumor embolism was unimportant.

There is no way that I can say from the anatomical findings whether the arterial thromboses, which were old enough to be completely organized, were independent of the carcinoma or secondary to it. I am inclined to think it was secondary, but I cannot prove the point.

DR KRANES Did you find thrombosis present in the areas where there was no tumor, or was it so widespread that you could not tell?

DR MALLORY The thrombosis was limited to small vessels, and virtually all of them were surrounded by tumor.

DR BLAND What we saw in the x-ray films was the lymphatic system of the lungs?

DR MALLORY Pulmonary lymphatics in normal conditions are so collapsed that they are scarcely visible. In this lung an artery was surrounded by four or five lymphatics, each so distended with tumor as to be of diameter equal to that of the artery.

CASE 35442

PRESENTATION OF CASE

A forty-six-year-old housewife was seen in the Out Patient Department complaining of pain under the right breast.

She was perfectly well until one month before admission, when after a particularly hard day's work a "catching" pain appeared in the right side of the

chest, increasing on deep inspiration. The pain persisted for several weeks and then slowly subsided. There was no cough, sputum, hemoptysis, nausea, vomiting or weight loss. Three weeks before admission, while in Canada on a vacation, she consulted a physician. After fluoroscopic examination she was told that she had pleurisy. She received pills for pain and returned home. Since then she was up and around doing housework. During the year before admission she noted a lump in the suprapubic region that swelled intermittently.

At the age of eighteen she had "wet pleurisy" on the right side and was treated at home by a homeopathic physician. Her father and mother were alive and well. Two of nine siblings had died of tuberculosis, but the patient had had no contact with them. An aunt and cousin had died of cancer.

Physical examination showed a well developed, well nourished woman who looked quite healthy. Her lungs were clear to percussion and auscultation. She took deep breaths without apparent difficulty. There was no pain over the ribs. The heart showed a normal sinus rhythm, and no murmurs were heard. Abdominal examination showed no spasm or tenderness. A large, irregular suprapubic mass was present. Pelvic examination confirmed this mass in the posterior cul-de-sac, which extended down to the posterior rim of the cervix. THE CONTINUING CHALLENGE OF PULMONARY EMBOLISM

AFTER World War I it was noted that post-operative pulmonary embolism was on the increase. To be sure, some of this was only apparent because of the better recognition of the condition both clinically and post mortem. An actual increase was, however, accepted and was variously ascribed to exhaustion and poor health resulting from the war, to the increasing age of patients subjected to surgery, and to the bolder operative procedures that improvement in anesthesia and surgical technics made possible in patients who would previously have been considered poor risks. It is quite probable that the last two factors as well as better recognition of the condition by internist, surgeon and pathologist alike accounted for the increasing awareness of this threat. The same reasons may still apply today,

as well as others not yet defined favoring an increased amount of thromboembolic disease.

As time went on it also became obvious that pulmonary embolism was much more common in medical patients than had been thought this important complication had been previously in many cases called something else, in particular hypostatic pneumonia or pulmonary edema due to heart failure.

Thus it was only natural that during the last decade vigorous action should have been taken to try to prevent pulmonary embolism which was often fatal after serious surgical operations and which was also one of the commonest causes of death in cases of chronic cardiac disease. Various measures were introduced to curb the threat. Two of the simplest and perhaps the best have been early mobilization after surgery and the use of penicillin to help to make such mobilization possible. Stasis favoring thrombosis in the leg veins, the commonest cause of pulmonary embolism was thus minimized. Also efforts were made to reduce pressures and positions causing stasis during surgical operations themselves and to ease the strain of bowel movements, to reduce "bedpan death."

Two special measures, which were widely introduced to limit the hazard of pulmonary embolism and which have had their vigorous proponents, have been the use of anticoagulants and ligation of the femoral veins both as prophylaxis and as treatment. Statistics have been presented to indicate the value of both methods in a more or less parallel fashion, and many individual cases have been known and some reported in which the institution of either or both of these therapies has apparently been life saving. But there have been failures, too, often not so distinctly delineated.

In the present issue of the *Journal* an interesting and important experience of the Department of Pathology of the Massachusetts General Hospital is presented. Despite the institution of the measures cited above during the five-year period from 1943 to 1947 inclusive, there was a definite increase in the notation of fatal pulmonary embolism found at autopsy over that in two previous five-year periods, 1931 to 1935 inclusive, and 1936 to 1940 inclusive (442 per cent of 2083 autopsies in 1943

violin-string type of adhesions That would be a tempting choice here except that it is extremely hard to envisage a salpingitis as large as this mass apparently was It is possible certainly, although I have never seen a pelvic mass as large as this due entirely to salpingitis

We come to the other straw here—namely, a great deal of talk that makes one think of tuberculosis, which is mentioned in the past history and which did not have to be mentioned Two siblings had tuberculosis, and it would seem that that at least is something we should try to work together I do not pretend to know very much about pulmonary tuberculosis The patient certainly had old scarring in the lungs It would seem to me that if she had tuberculous pleurisy on this occasion, it had cleared up very rapidly It is possible that she had mild pleurisy associated with it

How would that fit with the pelvic mass? Tuberculosis of the pelvis is not uncommon in relation to tuberculous salpingitis and endometritis, but again a mass of this size would seem quite unusual This would be easy if we could put in one or two other diagnoses such as concomitant fibroids

One thing that occurs to me is a cold abscess It seems unlikely, but it interests me a good deal I do not know why I thought of cold abscess in this case I have not seen one for a long, long time The fact that this mass varied in size and perhaps the description that Dr Castleman just gave—the uterus being incorporated in the mass—suggest a large cold abscess filling the cul-de-sac and emerging suprapubically

I do not like to bet very heavily on any of the possibilities I have mentioned I am sure there are plenty of others, but since one has to go out on a limb, I may as well make it a long limb and say that this woman had a tuberculous abscess

DR CASTLEMAN Does anyone else want to go out on a longer limb?

DR STURGIS Could Dr Hamlin amplify the statement about intermittent swelling?

DR HAMLIN I simply mentioned that in thinking of a cystic mass instead of a solid mass We have no description to indicate that it was cystic or solid I carefully did not ask for that because I did not want to hear that it was solid

DR STURGIS Is there any chance of digging out anything from the record in reference to the menstrual cycle? I wonder if endometriosis might come in as a vague possibility

DR HAMLIN It certainly could I think the fact that any reference to the menstrual cycle was carefully omitted made me ignore that possibility

DR CASTLEMAN I note in the record that the patient stated that the mass seemed to swell and become tender with her menstrual periods

DR HAMLIN I believe you can see the justification for my remarks when I began

DR ALLEN G BRAILEY Would Dr Hamlin consider Meigs-Cass disease?

DR HAMLIN I did and discarded it because of lack of described ascites

DR JACOB LERMAN Does the fluid in Meigs-Cass syndrome disappear rapidly?

DR CASTLEMAN The Meigs-Cass syndrome is a condition in which a fibroma of the ovary is associated with ascites and pleural fluid Some years ago Drs Meigs and Cass reported a group of these cases The pleural fluid does not reaccumulate after the ovarian tumor has been removed, I believe it is resorbed so slowly that, in most cases, it is removed by paracentesis

CLINICAL DIAGNOSIS

Fibroid uterus

DR HAMLIN'S DIAGNOSIS

Tuberculous abscess of pelvis

ANATOMICAL DIAGNOSES

Tuberculous salpingitis, endometritis, and peritonitis

Leiomyomas of uterus

PATHOLOGICAL DISCUSSION

DR CASTLEMAN Dr Hamlin's limb was pretty good, in spite of all the handicaps, unintentional as they were The large mass that was felt was the ordinary leiomyomatous uterus, but associated with it, on the serosal surface of the uterus, as well as on the tubes, ovaries and peritoneum, were very small, grayish nodules At the time of operation the surgeon thought they might possibly be carcinomatous Our microscopical sections proved that they were all tuberculous and that this patient had tuberculous salpingitis, endometritis and peritonitis, the peritonitis being present all over the pelvic cavity as well as on the surface of the appendix It is quite possible, although it was not explored, that she had a perihepatitis as a result of salpingitis The surgeon removed the uterus and both tubes but left the ovaries The tuberculosis appeared quite active, and I imagine that the patient has been sent to a sanatorium

notable also for restraint and factual basis. For its content of good sense, though not comparable to the first as a product of research, "Changing Concepts in Posture Training," by L. W. Irwin³ should also be mentioned.

But the collection of the last seven years includes much that must be discarded by the critical reader. Some of this material in the hands of unprotected parents seems almost certain to lead to improper care of children, and it is regrettable that it should receive the prestige of publication. These pages contain dogmatic instructions concerning the baby's standing and sitting habits, and especially his sleeping posture, which must be followed or deformity is said to result. It is indeed surprising that no attempt has yet been made to correct the posture of the fetus in utero. This somewhat cloistered stage of development certainly defies all the rules of the posturites, and for a time that seems long enough to lead to a permanent deformity if a cramped position for a sustained period can deform. There is room for doubt that even if a baby insists upon sleeping on his chin, to mention one practice strongly decried by these writers, such a position necessarily leads to deformity. A more important basis for fear is the menace to mother-child relations of constant nagging correction of such a habit in baby or child.

In appraising the posture of the school child it is apparent to many that unlovely slouches or slumps are more apt to be the result than the cause of ill health. It is apparent also that spontaneous correction occurs in the vast majority of school children when no true structural deformity exists. In view of this spontaneous tendency to correction, one is led to doubt the value of special corrective exercises as provided by some schools, especially if they include separation into special classes. The possibility exists that special classes themselves may lead to social maladjustment.

CHEST X-RAY PROGRAM—A REPORT OF PROGRESS

THE Boston Chest X-Ray Program, as of October 14, reported that 139,442 x-ray films had been taken, of which 99,939 had been processed. This encouraging beginning has been made in only eighteen operating days.

An analysis of the practically 100,000 processed films shows that 95.63 per cent were negative and 1891, or 1.89 per cent, gave some evidence of disease. Definite tuberculosis was evident in 826 cases and suspected tuberculosis in 489. Nontuberculous chest disease appeared on 360 films, and cardiovascular disease on 216.

The Committee on Nontuberculous Chest Disease, a subcommittee of the Medical Committee of the Program, is naturally concerned about the treatment and disposal of patients in whom chest disease of a nontuberculous nature is found, and has suggested procedures pertaining to their care.

These recommendations point out that cancer is the most important diagnosis to be considered in the evaluation of nontuberculous pulmonary disease, and emphasize the criteria necessary for its identification, as well as the necessity for rapid processing of films in order to facilitate early diagnosis. Particularly stressed are the definition of those lesions that should cause the patient to be designated as a cancer suspect, and the further management of such cases.

Suitable orientation of physicians in this regard is important in that all cases of nontuberculous pulmonary disease discovered will be referred back to the family doctor or to the Massachusetts Medical Society for advice if there is no family physician, but private care is desired. Other patients will be referred to established thoracic clinics in or near Boston.

One of the most persistently discouraging facts about cancer of the lung, as demonstrated by Overholt and Schmidt,* is the long interval of ten months that elapses, on the average, between the patient's first visit to the doctor and the time when the diagnosis is made. The lessons to be learned from the Boston Chest X-Ray Program should be of value in cutting down this "tragic interlude."

*Overholt, R. H. and Schmidt, I. C. Survival in primary carcinoma of lung. *New Eng J Med* 240:491-497 1949

to 1947 as compared to 2.16 per cent of 1991 in 1931 to 1935 and 3.66 per cent of 1832 in 1936 to 1940). This finding is, at first thought, discouraging and even appalling, and most certainly presents a continuing challenge, but there are certain features whose consideration is necessary before final conclusions are drawn.

In the first place the actual incidence of unquestioned fatal pulmonary embolism in patients whose femoral veins were bilaterally ligated either prophylactically (4) or therapeutically (6) was only 0.5 per cent (10 patients out of 1929 cases so treated). There was another group of 11 cases with smaller emboli after the ligation, making a total of 21, or 1.1 per cent. Four other patients had their veins ligated *after* embolism that subsequently proved to be fatal. One other had an embolus consisting of a renal-cell carcinoma. This leaves a balance of 63 cases with fatal pulmonary embolism, 14 with large, possibly fatal embolism, and 105 with small emboli who did not have leg-vein ligation, a total of 182 as compared with 21 who did have the ligation. One would, of course, like to know how many patients there were who were comparably ill or operated upon (not just total admissions) of whom these 182 made a part. It is quite possible that the ratio of pulmonary embolism might be found to be higher in that group than in those subjected to ligation, as data already published from the Massachusetts General Hospital have indicated.¹⁻³ This analysis, though difficult, would be well worth while in amplifying the data already presented. Incidentally, it is of much interest and doubtless of considerable importance to note the fact that, on the average, the patients admitted to the hospital in the last five-year period—that is, from 1943 to 1947 inclusive—were eight years older than those admitted in the first period, 1931 to 1935 inclusive. In addition, it has been stated that a diminished mortality from shock, infection and pneumonia in recent years has put thromboembolic disease more in the limelight.

However, even if ligation and anticoagulant therapy (800 cases received Dicumarol at the Massachusetts General Hospital during 1947 alone but were not analyzed in this report) reduce the threat of pulmonary embolism, as has been the experience

of most surgeons and internists, they are not yet good enough since death can occur despite them as clearly shown by the paper of Roe and Goldthwait in the individual case reports, several of which revealed thrombi in the veins proximal to (that is, nearer the heart than) the ligation site. Moreover, these measures have not, in all probability, been applied to enough cases or always in adequate degree to obtain the best results. Finally, the high percentage of unanticipated, fatal pulmonary embolism in this series is rather surprising especially in a hospital where the staff has presumably been on the alert, this fact simply indicates the need of still more attention to this frequent complication both postoperatively and in medical patients.

Thus, the challenge of pulmonary embolism still exists in major form.

FURTHER PSEUDODOXIA

THE "total health of the child" is a popular present-day concept, which hardly any physician contemplates without comprehension of the importance of child happiness and the security of his family relations. It is well that this should be so. However, this relatively new recognition of the importance of mental hygiene is likely to uncover practices that although dimly recognized as unsatisfactory, have not hitherto seemed enough of a menace to health to warrant serious attention. Some of these practices were mentioned by Bakwin¹ in 1945 as "pseudodoxia pediatrica," and among them is also the pseudoauthoritative writing that is found in some of the semiofficial and voluntary journals upon the subject of posture. A review of the literature of the last seven years reveals some strictly scientific articles on the posture of the child, among which should be mentioned, "New Approach to Quantitative Analysis of Children's Posture" by Robinow, Leonard and Anderson.² This, with its many illustrations, has a highly instructive value and is

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

CHANGES IN ACT FURTHER PROVIDING FOR THE CARE OF CERTAIN INFANTS

Changes in the law relating to the care of premature infants enacted by the General Court (Chapter 601 Acts of 1949) became effective on October 25, 1949. The responsibilities for the care of premature infants formerly allocated to local boards of welfare are now transferred to local boards of health. This transfer is made because this is primarily a matter pertaining to health and also because of the hope that it will remove the welfare stigma that has interfered with the full use of legal provisions in the past. Many families who could afford to pay for hospitalization of ordinary length find it impossible to meet the cost of the prolonged periods sometimes necessary for premature infants. It is the purpose of this legislation to help such cases.

The changes in Chapter 601 are outlined as follows:

Administration

Local boards of health or local health jurisdictions rather than local boards of welfare, are now responsible for the administration of this law.

Weight

Defined as $5\frac{1}{2}$ pounds or less at birth, instead of 5 pounds or less, to conform to federal and other state definitions.

Reporting of Premature Births

By hospital — to the local board of health or local health jurisdiction of the town where the mother resides instead of the local board of welfare of the town where the infant is born.

By physicians (for premature births outside hospitals) — to the local board of health or local health jurisdiction of the town where the infant is born instead of to both boards of health and welfare.

Payment for Hospitalization

Only for infants weighing $4\frac{1}{2}$ pounds or less at birth (if parents are unable to pay).

By local health agency — by local board of health or local health jurisdiction instead of by local board of welfare of the town of mother's residence. If the mother's settlement is in another town the board of health of the town of settlement will reimburse the board of health of the town of residence on written notification within sixty days.

No expense shall be reimbursed that was incurred more than ten days (instead of five) prior to receipt of original notice sent to local board of health.

Ceiling rates for hospitalization are established by the Massachusetts Department of Public Health.

By Massachusetts Department of Public Health — for cases with no legal settlement, hospitalization will be paid by the Massachusetts Department of Public Health.

Copies of the Act are being sent to all physicians, hospitals, boards of health, boards of welfare, public-health nursing organizations and others interested.

Attention is called to the importance of acquainting parents who may need financial assistance with the provisions of this act.

CORRESPONDENCE

ON THE HEATING OF INFANT FORMULAS

To the Editor — In the article by Drs. Joseph C. Merriam and C. G. Tedeschi which appeared in the August 25 issue of the *Journal*, the results of terminal heating of infant formulas under steam pressure were discussed. The conclusion was reached that although terminal heating at 15 pounds of pressure for five minutes or at 6 pounds for ten minutes produces bacteriologically safe products, there are some undesirable side effects in the form of coagulum in the formula and sticking of the nipple shields to the nipples. Reference is made to the New York State Sanitary Code, Chapter II, Regulation 35 as the source of these recommended procedures.

The terminal heating requirements of Regulation 35 are based on the experience of Cummings in the Michigan State Health Department, on the recommendations of the subcommittee of the American Hospital Association which made a study of terminal heating of formulas on extensive studies made in the New York State Department of Health and on suggestions submitted by hospitals in New York State at the time Regulation 35 was in preparation. Two of the three methods have been adopted by the American Academy of Pediatrics.

There is a wide experience in the use of all three methods of terminal heating. The success that one hospital has with a given method may not be duplicated in another hospital. This may be attributable to differences in formula, to differences in the heating efficiency of the equipment in use and to the human factors of careless timing and failure to remove the formula from the autoclave as soon as possible. Small bottles filled too full often result in nipple plugging. In general, the Department of Health personnel are in favor of lower temperatures for terminal heating of formulas. The requirement of 250° for five minutes was included in the regulation as a permissive provision at the request of certain hospitals that were using this method prior to the adoption of Regulation 35. In view of the fact that autoclaves can be equipped with an attachment that will make it possible to operate them at any one of the three temperatures allowable under Regulation 35, this regulation is applicable in any hospital. It is recommended that hospitals experiment with a few formulas in adequate size bottles until they find the method that seems best suited to their personnel and their types of formula. Since all hospitals in New York State are now carrying out terminal heating of formulas and many of them are using steam pressure, the formation of coagulum and the sticking of nipple shields to nipples do not seem to constitute a universal problem.

The bacteriologic results mentioned by Drs. Merriam and Tedeschi are parallel to those obtained in the New York State Department of Health and by others who have studied this problem.

These few comments have been submitted in an effort to clarify any misunderstanding that might arise concerning the practicability of the requirements of the New York State Sanitary Code for the terminal heating of infant formulas.

BOOK RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

George R. Mino Symposium on Hematology, by William Dameshek, M.D. and F. H. L. Taylor, Ph.D., editors. 4°, cloth, 984 pp., with illustrations and tables. New York: Grune and Stratton, 1949. \$12.00.

This honorary volume was issued in commemoration of the sixtieth birthday of Dr. George R. Mino in 1945. One hundred and fifty-five colleagues and friends of Dr. Mino contributed eighty-three articles on the blood and related

TALE OF TWO CITIES

Old ways are best in Budapest, according to observations recently published by Suranyi.* The infant mortality in the twin cities had reached the deplorable level of 269 per 1000 in July and August of 1945, in the corresponding months of 1948 it had dropped to 57. The reason given for the improvement was a health campaign in which breast feeding was emphasized, aided in a practical manner by the application of short-wave therapy to the breasts. Ten such treatments, it is said, resulted in a prolonged 50 per cent increase in milk excretion in a third of the cases.

Figures indicate that up to 4,166,500 gm of human milk have been collected and dispensed in one month through the 19 centers that have been established in the city. An average of 2500 infants per month have received the benefits of this service, preference being given to premature and sick babies. During a test period the mortality rate among infants receiving the breast milk was 36 per 1000, as against a rate for the city as a whole of 79 per 1000.

Like Horace's Spartans, the women of Hungary seem to have opposed to the strokes of adversity their gallant breasts.

AMERICAN ACADEMY OF PEDIATRICS

The annual meeting of the American Academy of Pediatrics, which will be held at the Palace Hotel in San Francisco from November 12 to 17, promises to be of great interest to all pediatricians as well as the many general practitioners whose practice includes pediatric cases. The program consists of seminars, original papers and round-table and panel discussions on the various pathologic conditions and infections encountered in infancy and childhood, attention will also be given to mental, emotional and endocrine problems.

This congress marks the eighteenth annual convocation of the Academy. The publication of the results of the surveys on child health services in various states^{1, 2} lends added significance to the

meeting of the organization primarily responsible for this investigation. The *Journal* wishes the Academy every success in the various surveys and in the continued efforts to solve the problems of child health in the United States.

MASSACHUSETTS MEDICAL SOCIETY

DEATHS

GARDNER — Edwin D. Gardner, M.D., of Marion, died on October 12. He was in his sixty-fifth year.

Dr. Gardner received his degree from Harvard Medical School in 1910. He was former chief of surgery at St. Luke's Hospital, and was chief of the surgical staff of Tohey Hospital, Wareham. He was a member of the American Urological Association and a fellow of the American College of Surgeons and American Medical Association.

His widow and two sisters survive.

HATT — Rafe Nelson Hatt, M.D., of Honolulu, Hawaii, died on May 27. He was in his sixtieth year.

Dr. Hatt received his degree from Tufts College Medical School in 1918. He was formerly chief surgeon at the Shriners' Hospital for Crippled Children, Springfield, and consulting orthopedic surgeon at Springfield and Wesson Memorial hospitals. He was a past president of the Springfield Academy of Medicine and was a nonresident member of the Massachusetts Medical Society. He was a member of the American Orthopaedic Association and the American Academy of Orthopaedic Surgeons and a fellow of the American College of Surgeons.

His widow, a son, two daughters and a granddaughter survive.

WATTERS — William H. Watters, M.D., of Boston, died on October 11. He was in his seventy-fourth year.

Dr. Watters received his degree from Boston University School of Medicine in 1900. He was professor emeritus of preventive medicine at Boston University School of Medicine and was a member of the American College of Physicians and a fellow of the American Medical Association.

His widow survives.

George R. Minot Symposium on Hematology, By William Dameshek, M.D. and F. H. L. Taylor, Ph.D., editors. 4°, cloth 984 pp. with illustrations and tables. New York: Grune and Stratton, 1949. \$12.00.

This honorary volume was issued in commemoration of the sixtieth birthday of Dr. George R. Minot in 1945. One hundred and fifty-five colleagues and friends of Dr. Minot contributed eighty-three articles on the blood and related

subjects. The articles were originally published in *Blood* during 1948 and 1949, and are here brought together in one volume as a "Festschrift" through the generous financial support of the Lederle Laboratories and Mr J K Lilly. The text is preceded by a full-page portrait of Dr Minot and by his biographic data. The first article is a reprint from the *Journal of the American Medical Association* of August 14, 1926. This article, "Treatment of Pernicious Anemia by a Special Diet," which was by Dr Minot and Dr William P Murphy, represented the outstanding contribution of these two physicians and won them the Nobel prize. The text is divided into seven parts into which the various articles are classified: pernicious anemia, hemolytic anemia, anemia other than pernicious or hemolytic, blood-clotting phenomena and hemorrhagic disease, leukemia, biologic and cytologic reactions of blood and blood-forming tissues, subdivided into red cells, white cells, blood-forming organs and certain biochemical aspects, and general practice, containing two contributions on peptic ulcer and on diabetic coma. There are indexes of authors and subjects.

The original article of Minot and Murphy has long been out of print and is made available in this volume. The book is recommended to all medical libraries.

NOTICES

ANNOUNCEMENTS

Dr Robert J Fahey announces the opening of offices for the practice of internal medicine at 119 High Street, Medford, and 520 Commonwealth Avenue, Boston.

Dr A William Reggio announces the change of his address from 2301 Connecticut Avenue, N W, Washington, D C, to School Street, Medfield, Massachusetts.

SOUTH END MEDICAL CLUB

A luncheon meeting of the South End Medical Club will be held at the headquarters of the Boston Tuberculosis Association, 554 Columbus Avenue, Boston, on Tuesday, November 15, at 12 noon. The speaker will be Dr Hans Waine, medical director of the New England Chapter of The Arthritis and Rheumatism Foundation, who will discuss arthritis and rheumatism, and especially Cortisone, the new treatment for these diseases.

Physicians are cordially invited to attend.

GREATER BOSTON ASSOCIATION OF MEDICAL TECHNOLOGISTS

A meeting of the Greater Boston Association of Medical Technologists will be held at the Nurses Home of the New England Baptist Hospital, on Tuesday, November 8, at 7 30 p m. Dr Donald A Nickerson will speak on the subject "Evaluation of Blood Sugar Technics."

NEW ENGLAND CARDIOVASCULAR SOCIETY

The following scientific program of the New England Cardiovascular Society for 1949-1950 has been announced (all meetings will be held on Monday evenings at 8 15).

November 7 Massachusetts General Hospital Edward Bland, M D, chairman

December 5 Peter Bent Brigham Hospital, Samuel Levine, M D, chairman

January 9 Boston City Hospital Laurence B Ellis, M D, chairman

February 6 Massachusetts Memorial Hospitals Robert W Wilkins, M D, chairman

March 6 Beth Israel Hospital Herrman Blumgart, M D, chairman

April 3 Children's Medical Center (House of the Good Samaritan and Children's Hospital) Benedict F Massell, M D, chairman

May 8 Annual meeting

Members who wish to give papers and are staff members of hospitals in which no meeting has been scheduled are requested to submit papers to the Secretary (Dr Benedict F Massell). If sufficient papers are submitted, an additional meeting will be arranged.

CARCINOMA OF THE EYELID*

Analysis of 301 Cases and Review of the Literature

CHARLES G. STETSON, M.D.,† AND MILFORD D. SCHULZ, M.D.‡

BOSTON

THE treatment of carcinoma of the eyelid presents many problems not encountered in the treatment of similar lesions elsewhere about the face and other body surfaces. A satisfactory cosmetic result is imperative, and the likelihood of disaster after delayed, inept or unsuccessful treatment is considerable. Several excellent studies have been carried out on this subject, and all workers of considerable experience have reported poor results in patients who have presented themselves with recurrent or persistent disease following previous therapy in other hands. The purpose of this paper is to evaluate the various methods of treatment of primary carcinoma of the eyelid by examination of locally available clinical material and by a review of the experience of others as recorded in the literature.

Carcinoma of the eyelid, like carcinoma of the skin elsewhere, is not a rare disease, occurring more commonly in the male than in the female, and increasing in incidence with age. Different authors have listed chronic irritation, sunlight, chemical irritants, old scars and precursory keratoses as the etiologic factors with about the same conviction as in cancer of the skin on other parts of the body.

The course of the disease is variable. Basal-cell lesions of the eyelid, as in other areas, invade and destroy adjacent tissue by direct extension, but they do not metastasize. Serious sequelae may ensue, however, from their extension from the lid to adjacent structures. Involvement of the bulbar conjunctiva with subsequent destruction of the globe may result and in cases in which there has been extension into the orbit, incurable involvement of the bony orbit may occur. Lesions about the inner canthus frequently invade the lachrymal duct and

may extend directly into the ethmoid sinuses. Hunt¹ states that basal-cell carcinoma of the lid may travel along lymphatics, penetrate the orbital fascia and give rise to orbital extension. Birge² found that 25.9 per cent of the basal-cell cases and 6.8 per cent of the mixed group extended into the orbit with ensuing blindness, all the latter group originated at the inner canthus.

Squamous-cell lesions of the eyelid not only spread by direct extension, giving rise to the complication of orbital and sinus invasion, globe destruction and bony involvement characteristic of an untreated basal-cell carcinoma, but also tend to metastasize to the orbit and regional lymph nodes. Birge² found that the conjunctiva was involved in 37 per cent of his squamous-cell lesions of the eyelid and that orbital extension almost always accompanied conjunctival and corneal involvement. Hunt¹ reported that 2 of 10 cases metastasized to regional lymph nodes and that the upper and outer lid lesions tended to spread to the preauricular nodes and lesions of the lower lid to the upper cervical nodes. In Martin's³ experience, the preauricular node is the common site of involvement.

The ultimate course of the disease, like cancer of the skin everywhere, depends in a large part upon its stage of advancement when treatment is undertaken and to a lesser degree upon its location. Small lesions, and others not so small that have not invaded the orbit or sinuses and have not seriously damaged the globe, may be controlled without significant deformity. Uncontrolled lesions may result in the loss of an eye and even in eventual death, owing to local extension or to metastasis in cases of squamous-cell carcinoma. Birge² found that the most important factor in prognosis of a basal-cell lesion is its location. In his opinion, cancer of the eyelid is an extremely serious condition because of its ability to blind and kill. He considers the basal-cell lesion a worse "killer" than the squamous-cell lesion, the inner canthus and upper lid to be associated with the greatest mortality, and the

chance of cure to be negligible if the disease has extended into the orbit. In his series, the mortality from basal-cell lesions was 11 per cent, and that of the entire group of cancer of the eyelid was 12 per cent. His experience with squamous-cell lesions has been wider than that of the other workers cited, and his observations therefore carry weight. In the group of cases with squamous-cell carcinoma of the eyelid the grade of malignancy and the clinical behavior correlated well, the greater the malignancy, the greater the tendency to involvement of lymph node or orbit. Grade IV lesions had the highest death rate, whereas Grade II and III had the highest over-all mortality because of their greater incidence. In Grade I lesions there were no deaths and no loss of the eye. Lesions of the inner canthus proved nearly as dangerous as those of the upper lid.

Martin³ found a mortality of 6 per cent in his group, the adenoid cystic epithelioma being more malignant than other types as well as being a potentially metastasizing lesion.

MATERIAL

The clinical material for this study consists of the

workers Birge,² in whose series the average duration was over one year, believes that the majority of lesions develop over a long period. Charters⁴ reported a duration of disease from two months to twenty years, and in Hunt's¹ group, 30 per cent of patients had had the disease for over three years.

Age and Sex

Sixty per cent of the lesions occurred in males. The median age of the group was fifty-eight, the youngest being twenty and the oldest eighty-nine. Seventy-five per cent of the group were between fifty and seventy-nine years of age, the peak falling in the sixth decade. If correction is made for normal population decay, however, the incidence is found to increase in a linear fashion after the age of forty.

Incidence of Eyelid Involvement Among All Carcinomas of Skin

During the twelve-year period under consideration, approximately 12,000 cases of cancer of the skin were observed, making the incidence of eyelid involvement 2.5 per cent. Birge² reported that cutaneous cancer represented 12 per cent of all

hospital records of 301 patients with primary carcinoma of the eye who were seen in the clinics of the Massachusetts General Hospital and of the Collis P. Huntington Memorial Hospital during the twelve-year period from January, 1933, through December, 1944. Only cases in which the carcinoma was primary in the eyelid and in which no previous treatment had been given were included, in all but 1 case the lesions were confined to the eyelid and immediately contiguous structures. Inasmuch as 86 per cent of all recurrences develop within three years of treatment, this particular period was selected so that the minimal follow-up interval would be that in which the recurrence of disease might be expected.

Duration of Disease

The average recognized duration of the disease in the group was three and a half years, the shortest period was one month, and the longest twenty years. This is in fair agreement with the findings of other

epitheliomas, and that 3 to 5 per cent of these were located on the eyelid. The group of 324 carcinomas of the eyelid studied by Driver and Cole⁸ constituted 16.8 per cent of 1925 epitheliomas of the skin seen in their clinic.

Topographic Distribution of Lesions

The lower lid was the most frequent site of involvement (48.2 per cent), and the inner canthus the second most common site (21.0 per cent). The upper lid and outer canthus follow in frequency of occurrence, 14.6 and 9.0 per cent respectively (Table 1). In 22 patients (7.2 per cent), several areas on the lids in the same patient were involved. Six patients exhibited two separate lesions, 3 with bilateral lesions and 3 with the two separate lesions on the same side. In Birge's series, 37 per cent of the squamous-cell cancers arose from the conjunctival surface, including the cornea, primary corneal squamous-cell neoplasm was rare.

Histology of Lesions

The diagnosis in 162 cases (54 per cent of the entire group) was confirmed by biopsy, in the remaining 139 cases the diagnosis was clinical only, the lesions bearing the expected characteristics of basal and squamous-cell carcinoma. Of the 162 histologically proved cancers (Table 2 and 3), 82 per cent were basal-cell (4 of the hair-matrix type), 14.5 per cent squamous-cell, and 2.4 per cent basal-

cell type group who had been followed three years or longer, since it was found that in 86 per cent a recurrence, if there were one, developed within three years. Figure 1 and 2 demonstrate the results in 2 cases eight and twelve years, respectively, after treatment. Of the 21 cases in which there was a recurrence of disease, it appeared within a year in 38 per cent, between one and two years in 24 per cent, and between two and three years in 24 per cent. In 2 cases the disease recurred in the

cell and squamous-cell lesions, and 1.2 per cent adenoïd cystic epitheliomas. Rare carcinomas arising in meibomian glands have been reported by Hagedoorn⁶ and Lebensohn⁷, none were observed in this series. Neither in the present group nor in the cases reported by Birge² or Hunt¹ did there seem to be any predilection of site for any particular type of tumor.

Treatment and Results

In 76 per cent of the entire group, irradiation treatment was used. The majority of 23 patients

fourth year, and in only 1 was the recurrence as long as the fifth year after treatment. The average follow-up period was six and three-tenths years.

The results of treatment were classified as follows: "cure" from primary treatment, "cure" after subsequent treatment, and failure (from recurrent disease, from persistent disease and from metastasis). The term "cure" is applied to cases in which there was no apparent disease during the follow-up period. "Recurrent disease" indicates recurrence in a previously treated area after an interval of at least three months following therapy during which

treated with 100 kv r received a single large dose. Of the 111 treated with 200 kv, 75 per cent were given a single large dose, and 25 per cent fractionated doses. The effective tumor dose was about 3000 r. When radon was applied topically, the average skin dose was 3275 gamma r. Seventy-one patients were treated surgically (electrosurgery or surgical excision).

Table 4 records the methods and results of treatment. The results are based on patients of the en-

tire group who had been followed three years or longer, since it was found that in 86 per cent a recurrence, if there were one, developed within three years.

From a percentage standpoint, no significant difference was noted in the number of failures of the various treatments employed. In an attempt to determine the causes of the unsatisfactory results of the primary treatment, it was found that inadequate radiation, or inadequate excision in patients treated surgically, headed the list. In 5

cases failure was due in part to error in x-ray technic (the size of the field was inadequate to cover the lesion) In 6 of the surgically treated cases, inadequate excision was demonstrated by recurrence of the disease in the suture line The tumor proved radioresistant in 11 cases, — for example, a superficial lesion 0.5 cm in diameter did not respond to

CASE 1 An uncontrolled recurrence in a 79-year-old man resulted from inadequate excision of an 0.5 cm basal-cell lesion of the upper eyelid The recurrent growth, which developed 5 months after excision, was re-excised and showed a mixed squamous-cell and basal-cell tumor The disease then extended into the orbit and was treated with 200 kv x-ray This was classed as a surgical failure (The patient died 3 years after the first excision from rupture of multiple hemangiomas of the gastrointestinal tract.)

*No evidence of disease after treatment for the period of follow-up study

a single dose of 3000 r (air) In one case the appearance of metastases accounted for failure, another failure was due to the fact that at the time the patient was first seen the disease had extended into the bony orbit

From the standpoint of topographic distribution, there was nothing to indicate that the position of

CASE 2 A 69-year-old man presented total involvement of all lids, globe and orbit at the time of his initial visit. Biopsy revealed a squamous-cell cancer, Grade III He received fractionated daily 200 kv x-ray therapy, to a field 10 by 10 cm, a total dose of 3000 r measured in air being given He refused further treatment He was known to be living five years after treatment and was assumed to have residual disease In all probability the disease was incurable at the time he was first seen, but adequate palliation was obtained

FIGURE 1 Photographs of Patient J. J. (U-328878), with a Basal-Cell Carcinoma about the Inner Canthus Involving the Punctum, Who Was Treated with 500 r per Day for 3500 r with 200-kv, 0.25-mm Copper Filter at a Skin-Target Distance of 20 cm

A shows the lesion before treatment, and B three years after treatment The patient was well and free of disease eight years after treatment, with only slight tearing as an undesirable complication

the lesion had any bearing on an unsatisfactory result, provided the disease had not already become uncontrollable because of extension to lymph nodes, the orbit or the sinuses The histologic characteristics of the tumor, however, appeared to be of significance Failure of the primary treatment was twice as frequent in squamous-cell lesions as in basal-cell lesions The 5 cases that were ultimate failures are briefly reported as follows

CASE 3 A 54-year-old man had persistent uncontrolled disease from an 0.5-cm basal-cell carcinoma at the inner canthus He refused to accept more than a single treatment, and was given 3500 r (air), 200 kv x-rays with 0.25-mm Cu and 1-mm Al filters being used Nine months later, when he was persuaded to return to the clinic, there was clinical evidence of residual disease The final outcome is unknown since the patient refused both further treatment and further follow-up study

CASE 4 An 84-year-old, extremely feeble woman had a squamous-cell carcinoma, Grade III, involving the entire

lower lid. She refused hospitalization, and was treated with x-rays generated at 200 kv, filtered with 0.25 mm Cu and 1 mm Al. At weekly intervals 400 r, measured in air, was given to a total dose of 1200 r (air). The patient was unable to return for further treatment because of increasing feebleness and died from bronchopneumonia 5 months from the date of her initial visit. She might have been cured.

CASE 5 A 57-year-old man died from metastatic disease from a Grade I squamous-cell lesion on the outer aspect of the upper lid. The primary cancer was destroyed by daily

treatment and 68 or 89 ± per cent with good results from the primary treatment.

Richards¹⁰ had 3 failures out of 102 cases treated, in 2 of the failures previous treatment had been given. Martin⁸ did not find five-year results revealing, he believed that the end-results must be evaluated on the basis of function and appearance. In 85 per cent of his patients the first treatment was

FIGURE 2 Photographs of Patient A S (U-346117), with a Squamous-Cell Carcinoma Involving the Inner Canthus and Punctum, who was Given a Single Treatment of 2000 r with 200-kv, 0.25-mm Copper Filter at a Skin-Target Distance of 20 cm.

A shows the appearance before treatment, and B three years after treatment. The patient was well twelve years after treatment with only slight telangiectatic formation at the lid margin.

treatments of 600 r (a r) to a total dose of 4200 r (air), 200 kv x-ray therapy with 0.25-mm Cu, 1-mm Al filters at skin-target distance of 50 cm being used. Eight months later, adenopathy of the upper cervical lymph nodes on the side of the original lesion developed, biopsy showed metastatic squamous-cell carcinoma. The metastases were considered to be too extensive for a radical neck dissection, particularly as the patient was a poor surgical risk. The nodes were irradiated with 200 kv, but the patient went downhill rapidly and died 18 months after the initial treatment to the eyelid. This case might have been salvaged had the cervical involvement been noted at an earlier date.

The results of treatment in this study are not comparable to those of other workers, since only patients who received their primary treatment in this clinic were included. It is interesting to note, however, that good results in the treatment of this disease have been reported by most of the clinics whose work has been published. Hollander and Krugh⁷ had good results in 97 of 125 cases and unsatisfactory results in 28, they concluded that no method of treatment is superior to any other.

Driver and Cole,⁵ in a follow-up study of 291 patients for one month or over, found 19 (6.5 per cent) recurrences and 272 (93.5 per cent) possible cures. There were 6 deaths from the disease. Among 193 cases followed for six months to ten years there were 12 relapses. Relapses after five years were rare, 181 cases, or 93.8 per cent, were possible permanent cures.

In 76 cases treated with radium, Charteris⁴ reported 2 failures, 6 patients requiring secondary

successful, 7 per cent required more than one treatment, and 6 per cent died of their disease.

Birge² followed 127 of 139 basal-cell carcinomas of the eyelid and found an 11 per cent mortality. In the basal-cell group, 46.1 per cent of patients lived fifteen years or more, 75 per cent with the mixed type of carcinoma lived fifteen years or longer. Of the squamous-cell cancers, 50 per cent recurred, Grade III showing the greatest tendency to recurrence. There were no deaths in the Grade I (squamous-cell) group, 15 per cent of patients with Grade II lesions died, and among those with Grade III tumors there was a 46 per cent death rate. The orbit was involved in 30 per cent of the Grade II squamous-cell group and in 53 per cent of Grade III, in Grade IV, the orbit was invaded in every case and no patient survived five years.

COMPLICATIONS OF TREATMENT

Complications of treatment of carcinoma of the eyelid — that is, undesirable by-effects incident to treatment that would otherwise have been considered satisfactory — are not numerous. Complications that follow surgical treatment are primarily unsightly scars or defects requiring plastic revision and lid-drop due to interference with the innervation or attachment of the elevator of the lid. Among 71 patients treated by means of surgical operation, 1 case of each of these complications occurred.

Undesirable side effects are more common after irradiation. The most frequent of these is stenosis of the tear duct when lesions involving the inner canthus and medial portions of the lids are treated. Out of 31 cases in which the inner canthus was irradiated, stenosis of the tear duct developed in 8, or 26 per cent. This complication is at times unavoidable, especially when the neoplasm has already invaded and destroyed the duct. Since lesions in this location do not lend themselves to surgical intervention, a certain number of stenosed ducts must be expected and accepted as the legitimate price paid for control of the disease.

It is the opinion of some investigators that attempts should be made to dilate and keep open the stenosed and destroyed duct. This procedure, however, is of benefit only in cases in which the stenosis is not complete and in which the duct has not been entirely destroyed by tumor.

The formation of cataract is a serious post-radiation complication and has often been reported. It should never occur, however, when the lesion is treated with x-rays and the globe has been properly protected with a lead shield. Protection of the lens when radium is used is difficult. In our series no case of radiation cataract has been observed. This is accounted for in part by the fact that the eye has always been carefully shielded during x-ray therapy. Radium and radon have been employed only in a limited and selected group of patients. A radium plaque was used once, interstitial radium needles three times, and interstitial radon seeds on two occasions, and in 35 other cases surface application of radon was utilized for superficial lesions, the average skin dose not exceeding 3300 r.

Several interesting observations have recently been reported concerning the time factor in the development of radiation cataract and the amount of radiation necessary to produce it. Hunt¹ found the average latent period to be twelve years, although the complication might develop in three months. He reported 5 cases in which lens opacities developed, 2 from radium and 3 from unshielded x-ray therapy (there were none in the shielded cases). He calculated the dose received by the lens in the 3 cases treated by radium to be 2400, 1500 and 1350 r, the opacities developing after six months, eight years and five years respectively. Of the 2 opacities that followed x-ray therapy, the dose in 1 was 875 r (air), 130-Kv x-ray, 1-mm Al filter, and in the other 4800 r in 6 treatments from 130-kv x-ray, 1-mm Al filter, both were unshielded.

Martin² states that cataracts may develop in twelve to thirty-six months after radiation. In Smithers's¹¹ experience, a five-year latent period is not uncommon. Charteris⁴ believes that eye damage is unlikely if the dose is below 2800 r although it may follow 1500 r. He found the implantation of radium to be most dangerous when applied to an upper-lid lesion. Of his 76 patients treated by

radium, 11 showed late ocular changes, 7 of which he attributed to radiation (4 lost their vision). Richards¹⁰ believes that cataract develops only as a result of long-continued use of hard rays.

In our opinion proper care and meticulous attention to details of technic when carcinoma of the eyelid is treated by x-rays should eliminate this hazard completely, except in cases in which extensive tumor involvement of the orbit and globe makes it impossible to protect the eye itself. In the 2 patients in the present series in whom destruction of the globe, subsequently necessitating enucleation, occurred there was extensive involvement of the bulbar conjunctiva at the time the patient was first seen, making protection of the eye impossible.

Persistent chronic, painful conjunctivitis following x-ray treatment has been observed only once in this group. Corneal ulcer, a theoretical complication of radiation, has never been seen. Proper protection of the globe and careful shielding of the adjacent normal tissues with lead should allow irradiation without damage to bulbar conjunctiva or cornea.

Severe deformity of the lids requiring plastic repair, observed in only 3 of the cases treated by radiation, occurs only when the disease is advanced and there is already destruction of tissue by tumor.

DISCUSSION

Good results in the treatment of carcinoma of the eyelid can be obtained by any of the available methods in skilled hands. Prior to any form of treatment, after the diagnosis has been established, the patient should have a thorough examination by a competent ophthalmologist. It is important to have a record of these findings in the event of subsequent ocular complications. In all fixed lesions about the lid, adequate x-ray studies of the sinuses and orbit, to rule out possible bony involvement, should be made. This is particularly necessary in infiltrating and fixed lesions about the inner canthus, which are prone to extend into the ethmoid sinuses; it is mandatory in cases in which the globe or orbital tissues are invaded by disease.

A capable plastic surgeon may obtain good results by the excision of small lesions. Against this choice of treatment stands the fact that there is often considerable nonvisible tumor infiltration, which results in recurrence of tumor in the suture line. Surgery plays an important role in a selected number of patients who have extensive involvement of the globe or orbit. Radical exenteration of the orbit may be required, the globe as well as other orbital tissues must be removed in case of involvement. When residual disease is suspected, radiation to the orbit should follow surgical operation.

Prior to the acquisition of suitable low-voltage therapy, most of the superficial lesions of the eyelid were treated by surface application of radon. Only limited use has been made of surface and interstitial

therapy with radium element. At the present time the routine use of radium with its possible sequelae does not seem justified when equally good results can be obtained with roentgen-ray therapy without the danger of damage to the eye.

If x-radiation is to be employed, the first consideration is protection of the eye. For low-voltage x-ray treatment Hunt¹ used a 12-mm lead shield coated with nickel. He found that a 1-mm lead shield removed 97 per cent of the radiation from 140-kv x-rays, filtered with 0.25-mm Cu and 1-mm Al. Smithers¹¹ points out that complete protection is impossible when the tumor has invaded the eyeball or orbit and states that the risk of damage to the eye from treatment must be considered as of secondary importance. When the tumor is limited to the lid, he uses for low-voltage therapy an accurately ground contact glass lens covered by 1 mm of lead. He states that less than half of 1 per cent of low-voltage radiation will penetrate this shield. He also describes a very practical type of plastic Perspex eyeshield covered by 1 mm of lead, this is available in multiple sizes and contours. Driver and Cole⁶ prefer lead shields coated by paraffin.

For the treatment of most primary carcinomas of the eyelid x-ray therapy seems to be the method of choice. The occurrence of failures or other undesirable results is no greater than with other forms of therapy, the discomfort to the patient is not great, and the cosmetic and functional results are equal to or better than those obtained by other means. An accepted technic of procedure, found to be satisfactory, is described below.

Technic of Irradiation of Eyelid

The eyeball is anesthetized, and a 2-mm lead shield coated with paraffin is inserted. The size of the shield is adequate to include a margin of normal surrounding tissue. An excellent protective device for lesions of the inner canthus is a lead nipple shield (Fig 3C). These nipple shields are no longer available commercially, but they can be easily made.

For small lesions, x-rays at 100 kv, unfiltered, with a skin-target distance of 20 cm are used. A single treatment of 2700 to 3000 r (air) may be delivered, or the fractionated technic may be employed. It is thought that the latter gives better cosmetic results. For the treatment of a small lesion with the fractionated method, daily doses of 1200 to 1500 r (air) are given to a total of 3600 to 4500 r (air). When the lesion is more extensive the daily dose may be reduced to 500 r (air) and carried to a total dose of 5000 to 6000 r (air).

For treatment of an infiltrating and fixed lesion, particularly one in the region of the inner canthus, 140-kv to 200-kv x-rays filtered by 0.25-mm Cu and 1-mm Al are used. The treatment is fractionated.

For a lesion that has involved the bony orbit or ethmoid sinus by extension, 200-kv x-rays with 0.5-mm Cu and 1-mm Al filters are employed.

Experience with Phillips contact therapy has not been of sufficient duration to evaluate results. It appears to have a definite place in the therapeutic armamentarium available for the treatment

FIGURE 3 Protective Shields for Lesions of the Inner Canthus. A shows various sizes and shapes of paraffin-covered lead shields, designed to fit beneath the lid and over the globe. These are made by hammering of pieces of lead, 2 mm thick, between the ball and peen of a mechanic's hammer. B illustrates larger lead shields, designed to fit over the lid and globe of the eye and made in essentially the same manner. C shows old-fashioned lead nipple shields, with holes of various sizes bored in their tips, used in the treatment of lesions about the inner canthus.

of carcinoma of the eyelid although its use should probably be reserved for superficial lesions.

SUMMARY AND CONCLUSIONS

The experience with treatment of carcinoma of the eyelid at the Massachusetts General Hospital and at the Collis P. Huntington Memorial Hospital during the twelve-year period from 1933 through 1944 is summarized, and the pertinent literature is reviewed.

The study was based on 301 cases of primary carcinoma of the eyelid having an average duration of three and a half years. Sixty per cent of the lesions occurred in males, the median age of the patients was fifty-eight years. Carcinoma of the eyelid

represented an incidence of 2.5 per cent of all skin cancers observed during the same period.

The lower lid was the most frequent site of involvement, the inner canthus was the second most common. Histologic examination showed that 82 per cent of the biopsied lesions were basal-cell carcinomas, 14.5 per cent were squamous-cell tumors.

The methods and the results of treatment are analyzed, 76 per cent of patients received irradiation, and 24 per cent were treated by surgical procedures. Evaluation of the results of treatment has been based on the group of cases in which the follow-up period was three years or longer, primary failure to control the disease was manifest within three years in 86 per cent of the group. Apparent cures were ultimately obtained in 97.5 per cent of the cases. Failures from the initial treatment, however, occurred in 13 per cent, all these 29 lesions were controlled by subsequent management except 5. The secondary treatment in most cases was not the same as the primary treatment had been. The net failures comprised 2.5 per cent of the cases.

From a percentage standpoint there was nothing to indicate that the method of treatment influenced the end-results. These results have been compared with those previously published by other workers.

The chief complications of treatment were scars and defects from surgical operation requiring plastic revision and stenosis of the tear duct following radiation therapy of lesions involving the inner canthus. No cases of radiation cataract have been encountered in this clinic.

The available methods of treatment of carcinoma of the eyelid are discussed, and the technic of x-ray therapy employed at the Massachusetts General Hospital outlined.

Primary carcinoma of the eyelid when limited to the lid has an excellent prognosis if the treatment is adequate. Even in the event of initial failure to control the disease, subsequent treatment is usually successful.

Squamous-cell carcinoma of the eyelid is more refractory to treatment and results in more complications than basal-cell carcinoma, and therefore has a poorer prognosis.

In the treatment of primary carcinoma of the eyelid, good results can be obtained by any of the available methods of treatment judiciously applied. The facility of treatment by x-radiation and the excellent cosmetic and functional results that usually follow make it, as a rule, the treatment of choice.

CHLOROMYCETIN IN THE TREATMENT OF PNEUMONIA IN INFANTS AND CHILDREN*

A Preliminary Report on Thirty-Three Cases

ADRIAN RECINOS, JR, M D,† SIDNEY ROSS, M D,‡ BENNETT OLSHAKER, M D,§ AND ELLSWORTH TWIBLE, M D §

WASHINGTON, D C

CHLOROMYCETIN is an antibiotic derived from a strain of *Streptomyces venezuelae*. Its antimicrobial spectrum is broad and embraces the following organisms: rickettsia, certain viruses of the psittacosis group, gram-positive cocci (including the pneumococcus, streptococcus and staphylococcus) and certain gram-negative organisms including *Eberthella typhosa*, shigella and several of the coliform group.¹ The drug is well tolerated orally, and few toxic reactions have followed its use in therapeutic doses. Chloromycetin is readily absorbed after oral administration, and blood levels of 10 to 40 mg per 100 cc are readily obtained when 50 to 100 mg per kilogram of body weight are administered daily to children in a four-hour to six-hour divided-dosage schedule.² The drug is also absorbed moderately well after rectal administration, the level, to a first approximation, representing 20 to 50 per cent of the absorption obtained after oral administration.² In view of the insolubility of chloromycetin in water or saline solution, parenteral administration of the drug is not feasible.

The sensitivities to chloromycetin of the pneumococcus, streptococcus, staphylococcus and *Haemophilus influenzae* have been found in vitro to range between 0.5 to 5 microgm per cubic centimeter—concentrations that are readily exceeded with therapeutic doses of the drug orally. Since these organisms constitute the most common etiologic agents of bacterial pneumonia in infants and children a clinical trial of the drug in the disease appeared to be indicated. Thus, during the winter of 1948-1949, a special pneumonia ward was set up at the Children's Hospital, Washington, D C to study the efficacy of chloromycetin (as well as aureomycin) in the treatment of pneumonia. During a four-month period, 39 patients were treated with aureomycin,³ and 33 with chloromycetin. The present report deals with the results obtained in the latter group.

METHOD OF STUDY

A uniform diagnostic workup was employed in each suspected case of pneumonia. This consisted of an x-ray examination of the chest, complete blood count, nasopharyngeal and blood cultures and agglutinins for streptococcus MG and cold hemagglutinins. After this initial study, repeat chest films, blood counts and nasopharyngeal cultures were taken every two or three days during the course of therapy, and the serologic studies were performed at intervals of seven to fourteen days. Strict clinical and laboratory criteria were employed before a case was included in this study, and any patient who presented equivocal findings on admission was summarily excluded from this series.

Thirty-three patients fulfilling the established diagnostic requirements of pneumonia were treated with chloromycetin. The ages of these children ranged from four months to twelve years. Of these, 3 patients were less than six months, and 6 ranged from six to twelve months, 8 from one to two years, 5 from two to six years, and 11 from six to twelve years of age.

The 33 cases in this series, all of which were considered to be bacterial pneumonias, were classified as follows: pneumococcal 18, streptococcal 1, staphylococcal 1, and unclassified, 13. A pneumococcus was the sole or predominating organism on the nasopharyngeal cultures of the first group, a finding that was considered strong evidence that this organism represented the pathogen in the lower respiratory tract. Beta-hemolytic streptococci in large numbers were cultured from the nasopharynx of 1 patient, and *Staphylococcus aureus* was isolated from the throat and empyema fluid of another. Nasopharyngeal cultures in the other 13 cases of pneumonia yielded *Staph aureus*, *Staph albus*, *Streptococcus viridans*, *Neisseria catarrhalis* and *H influenzae*, and the cases were therefore placed in the unclassified group. This is predicated on the fact that, with the exception of the pneumococcus, the isolation of an organism from the nasopharynx is not necessarily presumptive evidence that it represents the pathogen in the lower respiratory tract.⁴ It is possible that in several of the unclassified group, the organism isolated on nasopharyngeal culture was indeed the cause of the pneumonia, particularly in the 4 cases in which

*From the Research Foundation, Children's Hospital. This study was supported by a grant to the Children's Hospital from the Antibiotic Study Section of the Division of Research Grants and Fellowships, The National Institutes of Health, United States Public Health Service, and was conducted under the auspices of the Antibiotic Committee of Children's Hospital consisting of Drs. E. Clarence Rice, Frederic G. Burke and John A. Washington.

‡Instructor in pediatrics, George Washington University School of Medicine, junior attending physician, Children's Hospital, research fellow, National Institute of Health.

§Resident, Children's Hospital.

H influenzae was the predominant organism. However, definite proof was lacking, and thus the unclassified group constitutes a singularly large percentage of the total number of cases. In spite of the inability to indict a specific organism as the causative agent, the clinical manifestations together with the roentgenologic findings and leukocytosis were all compatible with a diagnosis of bacterial pneumonia in this unclassified group.

Twenty of the 33 patients were considered to be markedly ill at the time of admission, and 8 of these required oxygen. Eleven of the remaining 13 were regarded as moderately ill, and the other 2 cases were classified as mild. The temperature at the time of initiation of chloromycetin therapy ranged from 101 to 106°F. In 27 of the 33 cases, it was above 103°F. In 16 patients (48 per cent) the white-cell count at the time of hospitalization was above 20,000, and in 15 cases it ranged from 10,000 to 20,000. Two other patients showed white-cell counts below 10,000. In each patient in this series there was demonstrable x-ray evidence of pneumonia.

DOSAGE OF CHLOROMYCETIN

Chloromycetin* was administered orally in a dosage ranging from 50 to 220 mg per kilogram of body weight per twenty-four hours, or an average of 112 mg per kilogram per day. The dosage in-

TABLE 1 Results in 33 Cases of Bacterial Pneumonia Treated with Chloromycetin

	NO OF CASES	NO OF CASES	NO OF CASES
Pneumococcal	13	5	—
Streptococcal	1	—	1
Staphylococcal	11	2	—
Unclassified	—	—	—
Totals	25	7	1

terval was usually every three hours, an occasional patient receiving the drug every four hours. The duration of therapy ranged from two to six days, with an average of four and eight-tenths days per patient. The total dose of chloromycetin ranged from 3.4 to 11.3 gm, with an average of 5.9 gm per patient.

With reference to the administration of chloromycetin orally, only in the older age group was it possible to administer an intact capsule. In infants and younger children, it was necessary to empty the contents of the capsule and, in view of the extreme bitterness of the drug, to administer it in different vehicles. These included syrup of Santa Yerba, chocolate milk, chocolate syrup,

cherry syrup, applesauce and lemon juice. Our experience in this regard indicated that mixing the drug with syrup of Santa Yerba and following it with chocolate milk was perhaps the best method of administration in small children.

RESULTS

The therapeutic effect of chloromycetin on the 33 patients with bacterial pneumonia was favorable. The over-all results (based principally on the rapidity of return to normal of clinical, roentgenologic and laboratory findings) were considered good in 25 cases, fair in 7 and poor in only 1 (Table 1). In 1 case a relapse occurred a week after the drug had been discontinued, and the patient was retreated with chloromycetin. An uneventful recovery ensued. One patient who had a staphylococcal pneumonia with an associated empyema showed no improvement with chloromycetin after forty-eight hours. Penicillin and aureomycin were then substituted, but the patient failed to improve until surgical drainage was performed.

In 20 of the 33 patients the temperature returned to normal within eighteen hours of the initiation of chloromycetin therapy (Fig 1). In 7 other patients defervescence was observed eighteen to thirty-six hours after treatment had been started. In 5 of the 6 remaining cases, the temperature was normal after thirty-six to seventy-two hours. Thus, in 32 of the 33 cases, the temperature was normal within three days of the initiation of therapy. Concomitantly, there was striking clinical improvement characterized by prompt relief of the prostration, dyspnea and cough.

The rapidity of clearing of the nasopharyngeal pathogens following initiation of chloromycetin was observed by the performance of serial nasopharyngeal cultures on each patient. The first culture was obtained at the time of admission, and two to four subsequent cultures were obtained at two-day intervals. In 9 of the 18 cases of pneumococcal pneumonia, the organism was not demonstrable after the second day of therapy. In 2 other patients, the organisms had disappeared by the fourth day. In the remaining 7, pneumococci (usually in reduced number) were still demonstrable on nasopharyngeal culture after the fourth day. Of the 4 cases in which *H influenzae* was the predominant organism on the initial culture, 3 were negative for this organism two days after chloromycetin therapy had been started. In the case in which a hemolytic streptococcus was the sole organism isolated from the nasopharynx prior to treatment, the organism disappeared two days after therapy had been begun.

An analysis of the drop in white-cell counts revealed that in 21 of the 33 patients the count had returned to normal by the third day after the initiation of chloromycetin therapy. Of ancillary interest was the observation that in several cases

*Supplied by Parke-Davis Company, Detroit, Michigan, through the courtesy of Dr. E. A. Sharp.

the white-cell count dropped below 4000 three to five days after therapy had been started. However, the leukopenia was not progressive and was not associated with any granulocytopenia. In no case was it necessary to discontinue the drug because

Chloromycetin was discontinued after 4½ days, and the patient was discharged on the 7th hospital day after an uneventful recovery. Figure 2 shows the course in the hospital.

He was examined in the follow-up clinic 2 weeks after leaving the hospital and found to be in good condition. Repeat cold hemagglutinins and streptococcus MG titers at this time were negative.

FIGURE 1 Representative Cases of Pneumococcal Pneumonia Treated with Chloromycetin

of the leukopenia. There was no concomitant reduction in red-cell or platelet count.

Serial chest x-ray films showed appreciable resolution of the inflammatory process four to seven days after chloromycetin had been started in 24 out of the 33 patients.

Data on the therapy and results in 18 cases of pneumonia are presented in Table 2. The following cases serve to illustrate the response to chloromycetin.

T.E., an 11-month-old Negro boy, was admitted to the hospital with a 2-day history of fever, progressive cough and rhinorrhea.

Physical examination revealed an acutely ill and dyspneic infant with a temperature of 104°F by rectum. Fine crackling rales were heard in the right axilla and over the right lower portion of the chest posteriorly. The remainder of the examination was essentially negative.

The white-cell count on admission was 15,400, with 73 per cent neutrophils. Beta-hemolytic streptococci were cultured from the nasopharynx. A blood culture was sterile. Cold hemagglutinins and streptococcus MG titers were negative. X-ray study of the chest disclosed a disseminated area of infiltration in the right-lung field.

Chloromycetin therapy was instituted on admission in a dose of 250 mg initially followed by 125 mg every 3 hours. The infant improved rapidly, and in 12 hours was afebrile and considerably improved clinically. The white-cell count dropped very quickly, on the 2nd day it was 6000, with 40 per cent neutrophils, and on the 5th day it was 3700 with 22 per cent neutrophils. Nasopharyngeal cultures on the 3rd and 6th days yielded no pathogens. Repeat chest x-ray examination on the 5th day revealed no appreciable resolu-

R.J., a 2-year-old Negro boy, had had a high fever, cough and anorexia 2 days before entry. These symptoms progressed during the next 48 hours, at which time hospitalization was advised.

Physical examination revealed an acutely ill child with a temperature of 104.6°F by rectum, a pulse of 136 and res-

pirations of 72 per minute. The pharynx and the right eardrum were injected. Over the left posterior portion of the chest there were dullness to percussion, increased breath sounds and fine crepitant rales on auscultation.

X-ray study of the chest disclosed a diffuse inflammatory process throughout most of the left lung indicative of bronchopneumonia.

Pneumococci were isolated from the nasopharynx, and a blood culture was sterile. The white-cell count on admission was 24,400, with 90 per cent neutrophils. Cold hemagglutinins were present in a dilution of 1:128, and streptococcus MG agglutinins in a dilution of 1:10.

The patient was placed in an oxygen tent, and chloromycetin therapy was promptly begun in a dosage of 250 mg initially followed by 125 mg every 3 hours. Clinically, the child improved rapidly and was out of the oxygen tent in 24 hours and afebrile in 36 hours. Follow-up nasopharyngeal cultures failed to grow out pneumococci. There was con-

pneumonia treated with aureomycin or chloromycetin an attempt was made at the conclusion of the study to compare the efficacy of the two drugs in the disease.

There were 18 patients with pneumococcal pneumonia who received chloromycetin, and 11 who

FIGURE 2 Results of Chloromycetin Therapy in T. E.

siderable clearing of the area of infiltration on x-ray examination within 3 days and complete resolution in 6 days. The white-cell count returned to normal in 3 days.

Chloromycetin was discontinued after 4 days, and the patient was discharged in good condition on the 8th day.

FIGURE 3 Results of Chloromycetin Therapy in R. J.

were given aureomycin orally. In both groups the age range, the duration of illness prior to the initiation of therapy and the severity of the illness were quite comparable (Table 3). On the average, the patients treated with chloromycetin received a larger dose approximating 25 mg per kilogram of body weight per dose. The disparity was rather empirical since the optimal dose of both drugs for children has not as yet been conclusively worked

TABLE 3 Comparison of the Therapeutic Efficacy of Aureomycin and That of Chloromycetin in Pneumococcal Pneumonia

DRUG	NO OF PATIENTS	AVERAGE AGE	AVERAGE DURATION OF ILLNESS BEFORE TREATMENT	MAXIMUM TEMPERATURE	AVERAGE MAXIMUM WHITE CELL COUNT	NO OF PATIENTS WITH POSITIVE X-RAY FINDINGS	AVERAGE DOSE PER 24 HOURS	AVERAGE DURATION OF TREATMENT	AVERAGE DURATION OF FEVER AFTER START OF TREATMENT	NO OF TREATMENT FAILURES
		yr	days	°F	$\times 10^3$		mg/kg of body weight	days	hr

after an uneventful hospital course. The child was still asymptomatic when seen in the clinic 1 week later. At this time, 13 days after the onset of illness, the cold-hemagglutinin and streptococcus MG titers were negative.

The hospital course is shown in Figure 3.

COMPARISON BETWEEN CHLOROMYCETIN AND AUREOMYCIN IN THE TREATMENT OF PNEUMOCOCCAL PNEUMONIA

In view of the fact that the mode of management was essentially the same in cases of pneumococcal

out. The duration of therapy in both the aureomycin-treated and the chloromycetin-treated patients ranged between three and six days, with an average of five days.

After initiation of therapy with both chloromycetin and aureomycin, a rapid defervescence ensued. In the patients treated with aureomycin the temperature returned to normal within twelve to forty-eight hours, with an average of twenty and two-tenths hours, whereas in those treated with

chloromycetin, the duration of fever following institution of therapy ranged from twelve to sixty-four hours, with an average of twenty-three hours. This difference was not statistically significant. In regard to the rapidity of clearing of the nasopharyngeal culture of its pathogen, 61 per cent of the patients treated with aureomycin no longer showed pneumococci after five days and 70 per cent of those treated with chloromycetin were negative after a similar interval. In the aureomycin-treated group the time required for x-ray resolution ranged between four and seven days, with an average of five and nine-tenths days, whereas in the chloromycetin-treated series the range varied from three to twelve days, with an average of five and three-tenths days. In both groups the response to therapy was considered good in every patient and no failures were observed.

In view of the small number of cases treated in each group, only a few limited observations may be permitted from this comparative study. In the first place there did not seem to be any statistically significant difference in the response of patients with pneumococcal pneumonia to either aureomycin or chloromycetin since both drugs were extremely effective against this infection. No toxicity was observed when chloromycetin was employed except for a transitory leukopenia in several cases. On the other hand, the triad of nausea, vomiting and diarrhea was not infrequently encountered when aureomycin was used, and oc-

asionally the drug had to be discontinued in view of the persistence of gastrointestinal irritation. As for a comparison between either of these two new antibiotics with sulfonamides or penicillin in the treatment of pneumococcal pneumonia, no categorical statement is possible at the present time in view of the limited number of cases treated.

SUMMARY

Chloromycetin was used in the treatment of 33 cases of bacterial pneumonia in infants and children.

The therapeutic effect (based principally on the rapidity of return to normal of clinical, roentgenologic and laboratory findings) was considered favorable in all but 1 patient. In 32 of the 33 cases, the temperature was normal within three days of the initiation of the drug.

Chloromycetin may be regarded as an effective drug in the therapy of bacterial pneumonia.

We are indebted to Miss Sara Stevens, B.S., M.T., and Mrs. Susan Gouge for their technical assistance and to Miss Phyllis Allred, R.N., and Miss Lucie Knies, R.N., for their help in the compilation of statistics.

RELIEF OF CHEST PAIN BY TETRAETHYLAMMONIUM CHLORIDE*

HAROLD L. ISRAEL, M.D.,† FIRST LIEUTENANT EARLE L. KEETER, M.D., A.U.S.,‡
CAPTAIN FREDERIC E. URBACH, M.C., A.U.S.,‡ AND COLONEL WILLIAM D. WILLIS, M.D., U.S.A. §

PHILADELPHIA AND PHOENIXVILLE, PENNSYLVANIA

THE intravenous administration of tetraethylammonium chloride to a patient acutely ill with thrombophlebitis and pulmonary infarction unexpectedly relieved the patient's severe pleuritic pain. As a result of this observation, the effect of tetraethylammonium administration has been studied in other patients with chest pain.

The present report concerns observations made on 35 male and 5 female patients with chest pain due to infarction, trauma, pneumonia, pleuritis, tuberculosis, neoplasm, mediastinal emphysema or myocardial infarction.

Tetraethylammonium chloride was given intravenously, each cubic centimeter of solution containing 100 mg. of the drug. Syringe injection

RESULTS

In all cases a diminution of pain was noted. In some patients the effect was slight, being manifested chiefly by ability to breathe more deeply, in others the relief was considerable although brief in duration, but in the majority relief was marked and prolonged.

The results are summarized in Table 1. Included as having experienced marked relief are patients who were completely free of pain for at least an hour and a half or almost completely free for at least four hours, the majority of patients included in this group obtained relief for considerably longer periods, and in most cases the pain did not recur in its original intensity. The degree and duration of relief seemed to be influenced by the age of the patient as well as by the nature of the lesion responsible for the pain. Patients less than fifty years of age obtained satisfactory relief more often than older patients (Table 2), but relatively few older persons were treated because of reluctance to use this drug in patients with degenerative changes.

was made slowly, while the blood pressure was being measured in the other arm, administration was suspended if the diastolic blood pressure fell, and was resumed as the pressure rose. Only in older and in debilitated patients was there usually a marked fall in blood pressure.

Originally, an effort was made to give each patient 3 or 4 cc. of solution (300 to 400 mg.). These amounts were well tolerated by young patients with acute illnesses, but in others the fall in blood pressure often permitted injection of only 2 or 3 cc. More recently, a smaller dose of 3 mg. per kilogram of body weight has been employed. No severe reactions have been encountered, and in no case has it been necessary to use neostigmine for control of circulatory collapse. Patients were kept in a recumbent position for thirty minutes after administration of the tetraethylammonium chloride, to avoid symptoms due to postural hypotension.

Application of the chi-square test failed to demonstrate a significant difference between the results in the two age groups, this may have been due in part to the small number of older patients, and additional studies will be required before definite conclusions concerning the effect of age can be drawn.

Pulmonary Infarction

Eight patients with severe pleuritic pain due to pulmonary infarction were treated. In 5, aged twenty-four to fifty-four years, with pain unrelieved by morphine, the response to tetraethylammonium chloride administration was prompt, complete and prolonged. In another patient, aged fifty-five years, the relief of pain was marked but incomplete, whereas 2 patients, aged sixty-four and sixty-six,

remained in continued pain and discomfort although local tenderness over the thorax was diminished, and it was evident that deeper respirations were possible

Traumatic Injuries

Four patients with pleuritic pain due to rib fractures were treated. Prompt and almost complete relief of pain for a six-hour period was obtained in an Army nurse, and similar relief of pain for an interval of five hours occurred in another woman with rib fractures incurred in an automobile accident. Two men, both alcoholic, experienced only slight and transient relief from tetraethylammonium chloride.

Striking results were noted in a group of 11 patients with severe pleuritic pain following diagnostic and therapeutic procedures. The pain followed aspiration biopsies of the liver in 8 patients, administration of 200-mg doses of tetraethylammonium chloride gave prompt and impressive relief in all but 1. Severe pleuritic pain following a thoracentesis was completely relieved in 1 patient. Complete relief was obtained with only 150 mg in a patient whose pleuritic pain developed after a therapeutic brachial-nerve block. Pleuritic pain occurring after a first-stage thoracoplasty in a patient with tuberculosis disappeared almost completely after a 300-mg dose, but returned to its original intensity in forty-five minutes.

Pneumonia and Pleuritis

Six patients with moderately severe pain due to pneumonia were given tetraethylammonium chloride. The relief was complete and prolonged in 2 but was only partial in the others. Two patients who had severe pleuritic pain without roentgenologically demonstrable cause, presumably cases of pleuritis, were treated. Prompt and complete disappearance of pain was obtained. One patient noted a return of slight pain in twelve hours, the other patient experienced no recurrence.

Tuberculosis

Five tuberculous patients who had chest pain only on deep inspiration and cough were treated. The results were striking only in 1, although in the others the pain on respiration and cough was diminished for an average interval of four hours.

Neoplasm

Complete relief of severe pleuritic pain for an hour and a half was obtained in a patient with rib involvement by multiple myeloma, but only slight relief occurred in a patient with metastatic sarcoma.

Mediastinal and Cardiac Disease

A young woman with severe precordial pain due to spontaneous mediastinal emphysema obtained

prompt, complete and permanent relief after administration of 125 mg of tetraethylammonium chloride. A forty-two-year-old man with acute myocardial infarction whose precordial pain remained agonizing after 25 mg ($3/8$ gr) of morphine subcutaneously and 15 mg ($1/4$ gr) intravenously obtained immediate and permanent relief after injection of 300 mg of tetraethylammonium chloride. Continuous electrocardiographic and careful clinical observation during and after administration of the drug revealed no untoward effects.

COMMENT

An action of tetraethylammonium chloride upon pleural and mediastinal pain apparently has not been previously reported. Lyons and his associates¹ noted dramatic relief of pain in 2 patients with acute myocardial infarction who were given tetraethylammonium chloride, but these investigators considered that the drug was contraindicated in the presence of coronary-artery disease. More recently, Shea and his co-workers² have reported the use of tetraethylammonium chloride for relief of cardiac pain in 16 patients with myocardial infarction or coronary insufficiency, and Christy³ has studied intramuscular administration of this drug for the treatment of angina pectoris.

The pharmacologic and physiologic implications of these observations are of considerable interest. The action of tetraethylammonium chloride is not that of a general analgesic, during its action thoracic skin sensitivity to painful stimuli is not diminished.

Tetraethylammonium chloride is known to exert appreciable psychic side effects, and a psychogenic influence cannot be excluded in the patients who appeared to obtain slight or even moderate relief of chest pain after its use. It is unlikely, however, that the complete relief occurring in patients severely ill with definite organic lesions can be considered psychogenic, especially since in many cases injections of morphine and procaine had previously been ineffectual. In fact, the action of tetraethylammonium chloride was most striking in patients who manifested the least psychologic and physiologic disturbance.

The mode of action of tetraethylammonium chloride in relieving chest pain is uncertain. Capps⁴ demonstrated that pain can be elicited by trauma to the parietal but not to the visceral pleura. The belief that pleural pain is due to irritation or inflammation of the parietal pleura and is carried through sensory fibers of the intercostal nerves has been questioned by Price,⁵ who pointed out that intercostal-nerve blocks with procaine relieved pleuritic pain for much longer intervals than were attributable to the anesthetic action of procaine. Bennett and Latham⁶ offered as an explanation the theory that the pain of pleurisy, like the pain of a sprained ankle, is due to muscle spasm, and postulated that a vicious circle was thereby initiated.

so that temporary interruption of the chain by the anesthetic action of procaine resulted in a prolonged relief. Their observation that intravenous calcium administration and curare were effective in alleviating pleuritic pain supported this theory. If pleural pain were the result of intercostal muscular spasm, the effect of tetraethylammonium chloride might be due to its curare-like activity, which however, is exerted not by a curarizing action at the myoneural junction of skeletal muscles, but by a blocking effect at the ganglionic synapse.⁷

In addition to an action on a hypothetical muscle spasm it is necessary, to explain the relief of cardiac pain, to postulate, as Shea et al.² have done, an action upon coronary-artery spasm. This does not appear to be an adequate explanation for the effect of tetraethylammonium chloride upon pain due to acute myocardial infarction, and the possibility should be considered that the relief of chest pain by tetraethylammonium chloride is the result of a direct action on sensory pathways, interrupting afferent flow either at nerve ending, at synapse or centrally. Evidence suggesting a direct action upon sensory pathways has recently been provided by the observation of Sonnenschein, Jenny and Pfeiffer⁸ that alterations in pain thresholds of the finger pads and nail beds are produced by administration of tetraethylammonium chloride.

The cardiovascular effects of tetraethylammonium chloride limit the application of the drug for relief of chest pain, especially in older patients. Tetraethylammonium chloride is a drug that must be used with caution in patients with hypertension or arteriosclerosis, and should not be used in patients with high diastolic pressures or impaired renal function. The alarming or fatal reactions reported have followed use of high dosages⁹ or rapid administration,¹⁰ although a profound reaction occurred in a young woman after injection of only 230 mg.¹¹ Serious reactions appear to be infrequent, however, when small doses are administered with care. Naide¹² has observed no severe reactions in the course of 1000 injections in ambulatory patients. He administered 200 mg or less in patients under fifty years of age, but determined the dosage in patients over the age of fifty by response to a test injection of 50 mg.

Use of tetraethylammonium chloride should afford little danger to hospital patients free of advanced renal or cardiovascular disease when used at the rate of 3 mg per kilogram of body weight. The value, especially in patients with pulmonary disease, of an analgesic agent that does not, like morphine, suppress cough and encourage atelectasis is evident. Tetraethylammonium chloride in low dosage provides a method of treatment worthy of trial in patients with severe chest pain not relieved by small doses of codeine or meperidine.

SUMMARY

Tetraethylammonium chloride administered intravenously in relatively small dosage has been observed to relieve chest pain due to a variety of conditions, including pulmonary embolism, trauma, pneumonia, pleuritis, tuberculosis, neoplasm, mediastinal emphysema and myocardial infarction. Relief was notably complete and prolonged in patients with pain due to infarction and trauma. These results appear to justify a further trial of tetraethylammonium chloride for the treatment of severe chest pain.

THEPHORIN OINTMENT IN PRURITIC DERMATOSES

CHARLES S D'AVANZO, M D *

SPRINGFIELD, MASSACHUSETTS

SINCE the report of Fournau¹ and his French associates, there has been a widespread interest in the use of the so-called antihistaminics or histamine antagonists for diseases with an allergic background. Until quite recently, the antihistaminic drugs have been administered orally with good effect, especially in certain dermatoses such as the acute urticarias and urticarial drug reactions and some of the physical allergies.

The success achieved with the oral administration of the antihistaminic drugs in the allergic type of dermatoses led to their topical use in similar diseases. In 1947 Mayer² reported experimental evidence that the local application of 5 per cent triplennamine hydrochloride (Pyribenzamine) protected guinea pigs against epidermal sensitization to subsequent applications of paraphenyldiamine. Shortly thereafter, Feinberg and Bernstein³ used 2 per cent Pyribenzamine ointment in 33 cases of atopic dermatitis and stated that 24 of these patients noted consistent relief from the use of the ointment. At the same time, Sulzburger and his associates⁴ reported that the local use of Pyribenzamine cream was of

ment had good to excellent results in 55 per cent of his cases of atopic dermatitis, 75 per cent of lichen chronicus simplex and 60 per cent of miscellaneous pruritic dermatoses. Shelmire also noted a 13 per cent sensitization index in his series of cases and stated that Thephorin ointment was far superior to Pyribenzamine ointment in his experience.

In their series of cases, Laymon and Schmid found that Thephorin ointment had moderate to excellent results in 73.5 per cent of cases of circumscribed neurodermatitis. Their results in atopic dermatitis were as follows: excellent, 0; moderate, 55.5 per cent, and worse, 44.5 per cent. In their cases of miscellaneous pruritic dermatoses, they reported excellent results in 43 per cent and moderate improvement in 57 per cent of the cases.

PERSONAL EXPERIENCE WITH THEPHORIN OINTMENT

Because of the marked difference of opinion concerning the therapeutic value of the topical use of Thephorin ointment in so important a group of pruritic dermatoses, the study of the problem

TABLE 1 *Results of Treatment with Thephorin Ointment*

DIAGNOSIS	TOTAL No. OF CASES	INITIAL RESULTS			SUBSEQUENT RESULTS*		
		GOOD TO EXCELLENT	SLIGHT TO FAIR	NO EFFECT	PATIENT WORSE	REFRACTORY CONDITION	SENSITIZA- TION
Neurodermatitis disseminata	24	0	8 (33%)	10 (42%)	6 (25%)	6 (25%)	2 (8%)
Lichen chronicus simplex	26	10 (39%)	6 (23%)	10 (39%)	0	2 (8%)	0
Chronic dermatoses with pruritus	24	10 (42%)	2 (8%)	11 (50%)	0	4 (17%)	2 (8%)

*Improved patients.

distinct value only in lichen chronicus simplex and was of no value in atopic dermatitis.

In August, 1948, Woodridge and Joseph⁵ reported the local use of 2-methyl-9-phenyltetrahydro-1-pyridindene (Thephorin) in disseminated neurodermatitis. They used a 5 per cent ointment of Thephorin in a carbowax vehicle. Of 23 cases of neurodermatitis disseminata, Woodridge and Joseph stated that 9 (39 per cent) showed 75 per cent or more clearing and 8 (35 per cent) showed 50 per cent clearing. Thus, approximately 74 per cent of these patients were much improved with Thephorin. However, most of them also took Thephorin orally.

Later in 1948, Shelmire⁶ and Laymon and Schmid⁷ reported the use of Thephorin locally in pruritic dermatoses. Shelmire stated that Thephorin oint-

ment was undertaken. It was decided that, for a report of this nature to be of utmost value, the patients reported upon should be carefully followed over a period of months by the same observer. In this way, one could evaluate the results of the medication more exactly, and also determine whether any of the patients became resistant or sensitized to the topical remedy. All the patients were observed for a period before treatment with Thephorin ointment was instituted, to establish a definite diagnosis and to eliminate any cases that cleared up spontaneously.

In all, this report covers 74 cases. Of these, 24 were neurodermatitis disseminata, 26 were lichen chronicus simplex (neurodermatitis circumscripta) and 24 were miscellaneous dermatoses associated with pruritus. The group of neurodermatitis disseminata included typical cases of atopic dermatitis and allergic infantile eczema. The mis-

*Attending dermatologist, Mercy Hospital; consulting dermatologist, Springfield Municipal and Noble hospitals.

cellaneous group of chronic dermatoses associated with pruritus included typical cases of so-called nummular eczema. The results of treatment are shown in Table I.

DISCUSSION

Most of the cases of neurodermatitis disseminata did poorly with Thephorin ointment. Six of the 8 patients in whom there had been an initial slight to fair improvement subsequently became refractory to the ointment, and 2 of these patients became sensitized. A good percentage of the patients definitely became worse with the use of Thephorin ointment.

Thirty-nine per cent of the patients with lichen chronicus simplex were very much improved. Two (8 per cent) of these became refractory on continued use of the ointment.

Approximately half the miscellaneous group of chronic dermatoses associated with pruritus were improved with Thephorin ointment. Four (17 per cent) of these improved cases became refractory to the ointment, and 2 patients (8 per cent) became definitely sensitized.

CONCLUSIONS

Thephorin ointment is of very little use in neurodermatitis disseminata.

Thephorin ointment is of real therapeutic value in lichen chronicus simplex (neurodermatitis circumscripta) and chronic dermatoses associated with pruritus.

About half the patients with initial improvement became refractory to continued use of the ointment.

Thephorin ointment has a sensitizing index of 16 per cent.

THE USE OF WETTABLE DDT IN PEDICULOSIS

GEORGE E. MORRIS, M.D.*

BOSTON

MANY forms of therapy have been advocated for the control of the various types of infestation with pediculi. These have varied from the innocuous vinegar rinses to the more toxic derivatives of the benzene ring. Many of them are objectionable to the patient because of odor or difficulty of use. Not a few are severe skin sensitizers, and some are metabolic poisons.

With the advent of DDT, a new potent pediculicide was available and was used extensively as a powder by the armed forces. For the past two years, I have been using a "wetable DDT" in my practice with unprecedented success.

The wettable DDT that has been used is the type that is available through farm and seed stores and many gasoline stations. It is used by farmers, horticulturists, and others for the control of animal parasites of plant life. It is a fine, silky-smooth, white, fluffy powder, available in strength of 55 per cent active ingredient. When mixed with water, it forms, on agitation, a soapy emulsion that is very effective in the eradication of lice.

The patient is advised to wet the parts affected with water that is, the scalp hair in pediculosis

capitis, the pubic and axillary hair in pediculosis pubis and the clothing in pediculosis corporis — and then to make a lather with the wettable DDT powder. The lather is allowed to stay on the parts for fifteen minutes and then is washed out with water. One such treatment will kill all lice, but will not affect the nits or ova that contain unhatched lice. Since the remaining nits will hatch into live lice within two weeks,[†] it is necessary to repeat this fifteen-minute treatment once weekly for three weeks. The second weekly treatment will kill all the lice that have hatched from the first day to the seventh day and the third weekly treatment will kill all that have hatched from the seventh to the fourteenth day. Since it takes a louse eleven to thirteen days to mature, and since a louse less than eleven days old is unable to copulate and lay eggs,[‡] it is at once obvious that with this method of treatment, no nits will be laid down after the first treatment. Since nits hatch within fourteen days, it is evident that by the third treatment (the fourteenth day) all the eggs originally present will have hatched and no further lice will be produced from

*Instructor in dermatology, Tufts College Medical School; junior visiting physician in dermatology, Boston City Hospital; assistant in dermatology, St. Elizabeth's Hospital.

[†]Craig C. F. and Faust, E. C. *Clinical Parasitology*. Fourth edition. 871 pp. Philadelphia: Lea & Febiger, 1945.

them by the end of the fourteenth day (third day of treatment)

Itching is relieved immediately after the first treatment (unless there is a dermatitis, pyogenic infection or scabies complicating the picture)

No dermatitis has resulted from this exposure to DDT, nor have there been any toxic metabolic manifestations. It is a simple procedure and is especially time and labor saving.

The following, a simple, large-scale scheme, will eradicate all lice from institutions, such as orphanages and hospitals for the care of patients with chronic disease, that are plagued by such infestations. All persons in the institution (including not only the inmates but all the personnel of the institution that are affected) are treated once weekly for three weeks. All new patients are given the same treatment for the first three weeks of their hospitalization. This eradicates the infestation and prevents any new patient from bringing in the disease again.

If wettable DDT is not available, a satisfactory substitute is a paste of equal parts of 55 per cent regular DDT powder with one of the newer synthetic shampoos or detergents, such as Drene, Halo,

Vel and Phisoderm, or a powder from equal parts of regular DDT and Dreft, Swerl and so forth. This paste or powder is used in the same manner as the 55 per cent wettable powder.

Approximately, 15 gm (1 tablespoonful) of wettable powder will be sufficient for the average male scalp and about 60 gm (4 tablespoonfuls) for the average female scalp, 15 gm is sufficient for each treatment of pediculosis pubis, and about 120 gm for that of a tubful of clothing. In pediculosis corporis a single treatment of the clothing followed by ironing with a hot iron is sufficient to eradicate the disease.

It is important to treat all the infected members of the household at the same time.

SUMMARY

Wettable DDT powder (55 per cent) is an effective remedy for pediculosis.

Its use is simple, clean and economical.

A method of therapy is presented for the eradication of lice in large institutions as well as in individual cases.

WALTER B. FROMMEYER, M.D.,† and ROBERT D. EPSTEIN, M.D.‡

BIRMINGHAM, ALABAMA, AND YONKERS, NEW YORK

CLOTTING TIME OF RECALCIFIED PLASMA — "RECALCIFICATION TIME"

Principle

If an optimal amount of calcium is added to oxalated plasma, containing an optimal number of platelets, coagulation results, and the time required for clotting has been termed the "recalcification time." Such a recalcification time depends on the concentrations of the various factors necessary for coagulation, including the blood platelet. In essence, it is a measurement of the coagulation time of plasma.

Method

A sample of 4.5 cc of venous blood is mixed with 0.5 cc of 0.1 molar solution of potassium oxalate.

*Adapted from *A Syllabus of Laboratory Examinations for Clinical Diagnosis* (in press) by permission of the Harvard University Press.

From the Thorndike Memorial Laboratory and the Second and Fourth Medical Services (Harvard) Boston City Hospital and the Department of Medicine Harvard Medical School.

†Instructor in medicine Medical College of Alabama University of Alabama.

‡Assistant in medicine University Hospital New York University—Bellevue Medical Center clinical assistant physician St. Joseph's Hospital Yonkers New York.

The blood is centrifuged§ at 1000 rpm for five minutes, and the plasma removed. Then, 0.1 cc of this plasma is added to a 10 by 75 mm test tube without a lip, and the tube is placed in a water bath at 37.5° C. To the plasma is added 0.2 cc of 0.025-molar calcium chloride solution, a stop watch is started, and the contents are gently mixed. The tube is observed for coagulation at sixty seconds and every fifteen seconds thereafter, *the tube being kept in the water bath with as little agitation as possible*. The end point is complete coagulation of the plasma. The normal range of coagulation time with plasma centrifuged at 1000 rpm for five minutes is 90 to 120 seconds.^{79¶}

Limitations and Interpretations

In general it can be said that any condition associated with prolongation of coagulation of whole blood is also associated with prolongation of the clotting time of recalcified plasma. Such prolonga-

§The platelet content of plasma centrifuged under these conditions is 350 to 800 × 10³/mm³; an optimal number thus being insured when the platelet count of the whole blood is normal.

¶Note that the coagulation time of recalcified plasma is more rapid than that for whole blood; the mechanism of this is unknown.

tion is nonspecific and not indicative of any single disorder, and the interpretation of results is essentially the same as for the coagulation of whole blood. The primary point of difference between the coagulation time of recalcified plasma and the coagulation time of whole blood is the profound effect platelets have on the former and the slight effect on the latter when observed in glass tubes.

In severe *thrombocytopenia* the recalcification time is prolonged, such prolongation being directly proportional to the total number of blood platelets. The critical level of platelets at which prolongation occurs is about $100 \times 10^3/\text{mm}^3$ of plasma with the direct method of counting. This would correspond to a platelet count of 50 to $60 \times 10^3/\text{mm}^3$ of whole blood*. Thus, it is evident that the platelet count must be rather severely depressed before an alteration in recalcification time occurs. Prolongation of the recalcification time is also seen in hemophilia, *parahemophilia* (lack of "Factor V")¹² and *afibrinogenemia*. In *scurvy* and *thrombasthenia* the recalcification time is normal. Thus, it becomes evident that prolongation of the recalcification time may result from a deficiency of platelets and a deficiency of one or more of the factors of plasma necessary for coagulation.

SCREENING TESTS FOR ABNORMAL COAGULATION OF BLOOD

Principle

When mixtures are made of whole unaltered venous blood from a patient and from a normal subject, the coagulation time may be used as a screening test to detect abnormalities of the clotting mechanism. For example, in coagulation defects resulting from a *deficiency of a plasma factor*, the addition of normal blood may restore the coagulation time toward normal. This may occur in conditions such as hemophilia, afibrinogenemia and deficiency of "prothrombin accelerator" substances. Conversely, in cases of *circulating anticoagulant*, the addition of the patient's blood to that of the normal subject will prolong the coagulation time of the normal blood, as in heparinemia and other conditions with circulating anticoagulants of undetermined nature.

Technically, mixtures may be made of samples of whole unaltered blood or of oxalated plasma with subsequent recalcification of the plasma. Because of the convenience of handling oxalated plasma, it is more frequently used.

Methods

Mixtures of whole blood. Two 10-cc sterile syringes and needles are rinsed with sterile saline solution, and 3 cc of sterile saline solution is then placed in each syringe. Simultaneous venipunc-

tures are performed on the patient suspected of abnormal coagulation and on a normal subject. The saline solution† is then injected at the same time and same rate into each subject. A stop watch is started, and 10 cc of venous blood is withdrawn from each subject at the same rate. Mixtures are then made of the blood of the patient and that of the normal subject by gentle transfer of samples to six saline-rinsed culture tubes without lips (13 by 100 mm) in the amounts shown in Table 2.

In this system the coagulation times are determined for the whole bloods of both subjects as well as for mixtures.

Mixtures of oxalated plasma. Reagents Potassium oxalate is used as an anticoagulant. One makes a

from a normal subject, each sample is accurately added to 0.5 cc of 0.1-molar solution of potassium oxalate and thoroughly mixed. The plasma is obtained by centrifugation of the oxalated whole blood at 1000 rpm for five minutes. Centrifugation is done simultaneously in the same centrifuge, thus ensuring the same speed of centrifugation for an

*When blood is centrifuged at 1000 rpm for five minutes the platelets are concentrated in the plasma layer being separated from the red cells.¹¹

†This step permits each operator to synchronize his obtaining of a blood sample and serves to decrease contamination of blood by tissue juice.

‡There is no need to perform venipunctures simultaneously and blood samples can be handled without hurry.

identical period for the two plasmas. The plasmas are mixed in a series of six dry culture tubes without lips (10 by 75 mm) in the amounts shown in Table 3, and the contents of each tube is mixed by inversion. Then 0.1-cc samples of each tube are transferred to separate dry culture tubes without lips (10 by 75 mm) and the tubes are placed in a water bath at 37.5°C. The coagulation times of recalcified mixtures of plasma and of each subject's plasma are then determined in duplicate, as described above, by the addition of 0.2 cc of 0.025-molar solution of calcium chloride.

Limitations and Interpretations

The technical limitations of these procedures are identical to those for the determination of the coagulation time. It is important to execute an immediately successful venipuncture on each subject so as to reduce to a minimum contamination of the blood with tissue juice. By the injection of 3 cc of sterile saline solution contamination is further reduced. A small amount of tissue juice will grossly accelerate blood coagulation and obscure mild plasma defects or mild anticoagulant activity. When mixtures of oxalated plasma are used as a screening test for abnormal coagulation it is essential that the speed and duration of centrifugation be identical for both samples, since marked reduction in the number of platelets will result in prolongation of the coagulation time of recalcified plasma.

In any condition in which there is a deficiency of one or more of the plasma components necessary for proper coagulation there is prolongation of the coagulation time. By addition of plasma factors to the abnormal blood, in the form of unaltered whole blood or plasma, the coagulation time of the abnormal blood is reduced toward normal. Thus, in such conditions as *hemophilia*, *fibrinogenopenia*, *afibrinogenemia*, *severe hypoprothrombinemia* and *parahemophilia*, the procedures outlined above will give normal coagulation times in all tubes except No. 1, in which the coagulation time will be variously prolonged depending on the severity of the plasma defect. In cases of deficiency of plasma factors the coagulation time of mixtures of whole blood or of mixtures of recalcified plasma will *not* be prolonged. Once a plasma defect is discovered, it becomes necessary to determine its nature more specifically; detailed methods are described by Owren.¹⁹

Abnormal coagulation as the result of *anticoagulant activity*, however, characteristically results in prolongation of the coagulation time of mixtures of whole blood and of recalcified plasma (prolonged in tubes No. 1 to 5 in Table 2 and 3). As the concentration of abnormal blood or of plasma is increased in the mixtures greater prolongation of the coagulation time results. Once such anticoagulant activity is demonstrated, an attempt must be made to determine the type of anticoagulant that is present. This is done by diagnostic

procedures involving the use of special reagents that are, as a rule, only available for research purposes. Therefore, reference should be made to the methods for determination of *antithrombin* and *antithromboplastin* as outlined by Quick.¹ *Hyperheparinemia* as a cause of abnormal coagulation has recently been shown to occur with *ionizing radiation*¹¹ in *leukemia*¹² and in certain cases of *thrombocytopenia*.¹² The method of determining the degree of hyperheparinemia consists in adding a natural antiheparin (protamine sulfate) in increasing amounts to accurately heparinized venous blood and determining the amount of protamine required to reduce the coagulation time of the heparinized blood to normal. A normal control is always used for comparison (Allen et al.¹³).

By determination of the coagulation time of mixtures of whole blood or oxalated plasma, it is thus possible to differentiate plasma defects from circulating anticoagulants as cause of abnormal coagulation. Once such a distinction has been made it is necessary to carry out special procedures for the more specific identification of the defect or anticoagulant.

DETERMINATION OF PROTHROMBIN ACTIVITY

Principle

When optimal amounts of thromboplastin and calcium are added to citrated plasma, the factor measured is the speed of conversion of prothrombin to thrombin if other abnormalities* can be excluded. The time required for this conversion has been measured quantitatively as an arbitrary and biologic test in which the clotting time of the plasma becomes a measurement of its prothrombin activity. Measurement of prothrombin activity of plasma has become an important laboratory examination because it has important diagnostic and prognostic significance in diseases of the liver and in hemorrhagic diatheses and because the use of Dicumarol in the treatment of thromboembolic disease requires careful control of the prothrombin level, since death may occur from hemorrhage due to extreme hypoprothrombinemia.

Accordingly, the method of determining prothrombin activity in terms of its concentration in percentage of normal is of importance. The method of Quick¹ is a standard one-stage procedure and is described below in detail. Many modifications of this technic have evolved. One such modification, using dilution of the plasma with prothrombin-free plasma,³⁵ is known to give a high degree of accuracy and is also described below. The more complete two-stage method³⁶ is too demanding for clinical purposes; in essence, this method measures quantitatively the amount of thrombin formed from prothrombin.

*Rarely there may be fibrinogenopenia or afibrinogenemia, deficiency of prothrombin accelerators or a circulating anticoagulant.

Quick Method

Reagents A 0.1-molar solution of sodium citrate is used as an anticoagulant. It is made by dissolving of 29.412 gm of sodium citrate ($\text{Na}_3\text{C}_6\text{H}_5\text{O}_7 \cdot 2 \text{H}_2\text{O}$) in 1000 cc of distilled water, 10 cc of this solution is used to prevent coagulation of 90 cc of whole blood.

Thromboplastin is prepared by the addition of 4 cc of a sterile solution of sodium chloride (0.85 gm per 100 cc) and 0.05 cc of a solution of sodium oxalate (1.34 gm per 100 cc) to one ampoule (0.15 gm) of lyophilized rabbit brain (Difco) that has been extracted with acetone. This mixture is incubated at 48°C for ten minutes, with agitation every three minutes. Large particles of rabbit brain are then removed from the mixture by "filtration" through cotton: a small piece of cotton is loosely placed over the tip of a 20-cc volumetric pipette, the cotton-covered tip of the pipette being immersed in the emulsion and gentle suction applied. One should not centrifuge or filter through paper.*

FIGURE 1 Effect of Three Different Diluents of Normal Human Plasma on the Prothrombin Time in Seconds¹⁸ (The Method of Rosenfield and Tuft⁵⁸ as Modified by Alexander and deFries,⁴⁰ Uses Prothrombin-Free Human as a Diluent, Frommeyer¹⁸ Uses Prothrombin-Free Bovine Plasma)

When used as a chart for the conversion of prothrombin time (seconds) to prothrombin concentration (per cent), the activity of the thromboplastin must be determined by replotting of the curve whenever the thromboplastin is changed.

Thromboplastin as thus prepared is quite stable for many weeks if kept frozen (-20°C) in 0.1-cc aliquots in standard culture tubes (10 by 75 mm) until ready for use. The potency of the thromboplastin is an essential element of the procedure and is standardized for each aliquot of material, as described below.

Calcium chloride, 0.025-molar solution, is made as described above under screening tests for abnormal coagulation.

Technic All tubes and reagents are maintained at 37.5°C in a water bath. To 0.1 cc of thrombo-

plastin solution in a standard culture tube with lip (10 by 75 mm) 0.1 cc of citrated plasma is accurately added. The tube is gently shaken to ensure mixing. With stop watch in hand, exactly 0.1 cc of calcium chloride (0.025-molar) solution is added, and at the same instant the stop watch is started. The tube is held in the water bath, and the contents are gently mixed. A few seconds before clotting is anticipated, the tube is removed from the water bath, held in a horizontal position and moved gently back and forth. Clotting of the plasma is the end point, it is taken as occurring at the instant at which the plasma is no longer completely fluid. This procedure is repeated as a check, and the second determination should agree with the first within half a second to one second to be considered accurate. The prothrombin time is recorded in terms of seconds. With knowledge of the prothrombin time, it is possible, by means of a prothrombin-time-concentration curve (Fig. 1), to determine the value in terms of percentage of normal.

Determination of Prothrombin by Means of Dilution with Prothrombin-Free Plasma

The problems in determining prothrombin by the Quick method may be largely resolved by the use of a modification⁴⁰ of the method of Rosenfield and Tuft⁵⁸.

Principle The principles of the method are as follows: the prothrombin time is determined on a sample of citrated plasma by the usual method of Quick to estimate the activity of the sample, and the citrated plasma is then diluted with prothrombin-free normal plasma. Dilution with prothrombin-free plasma is necessary if the prothrombin time is relatively short, corresponding to a prothrombin concentration of 30 per cent or more. It is immediately apparent from inspection of Figure 1 that a difference of a few seconds in prothrombin time in this range of the curve is equivalent to large differences in the concentration of prothrombin. For example, in Figure 2 a prothrombin time of fourteen seconds corresponds to 30 per cent prothrombin, whereas thirteen seconds corresponds to an apparent concentration of 45 to 100 per cent. Manifestly, there are two technical limitations of this method that make it unsound: the concentration cannot be read accurately on the steep part of the curve, and small errors of estimating the end point may be greatly magnified when the time in seconds is converted to concentration. To remove these limitations, the plasma is diluted so that the prothrombin concentration of the mixture will be approximately 10 per cent of normal, as shown in Figure 2, thus permitting observation of the prothrombin time in part of the curve in which the deviation of a few seconds produces insignificant changes in apparent prothrombin concentration. *Dilution with saline solution cannot be recommended since all clotting factors are thereby diluted.*

*The thromboplastin solution is a milky-appearing emulsion. Removal of the small particulate matter will remove most of the thromboplastin activity.

Reagents Thromboplastin and calcium chloride solution are prepared as described above. Potassium oxalate is used as an anticoagulant since oxalated plasma can be depleted of its prothrombin, whereas citrated plasma cannot. A 0.1-molar solution of potassium oxalate is made as described above under screening tests for abnormal coagulation, 10 cc of this solution is used to prevent coagulation of 90 cc of whole blood.

Adsorption of prothrombin Prothrombin is readily adsorbed by the addition for each 10 cc of oxalated plasma, of 100 mg of powdered barium sulfate. The mixture is shaken, incubated for ten minutes at 37.5°C with agitation every three minutes, and centrifuged at 3000 rpm for thirty minutes, the supernatant is poured off and put in the refrigerator at 4°C until ready for use. The prothrombin-free plasma should be used within 2 hours of its preparation and kept in the refrigerator during this period. This disadvantage can be overcome by lyophilizing of large quantities of prothrombin-free normal plasma and reconstitution of this plasma with buffered distilled water immediately prior to use.⁴⁸ According to Owren¹⁹ 50 per cent of "Factor V" is also removed by the barium sulfate adsorption of prothrombin although the amount used is not stated. This can be obviated by the use of prothrombin-free ox plasma as the diluent, since it is rich in "prothrombin accelerators."

Preparation of time-concentration curve In each laboratory a curve, such as that shown in Figure 1, must be prepared to determine the activity of the available thromboplastin for the conversion of prothrombin time to prothrombin concentration in percentage. The time-concentration curve is derived with prothrombin-free plasma, rather than physiologic saline solution, as the diluent of fresh normal plasma. The principle of the method is to collect and pool equal quantities of plasma from at least 5 to 10 normal subjects (preferably young males), 1 part of 0.1-molar solution of potassium oxalate being used for 9 parts of venous blood. A portion of the pooled plasma is treated with barium sulfate to remove prothrombin. With this prothrombin-free plasma as a diluent, the fresh pooled plasma is diluted serially to known concentrations of fresh plasma and the prothrombin time of each dilution determined as described below. From the known concentrations and times, a conversion curve is plotted as in Figure 1.

Technic of measuring prothrombin with prothrombin-free plasma A sample of 4.5 cc of venous blood is withdrawn and mixed with 0.5 cc of 0.1-molar solution of sodium citrate. This blood is centrifuged and the plasma removed. The prothrombin time of the undiluted sample of plasma is determined, the method of Quick, as outlined above being employed as the first step. If the prothrombin time is so short as to represent a prothrombin concentration of 20 to 30 per cent or more the prothrombin concen-

tration cannot be read accurately enough from the curve for proper reporting. The plasma is then diluted as described below.

As a second step, the plasma is diluted with prothrombin-free normal plasma so that the prothrombin concentration will be approximately 10 per cent of normal. The prothrombin time is then determined for the diluted sample, and the corresponding concentration in per cent is read from the curve, the

FIGURE 2 Chart for Conversion of Prothrombin Time (seconds) to Prothrombin Concentration (Per Cent)

The curve is made by dilution of a pool of fresh normal plasmas, prothrombin-free normal plasma being used as a diluent. This is the method of Rosenfield and Tuft,³⁰ as modified by Alexander and deLies.⁴⁰ The curve will vary with the activity of the thromboplastin and must be remade when the thromboplastin is changed.

concentration is then multiplied by the dilution factor and reported in terms of percentage.

As an example the prothrombin time of an undiluted sample of plasma is 13 seconds, corresponding to concentrations of prothrombin of from 40 to 100 per cent. The plasma is diluted, — 1 part of fresh citrated plasma with 9 parts of prothrombin-free plasma, — and the prothrombin time determined. If the time is twenty-eight seconds, this corresponds on the curve to a prothrombin concentration of 10 per cent, this is multiplied by 10 to correct for dilution, giving a final value of 100 per cent for the concentration of prothrombin.

Limitations and Interpretations

Many of the time-concentration curves for prothrombin that are reported in the literature have been prepared from *saline* dilutions of plasma. Such dilutions diminish the amount of other factors necessary for coagulation and will show erroneously delayed prothrombin times, which may not be reliable or accurate in the determination of prothrombin concentrations in the range of 30 to 100 per cent of normal. If prothrombin-free plasma is used as a diluent, as described above, more reproducible time-concentration relations are obtained since all elements essential for coagulation have been preserved, with the possible exception of a part of the "prothrombin accelerators" mentioned above.^{19, 46, 51, 55} This difficulty can be obviated by the use of lyophilized prothrombin-free ox plasma, which contains an excess of all these substances. The determination of prothrombin on plasma diluted to a 10 per cent concentration with prothrombin-free ox plasma permits a new order of *reproducibility* and *accuracy* and makes obsolete methods that attempt to interpret differences of one or two seconds that are equivalent to 50 per cent difference in prothrombin concentration.⁵⁸

The use of *Dicoumarol* to prevent the complications of thromboembolic phenomena has required a wide clinical application of the determination of prothrombin concentration. *Dicoumarol* presumably prevents the formation of prothrombin by the liver. Excessive administration produces a severe hypoprothrombinemia and a hemorrhagic tendency. The dosage is controlled by observation of the prothrombin time. Usually, it has been considered necessary to keep the prothrombin time approximately thirty to forty seconds, or the concentration between 4 and 8 per cent of normal, to prevent thrombotic phenomena.

The prothrombin determination is of value in detecting the absence of prothrombin as a cause of hemorrhagic diathesis and in the study of response to vitamin K therapy.

In diagnosis the interpretation of the prothrombin time requires a knowledge of factors other than prothrombin deficiency that may cause prolongation, and a knowledge of the sources of error in the test. A prolonged prothrombin time by Quick's method is found in *afibrinogenemia* even though the prothrombin concentration may be entirely normal as determined by the dilution method using prothrombin-free plasma as a diluent. In addition, deficiencies of "prothrombin accelerators" result in prolongation of prothrombin time unless the dilution method using prothrombin-free plasma is employed. The prothrombin concentration is usually normal in the other hemorrhagic diseases as shown in Table 1.

PROTHROMBIN CONSUMPTION

Principle

When unaltered normal venous blood is placed in a test tube, as in the determination of the coagulation time, clotting will normally occur within six to twelve minutes. When the clot is allowed to remain undisturbed for one hour after initial coagulation so as to ensure maximum coagulation, serum is expressed. The serum contains variable amounts of prothrombin, calcium, thrombin and serum "prothrombin accelerators," but *no fibrinogen*. Within two or three hours the thrombin present is converted to an inactive form, metathrombin. Various intervals are required for inactivation of the serum "prothrombin accelerators," but it appears likely from the available data that essentially complete inactivation occurs within twelve hours at a temperature of 37.5°C.^{19, 60, 64} Such serum will then contain prothrombin and calcium. If this serum is added to a mixture of thromboplastin, fibrinogen and calcium, clotting will usually occur. The time required for clotting of this mixture becomes a function of the prothrombin that was not used (consumed) in the formation of the clot and that remains in the serum. Apparently, the prothrombin is the major variable in such a reaction mixture, and thus a prothrombin time and prothrombin concentration are obtained from the clotting time. The difference between the original plasma concentration time and the residual serum concentration of prothrombin is termed the "prothrombin consumption." The technic of the test is that used by Quick,⁶⁵ with the exception that prothrombin-free human plasma is used as a source of fibrinogen rather than prothrombin-free rabbit plasma.

Modified Quick Method for Prothrombin Consumption

Reagents Thromboplastin and calcium chloride solution and prothrombin-free human plasma are prepared as described above.

Technic Venous blood is allowed to coagulate according to the method described above. The clotting time is noted. One hour after initial coagulation the tubes are centrifuged at 800 rpm for five minutes, the serum is removed and kept at 37.5°C for twenty-four hours.* A "prothrombin time" is determined as follows: to a mixture of exactly 0.1 cc of thromboplastin, 0.1 cc of prothrombin-free human plasma and 0.1 cc of 0.025-molar solution of calcium chloride is quickly added 0.1 cc of the unknown serum. A stop watch is started immediately upon addition of the serum to the mixture. The contents of the tube are shaken gently, and the instant the mixture is no longer *completely* fluid is taken as the end point. The prothrombin concentration can then be determined from the prothrom-

*Although serum is bacteriostatic a sterile technic may be employed without increasing greatly the difficulty of the procedure.

bin time in seconds, as outlined above. This procedure is done at one, three and twenty-four hours after coagulation.

Limitations and Interpretations

The limitations of a one-stage method for measuring prothrombin time are the same as those described above. However, the difference in prothrombin consumption between the normal and abnormal is so large that these technical limitations are of secondary importance. The method for determination of prothrombin concentration described by Rosenfield and Tuft⁵⁸ may be used, however, if desired. Biologic limitations exist, in that serum contains active "prothrombin accelerators" that govern the speed of the coagulation reaction and therefore the prothrombin time. There still remains considerable doubt concerning exactly when these "accelerators" become inactivated in serum that is stored at 37.5°C. From the available literature^{19, 60} the impression is gained that such inactivation is relatively rapid, there being little evidence of "prothrombin-accelerator" activity at the end of three hours of storage at room or water-bath (37.5°C) temperatures. On the other hand, one investigator⁶¹ reports 80 to 83 per cent activity after four hours of storage at 37.5°C. Because of the presence of active serum "prothrombin accelerators" as well as thrombin in the serum at one and three hours after coagulation, determinations of prothrombin concentration at these times are very difficult to evaluate. After a storage interval of twelve hours at 37°C, however, it is quite likely that the serum "prothrombin accelerators" are completely inactivated. By the use of prothrombin-free human plasma as a source of fibrinogen in the procedure, it is possible to maintain a relatively constant amount of available "prothrombin accelerators" in each reaction mixture after twelve hours of incubation of the serum.

By the procedure described, normal serum is found to have a residual prothrombin concentration of 10 to 20 per cent (80 to 90 per cent prothrombin consumption).

In *hemophilia* the serum has a prothrombin concentration of 80 to 100 per cent, and hence a low prothrombin consumption (0 to 20 per cent). Such a finding confirms the theory that in hemophilia prolonged coagulation is the result of improper formation of thrombin from prothrombin. That hemophilic blood ultimately coagulates is explained⁶² on the basis that a small amount of prothrombin is eventually converted to thrombin over a prolonged period. Since thrombin is enzymatic in action, even a small amount is capable of converting fibrinogen to fibrin and thus resulting in superficial clotting as arbitrarily measured in glass tubes. The small amount of thrombin so formed will then slowly and continuously convert fibrinogen to fibrin until no fibrinogen remains in the

serum. On the other hand, the total conversion of prothrombin to thrombin depends largely on the amount of active plasma thromboplastin and "prothrombin accelerators" present, the reaction between thromboplastin and prothrombin being, most likely, stoichiometric.⁵⁰ Thus, the lower the plasma thromboplastin concentration the smaller the amount of prothrombin that will be consumed or converted to thrombin in the process of coagulation. In *hemophilia* the plasma thromboplastin concentration is considered to be extremely low, whereas the "prothrombin accelerator" concentration is normal.¹⁹

In *thrombocytopenia* the prothrombin consumption is approximately 40 to 60 per cent.^{64, 66} The mechanism for reduced prothrombin consumption may result from a reduction in a "platelet enzyme," as described above. This enzyme is considered necessary for activation of a precursor (thromboplastinogen) of plasma thromboplastin. Plasma thromboplastin, as mentioned above, converts prothrombin to thrombin stoichiometrically. As a result of decreased numbers of platelets or alteration in platelet function or both, only a small amount of active plasma thromboplastin is formed.

Prothrombin consumption is normal in *afibrinogenemia*, which indicates normal production of thrombin. The lack of coagulation in this disease is due to complete absence of fibrinogen, which thrombin would normally convert to fibrin, and is not concerned with any abnormality of prothrombin conversion.

In *parahemophilia* the conversion of prothrombin to thrombin has been shown to be slow owing to absence of an "accelerator substance." The total amount of prothrombin consumed in the process of clot formation, apparently, is of the degree of that seen in thrombocytopenia.¹⁹ This is explained on the basis that the "prothrombin accelerators" may be concerned primarily with the speed of conversion of prothrombin to thrombin and are therefore indirectly concerned with the total amount of prothrombin converted or consumed in a given period. Prothrombin consumption is normal in the remainder of the hemorrhagic diseases, as shown in Table 1. In the hemorrhagic diseases resulting from circulating anticoagulants and in thrombasthenia prothrombin consumption has not been reported.

It is evident, therefore, that the degree of prothrombin consumption depends on the presence of adequate amounts of plasma thromboplastin, platelet enzyme and "prothrombin accelerators."

DETERMINATION OF FIBRINOLYSIS

Normally, human plasma contains a balanced enzyme system consisting of the inactive precursor of a proteolytic enzyme, designated as profibrinolysin or plasminogen, and an antiproteolytic substance, designated as antifibrinolysin or antiplasmin. Under certain circumstances, the proenzyme be-

Limitations and Interpretations

Many of the time-concentration curves for prothrombin that are reported in the literature have been prepared from *saline* dilutions of plasma. Such dilutions diminish the amount of other factors necessary for coagulation and will show erroneously delayed prothrombin times, which may not be reliable or accurate in the determination of prothrombin concentrations in the range of 30 to 100 per cent of normal. If prothrombin-free plasma is used as a diluent, as described above, more reproducible time-concentration relations are obtained since all elements essential for coagulation have been preserved, with the possible exception of a part of the "prothrombin accelerators" mentioned above.^{19 46 51 55} This difficulty can be obviated by the use of lyophilized prothrombin-free ox plasma, which contains an excess of all these substances. The determination of prothrombin on plasma diluted to a 10 per cent concentration with prothrombin-free ox plasma permits a new order of *reproducibility* and *accuracy* and makes obsolete methods that attempt to interpret differences of one or two seconds that are equivalent to 50 per cent difference in prothrombin concentration.⁵⁸

The use of *Dicoumarol* to prevent the complications of thromboembolic phenomena has required a wide clinical application of the determination of prothrombin concentration. *Dicoumarol* presumably prevents the formation of prothrombin by the liver. Excessive administration produces a severe hypoprothrombinemia and a hemorrhagic tendency. The dosage is controlled by observation of the prothrombin time. Usually, it has been considered necessary to keep the prothrombin time approximately thirty to forty seconds, or the concentration between 4 and 8 per cent of normal, to prevent thrombotic phenomena.

The prothrombin determination is of value in detecting the absence of prothrombin as a cause of hemorrhagic diathesis and in the study of response to vitamin K therapy.

In diagnosis the interpretation of the prothrombin time requires a knowledge of factors other than prothrombin deficiency that may cause prolongation, and a knowledge of the sources of error in the test. A prolonged prothrombin time by Quick's method is found in *afibrinogenemia* even though the prothrombin concentration may be entirely normal as determined by the dilution method using prothrombin-free plasma as a diluent. In addition, deficiencies of "prothrombin accelerators" result in prolongation of prothrombin time unless the dilution method using prothrombin-free plasma is employed. The prothrombin concentration is usually normal in the other hemorrhagic diseases as shown in Table 1.

PROTHROMBIN CONSUMPTION

Principle

When unaltered normal venous blood is placed in a test tube, as in the determination of the coagulation time, clotting will normally occur within six to twelve minutes. When the clot is allowed to remain undisturbed for one hour after initial coagulation so as to ensure maximum coagulation, serum is expressed. The serum contains variable amounts of prothrombin, calcium, thrombin and serum "prothrombin accelerators," but *no fibrinogen*. Within two or three hours the thrombin present is converted to an inactive form, metathrombin. Various intervals are required for inactivation of the serum "prothrombin accelerators," but it appears likely from the available data that essentially complete inactivation occurs within twelve hours at a temperature of 37.5°C.^{19 60, 64} Such serum will then contain prothrombin and calcium. If this serum is added to a mixture of thromboplastin, fibrinogen and calcium, clotting will usually occur. The time required for clotting of this mixture becomes a function of the prothrombin that was not used (consumed) in the formation of the clot and that remains in the serum. Apparently, the prothrombin is the major variable in such a reaction mixture, and thus a prothrombin time and prothrombin concentration are obtained from the clotting time. The difference between the original plasma concentration time and the residual serum concentration of prothrombin is termed the "prothrombin consumption." The technic of the test is that used by Quick,⁶⁵ with the exception that prothrombin-free human plasma is used as a source of fibrinogen rather than prothrombin-free rabbit plasma.

Modified Quick Method for Prothrombin Consumption

Reagents Thromboplastin and calcium chloride solution and prothrombin-free human plasma are prepared as described above.

Technic Venous blood is allowed to coagulate according to the method described above. The clotting time is noted. One hour after initial coagulation the tubes are centrifuged at 800 rpm for five minutes, the serum is removed and kept at 37.5°C for twenty-four hours.* A "prothrombin time" is determined as follows: to a mixture of exactly 0.1 cc of thromboplastin, 0.1 cc of prothrombin-free human plasma and 0.1 cc of 0.025-molar solution of calcium chloride is quickly added 0.1 cc of the unknown serum. A stop watch is started immediately upon addition of the serum to the mixture. The contents of the tube are shaken gently, and the instant the mixture is no longer *completely* fluid is taken as the end point. The prothrombin concentration can then be determined from the prothrom-

*Although serum is bacteriostatic, a sterile technic may be employed without increasing greatly the difficulty of the procedure.

bin time in seconds, as outlined above. This procedure is done at one, three and twenty-four hours after coagulation.

Limitations and Interpretations

The limitations of a one-stage method for measuring prothrombin time are the same as those described above. However, the difference in prothrombin consumption between the normal and abnormal is so large that these technical limitations are of secondary importance. The method for determination of prothrombin concentration described by Rosenfield and Tuft⁵⁵ may be used however, if desired. Biologic limitations exist, in that serum contains active "prothrombin accelerators" that govern the speed of the coagulation reaction and therefore the prothrombin time. There still remains considerable doubt concerning exactly when these "accelerators" become inactivated in serum that is stored at 37°C. From the available literature^{19, 60} the impression is gained that such inactivation is relatively rapid, there being little evidence of "prothrombin-accelerator" activity at the end of three hours of storage at room or water-bath (37°C) temperatures. On the other hand, one investigator⁶⁴ reports 80 to 83 per cent activity after four hours of storage at 37.5°C. Because of the presence of active serum "prothrombin accelerators" as well as thrombin in the serum at one and three hours after coagulation, determinations of prothrombin concentration at these times are very difficult to evaluate. After a storage interval of twelve hours at 37°C, however, it is quite likely that the serum "prothrombin accelerators" are completely inactivated. By the use of prothrombin-free human plasma as a source of fibrinogen in the procedure, it is possible to maintain a relatively constant amount of available "prothrombin accelerators" in each reaction mixture after twelve hours of incubation of the serum.

By the procedure described, normal serum is found to have a residual prothrombin concentration of 10 to 20 per cent (80 to 90 per cent prothrombin consumption).

In *hemophilia* the serum has a prothrombin concentration of 80 to 100 per cent, and hence a low prothrombin consumption (0 to 20 per cent). Such a finding confirms the theory that in hemophilia prolonged coagulation is the result of improper formation of thrombin from prothrombin. That hemophilic blood ultimately coagulates is explained⁶⁵ on the basis that a small amount of prothrombin is eventually converted to thrombin over a prolonged period. Since thrombin is enzymatic in action even a small amount is capable of converting fibrinogen to fibrin and thus resulting in superficial clotting as arbitrarily measured in glass tubes. The small amount of thrombin so formed will then slowly and continuously convert fibrinogen to fibrin until no fibrinogen remains in the

serum. On the other hand, the total conversion of prothrombin to thrombin depends largely on the amount of active plasma thromboplastin and "prothrombin accelerators" present, the reaction between thromboplastin and prothrombin being, most likely, stoichiometric.⁵⁰ Thus, the lower the plasma thromboplastin concentration the smaller the amount of prothrombin that will be consumed or converted to thrombin in the process of coagulation. In *hemophilia* the plasma thromboplastin concentration is considered to be extremely low, whereas the "prothrombin accelerator" concentration is normal.¹⁹

In *thrombocytopenia* the prothrombin consumption is approximately 40 to 60 per cent.^{64, 66} The mechanism for reduced prothrombin consumption may result from a reduction in a "platelet enzyme," as described above. This enzyme is considered necessary for activation of a precursor (thromboplastinogen) of plasma thromboplastin. Plasma thromboplastin, as mentioned above, converts prothrombin to thrombin stoichiometrically. As a result of decreased numbers of platelets or alteration in platelet function or both, only a small amount of active plasma thromboplastin is formed.

Prothrombin consumption is normal in *afibrinogenemia*, which indicates normal production of thrombin. The lack of coagulation in this disease is due to complete absence of fibrinogen, which thrombin would normally convert to fibrin, and is not concerned with any abnormality of prothrombin conversion.

In *parahemophilia* the conversion of prothrombin to thrombin has been shown to be slow owing to absence of an "accelerator substance." The total amount of prothrombin consumed in the process of clot formation, apparently, is of the degree of that seen in thrombocytopenia.¹⁹ This is explained on the basis that the "prothrombin accelerators" may be concerned primarily with the *speed* of conversion of prothrombin to thrombin and are therefore indirectly concerned with the *total amount* of prothrombin converted or consumed in a given period. Prothrombin consumption is normal in the remainder of the hemorrhagic diseases, as shown in Table 1. In the hemorrhagic diseases resulting from *circulating anticoagulants* and in *thrombasthenia* prothrombin consumption has not been reported.

It is evident, therefore, that the degree of prothrombin consumption depends on the presence of adequate amounts of plasma thromboplastin, platelet enzyme and "prothrombin accelerators."

DETERMINATION OF FIBRINOLYSIS

Normally, human plasma contains a balanced enzyme system consisting of the inactive precursor of a proteolytic enzyme, designated as profibrinolysin or plasminogen, and an antiproteolytic substance, designated as antifibrinolysin or antiplasmin. Under certain circumstances, the proenzyme be-

comes activated, resulting in the elaboration of the proteolytic enzyme, fibrinolysin or plasmin. The active enzyme received the name fibrinolysin from Dastre,⁸⁰ who found it to "destroy fibrin." Subsequent investigation has shown fibrinolysin to digest not only fibrin but also fibrinogen,⁸¹ prothrombin⁸² and, at least in one instance, a "prothrombin accelerator."⁸³ Because of the widespread alteration that can occur in the circulating blood and in clot formation, it becomes important to ascertain the presence or absence of this proteolytic enzyme as a cause of hemorrhagic diathesis. Since fibrinolysin (plasmin) is capable of digesting both fibrinogen and fibrin, it is evident that this enzyme can alter coagulation in any one of the following ways, depending upon its concentration: coagulation may be normal with subsequent *partial lysis* of the clot, coagulation may be normal with subsequent *complete lysis* of the clot, and there may be *no coagulation* because of rapid fibrinogenolysis and resultant afibrinogenemia.

Fibrinolytic activity is measured by observation of the stability of a clot of whole blood or of recalcified plasma. Further details are given in the excellent review by Macfarlane and Biggs.⁶⁷

Method

Whole-blood technic With sterile technic blood is obtained for determination of the coagulation time as outlined above, and the coagulation time is recorded. *It is important to watch closely for coagulation because fibrinolysis may be of such activity as to give the impression of incoagulability of the blood.* After coagulation has occurred the sample is maintained at 37.5°C in a water bath and observed for dissolution of the clot at half an hour, one, two, three, four and twenty-four hours. Normally, the clot will remain intact and retain its content of red cells. If fibrinolysin is present the clot will be observed to decrease in size with loss of many of its red cells.

Plasma-saline technic With sterile technic 0.2 cc of citrated plasma is placed in a culture tube with lip (13 by 100 mm), and 5 cc of sterile saline solution added. To this mixture is added 0.2 cc of thromboplastin and 0.2 cc of calcium chloride (0.025-molar) solution, and the contents of the tube are mixed by inversion. Observations are made for lysis of this plasma clot as stated above. This method has advantage over the use of whole blood since the clot can be visualized more easily when the red cells are not present.

Limitations and Interpretations

Fibrinolysin occurs in severe burns and is possibly due to the presence of shock.⁷⁸ It has also been observed after surgical procedures as well as before them.⁸⁴ This observation led to the hypothesis that possibly the release of epinephrine during anxiety states operated as a mechanism for activation of pro-fibrinolysin (plasminogen) normally found in plasma.⁸⁴ This hypothesis has since been tested, and it is possible to develop fibrinolytic activity in circulating blood upon the administration of epinephrine⁸⁵, however, such activity does not develop upon the addition of epinephrine to whole blood in the test tube. Epinephrine release may be the mode of activation of the proteolytic enzyme that is frequently encountered in shock of all types. Since fibrinolysin digests fibrinogen, prothrombin, fibrin and possibly "prothrombin accelerators," there can be maintained, in shock, a vicious circle whereby fibrinolysin causes prolonged hemorrhage with further maintenance of shock and continued production of fibrinolytic activity. In any condition in which hemorrhage is unexplained the stability of the clot should be observed for the presence of fibrinolytic activity.

CASE 35451

PRESENTATION OF CASE

A sixteen-year-old schoolboy entered the hospital complaining of constipation.

Three months before entry while at a preparatory school the patient passed half a cupful of red blood one night, soiling his pajamas. A few days later he noted constipation, for which he saw the school nurse, who treated him with mineral oil and an enema. School closed shortly after this, and the patient went home. The constipation continued, and he frequently passed small amounts of semi-solid or liquid feces each day. At times he noted red blood on the toilet tissue and in the bowl. During the summer he worked as a caddie without undue fatigue. He lost 20 pounds, which was ascribed to a more active life and change in diet. For two weeks before entry he had anorexia and nausea in the morning. He also began to have frequent, small bowel movements at night and a dull discomfort in the rectum, which interfered with sleep. He was seen by a physician for a pre-school routine examination. Following this he was sent to the hospital.

The past and family histories were noncontributory.

Physical examination showed a healthy-appearing, well nourished boy. The only positive finding was a hard mass just inside the anus encircling the rectum. No definite ulceration was felt.

The urine was normal. The blood hemoglobin was 15.1 gm, and the white-cell count 10,000. The blood chemical findings were normal.

A barium enema showed partial obstruction in the rectum. Sigmoidoscopy was painful and therefore unsatisfactory, but some hard, red tissue was seen 2.5 cm from the anus, from which a biopsy was taken.

DIFFERENTIAL DIAGNOSIS

DR E PARKER HAYDEN* At first glance this case sounds as if it should be a clear-cut diagnostic problem, and it probably was a clear-cut problem for whoever was in attendance. The story, as far as bleeding is concerned, might suggest almost anything. Bleeding in a sixteen-year-old boy or girl is not common. The usual cause of bleeding in a person that age, in my experience, has been either polyp or fissure. This lad, however, had the symptoms of constipation, and as we read through the history it seems to be a progressive story, with bleeding becoming more frequent. The stools became more fluid, and there was some loss of weight, which I do not believe could be ascribed to the healthy summer occupation of caddying. The average boy would not lose 20 pounds, unless he was very fat, just from caddying in a healthy environment. The onset, two weeks before entry, of anorexia and nausea, together with increasing constipation, suggests a progressive ailment in the rectum. The statement that a definite hard mass was felt low down would suggest that the diagnosis ought not to be difficult, particularly with a biopsy, the result of which we do not have available in this report.

The first thing that one would think of from this description, despite the patient's youth, is a carcinoma of the lower rectum. Carcinoma can occur in a boy of sixteen. I have personally operated upon a boy of seventeen with carcinoma. We know that cancer does occur, usually in association with multiple polyposis, in a fair number of young people. The statement that no ulceration was felt would have to be taken with a grain of salt. One cannot always tell by palpation whether ulceration is present. With frequent movements and bleeding one would expect ulceration, and it probably was present. The normal hemoglobin is a little unusual with a cancer that has been present very long. On the other hand, that is entirely possible. The boy actually did have an annular mass—one that had grown all the way around the bowel wall. It would seem, therefore, that it must have been some sort of infiltrative lesion rather than a benign polyp. In inflammatory stricture there would, of course, be an annular ring, which could be due to tuberculosis or to lymphogranuloma inguinale.

If I were to hazard a guess on this case it would seem to me that carcinoma of the lower rectum was the obvious diagnosis to make on the basis of the résumé, but since it seems so obvious it is very likely something else. It also ran through my mind that he might have had an annular foreign body. A foreign body can produce ulceration, with blood and frequent bowel movements. I think ulcerative colitis can probably be excluded on the basis of the finding of the mass, although the symptoms

*Associate visiting surgeon, Massachusetts General Hospital.

matology of ulcerative colitis and that of cancer are often just about the same, and the latter can occur in the presence of the former

There are other types of tumors that one sees occasionally in the colon, such as lymphosarcoma. If a sarcoma was present it might not be ulcerated, and one would not expect very much bleeding. I think the first diagnosis I would make, however, is carcinoma of the rectum, and if he had a carcinoma of the rectum it would most likely be based on multiple polyposis, although not necessarily so.

Are there any x-ray films available?

DR JOSEPH HANELIN These are films of the barium enema, apparently the only films made. The examiner was loath to put much barium into the bowel because after evacuation there was still a fair amount present, and he was afraid to get too great an accumulation above the lesion. There is clearly demonstrated in these films an annular constrictive lesion involving the rectum, beginning at the anus and going up for 5 or 6 cm. The appearance is quite characteristic of a malignant neoplasm. I would say undoubtedly that it is ulcerated.

DR HAYDEN On the basis of the x-ray report I certainly see no reason to change my first diagnosis. The description of the tissue biopsy would be consistent with carcinoma—a reddened and rather hard bit of tissue. Also the difficulty in proctoscopy is understandable from the degree of narrowing and its proximity to the anal canal, which is sensitive. I do not see how I can make any diagnosis but carcinoma of the rectum, which seems obvious in this case.

A PHYSICIAN Would you consider lymphogranuloma inguinale?

DR HAYDEN That is a lesion in which one does not feel a true mass, although one might get that impression. Lymphogranuloma inguinale is simply an annular inflammatory condition going on long enough to produce scar tissue and gradual narrowing of the rectum. It may take the form of a short diaphragmatic stricture, 10 to 25 cm above the anus, or may produce a tubular stricture.

DR BENJAMIN CASTLEMAN How often does one see rectal stricture in a male patient with lymphogranuloma inguinale?

DR HAYDEN Quite often. Dr Earle Chapman and I gathered together a series of cases of lymphogranuloma inguinale in white people. As I recall it there was a predominance of males, although it has been stated in the literature that females predominate.

DR CASTLEMAN As far as stricture is concerned?

DR HAYDEN I was referring to the incidence of the disease in general.

DR GORDON A DONALDSON Would tuberculosis give this sort of constricting lesion?

DR HAYDEN Tuberculosis of the lower rectum in a hyperplastic form is uncommon. I cannot accurately remember whether I have ever seen one.

The disease usually takes the form of ulceration of the anus, whereas the hyperplastic form is encountered more often in the cecum, though it has been described in the rectum.

DR THOMAS RISLEY I saw this boy first in the office after he was sent in by his doctor. The feeling of the mass was not characteristic of carcinoma. It was extremely rubbery in consistence. It lay just inside the anal ring and on examination was painful. It was not possible to feel an ulceration or a crater. It felt as though the mass were completely covered by mucous membrane, and this was confirmed on introducing the sigmoidoscope. However, some tissue was removed and sent to the laboratory. On the day of operation we had not yet received the report from that tissue and because of the rubbery feeling we biopsied it again in the operating room and waited for a frozen section. On the basis of the frozen section we proceeded with a combined abdominoperineal excision of the rectum. There was a suggestion of lymphoma in the way the tissue felt.

CLINICAL DIAGNOSIS

Carcinoma of rectum

DR HAYDEN'S DIAGNOSIS

Carcinoma of rectum

ANATOMICAL DIAGNOSIS

Colloid carcinoma of rectum, with metastases to regional lymph nodes in a sixteen-year-old boy

PATHOLOGICAL DISCUSSION

DR CASTLEMAN The biopsy showed carcinoma. When we received the entire specimen, there was a large ulcerated tumor that looked like the garden-variety type of adenocarcinoma of the bowel. Microscopically, however, it was not the type of adenocarcinoma that we see ordinarily with well formed glands but a signet-ring-cell type of colloid carcinoma, a type that is more often seen in the stomach. The cytoplasm of each cell was replaced by mucoid material pushing the nucleus to one side to form what is known as a signet-ring cell. This type of tumor is usually a very malignant one. In this particular case the tumor had extended anteriorly to involve the serosa. Sixteen out of seventeen lymph nodes examined were involved.

We had some years ago, I believe, a carcinoma of the bowel, also colloid in type, in a child of seven or eight years. That child came in to the hospital because of a mass in the groin, and on biopsy it proved to be a metastatic lymph node full of colloid carcinoma. The primary site was found in the rectum.

DR HANELIN Was any calcification found?

DR CASTLEMAN I do not believe so.

DR HANELIN The reason I ask this question is that I am thinking of a similar case in which extensive calcification was demonstrated in the x-ray films

CASE 35452

PRESENTATION OF CASE

A seventy-three-year-old housewife was admitted to the hospital because of abdominal pain

Approximately two and a half weeks previous to admission the patient had a sudden onset of severe substernal pain radiating through to the back and associated with dyspnea but no sweating or pallor. She was agitated and in acute discomfort for several hours. For two days following this episode of pain she remained in bed, and the only complaint was nausea with several attacks of vomiting. On the third day after this episode an electrocardiogram showed a small Q wave and inverted T wave in Lead I, with changes in one of the chest leads suggestive of "a small posterior infarct." After ten days of bed rest she became active again and seemed well. Twenty-four hours before admission, following her lunch, she felt somewhat nauseated. An hour or so later she had a sudden onset of persistent vomiting and retching, followed in a short time by urgent watery diarrhea. She gradually developed severe abdominal pain. This was not relieved by morphine administered by a physician, but the nausea and diarrhea subsided somewhat. Several hours before admission the temperature was 102°F. Examination by a physician disclosed a blood pressure of 140 systolic, (?) diastolic, rales at both bases and a diffusely tender abdomen. She was sent to the hospital. During this time she developed a feeling in the left leg as though "her leg had gone to sleep."

Five years before admission the patient had an attack of substernal pressure, pain in both upper arms and dyspnea. She had been seen by a physician, who diagnosed the condition as myocardial infarct. After several weeks of bed rest she resumed activity and was asymptomatic until the present episode.

Physical examination revealed a dehydrated, febrile, seriously ill woman. The thyroid gland was bean-sized and hard. The heart was enlarged 12 cm to the left in the fifth intercostal space. The sounds were of poor quality. There were fine sticky rales throughout the entire right chest up to the midscapula anteriorly and posteriorly on the left, with diminished breath sounds at both bases. The left leg was cool from the hip to the knee and cold from the knee down, it was mottled with bluish discoloration. The left femoral pulse was not palpable. There was some pallor and a greenish tint to the toes. There was moderate abdominal spasm throughout. Peristalsis was diminished and somewhat high-pitched.

The temperature was 102°F, the pulse 110, and the respirations 18. The blood pressure was 90 systolic, 70 diastolic.

Examination of the blood showed a hemoglobin of 14 gm and a white-cell count of 18,500. The urine had a specific gravity of 1.020 and gave a ++ test for albumin. The sediment contained frequent granular casts, rare red cells and 10 white cells per high-power field. An electrocardiogram was interpreted as showing slight tachycardia and abnormal T and S waves that could be due to coronary disease or to the combined effects of coronary disease and high blood pressure or aortic-valve disease. The T waves were unusually wide, and the QT interval was long. An electrolyte imbalance was suggested.

The patient was given digitalis, and fluid was administered by clysis. Attempts at deflation with a Miller-Abbott tube were unsuccessful. On the third hospital day the blood chloride was 90 milliequiv per liter, the nonprotein nitrogen 64 mg, and the total protein 5.8 gm per 100 cc. The temperature showed a definite upward trend. On the fourth hospital day it was noted that the right femoral artery also was not palpable. The abdomen was distended and had a doughy feel, but peristalsis was audible.

The patient gradually became comatose and died on the sixth hospital day.

DIFFERENTIAL DIAGNOSIS

DR JOHN T. QUINBY* This clinical history is that of a seventy-three-year-old woman with a fatal illness of two and a half weeks' duration. It seems to me that most of the features of this case may be accounted for by a dissecting aneurysm of the aorta, with a number of sequelae that follow very logically from this not too uncommon lesion.

To recapitulate briefly, this woman had, five years before admission, an episode of substernal pressure and dyspnea considered by a physician to have represented a myocardial infarct. I see no reason to doubt that diagnosis. One notes that there was associated pain in both upper arms. Her terminal illness began with severe substernal pain, sudden in onset, with radiation through to the back and dyspnea. This time pain was not experienced in the arms. About two weeks later, she experienced, with fairly sudden onset, an acute and severe abdominal disorder. It was characterized by persistent vomiting and retching followed by urgent watery diarrhea and severe abdominal pain, and a day later a maximum temperature of 102°F. The abdomen showed "moderate spasm throughout", peristalsis was diminished and somewhat high-pitched. Rather rapid pulse and falling blood pressure, to near-shock levels, were noted, though it does not seem from the history that frank clinical shock — that is, peripheral vascular collapse — ex-

On the day of operation we had not yet received the report from that tissue and because of the rubbery feeling we biopsied it again in the operating room and waited for a frozen section. On the basis of the frozen section we proceeded with a combined abdominoperineal excision of the rectum. There was a suggestion of lymphoma in the way the tissue felt.

CLINICAL DIAGNOSIS

Carcinoma of rectum

DR HAYDEN'S DIAGNOSIS

Carcinoma of rectum

ANATOMICAL DIAGNOSIS

Colloid carcinoma of rectum, with metastases to regional lymph nodes in a sixteen-year-old boy

PATHOLOGICAL DISCUSSION

DR CASTLEMAN The biopsy showed carcinoma. When we received the entire specimen, there was a large ulcerated tumor that looked like the garden-variety type of adenocarcinoma of the bowel. Microscopically, however, it was not the type of adenocarcinoma that we see ordinarily with well formed glands but a signet-ring-cell type of colloid carcinoma, a type that is more often seen in the stomach. The cytoplasm of each cell was replaced by mucoid material pushing the nucleus to one side to form what is known as a signet-ring cell. This type of tumor is usually a very malignant one. In this particular case the tumor had extended anteriorly to involve the serosa. Sixteen out of seventeen lymph nodes examined were involved.

We had some years ago, I believe, a carcinoma of the bowel, also colloid in type, in a child of seven or eight years. That child came in to the hospital because of a mass in the groin, and on biopsy it proved to be a metastatic lymph node full of colloid carcinoma. The primary site was found in the rectum.

DR HANELIN Was any calcification found?

DR CASTLEMAN I do not believe so.

that occurs between the end vessels of the systemic arteries and the inferior mesenteric branches

The basal rales extending on the left half way up the chest, in addition to the suggestion of bilateral pleural fluid and the finding of definite cardiac enlargement point to congestive failure. This, I think, can be explained without postulating a further coronary occlusion in the present illness. I think the patient must have had hypertension. In the reported cases of dissecting aneurysm of the aorta this has been an invariable finding. We also are assuming that five years before this episode she suffered a myocardial infarction. The fact that no blood-pressure reading over 140 systolic is recorded during her hospital stay almost certainly is a reflection of the profound prostration going with intestinal infarction and obstruction. Thus I think heart damage by coronary-artery disease and by hypertension manifested itself before the present illness. If tachycardia, fever and azotemia possibly with increased serum potassium level are added to this, cardiac decompensation is understandable. If further coronary occlusion did occur, the most likely mechanism would be a progression of the dissecting aneurysm in a retrograde fashion, as mentioned earlier.

The urinary findings are a good specific gravity of 1.020, a ++ test for albuminuria and frequent granular casts, rare red cells and 10 white cells per high-power field in the sediment. The serum nonprotein nitrogen was 64 mg per 100 cc. Except for the 10 white cells per high-power field in the sediment, there is nothing not entirely compatible with congestive failure and dehydration. Vascular nephritis of more than minimal degree I should doubt to have been present, with a good concentrating power. The moderate azotemia should be classed as pre-renal, I think, and the pyuria—if the leukocytes came from the bladder—could reflect the low-grade cystitis that is almost the rule in elderly women.

The fact that renal function was fairly well preserved does not throw out the diagnosis of dissecting aneurysm of the aorta. Frequently, the renal arteries are not involved though the dissection extends distal to them and in other cases when they are involved renal function has not appeared greatly impaired. The exact anatomical explanation for this is beyond my knowledge to discuss.

The description of the thyroid gland as bean-sized and hard is difficult to interpret. I cannot

see that the clinical history points to thyroid disease of any type. It would seem that the gland was perhaps smaller than normal and harder than normal. An adenoma may have been present, or perhaps this was an involuted gland in an elderly person.

The low serum protein of 5.8 gm per 100 cc is consistent with the patient's nutritional defect combined with her age. The blood chloride value of 90 milliequiv per liter is somewhat below the normal range of 98 to 103 milliequiv and is consistent with the loss of chloride through vomiting and diarrhea. The white-cell count of 18,500 is characteristic of mesenteric thrombosis and bowel infarction.

Electrocardiographic studies in this patient are certainly consistent with the diagnosis of dissecting aneurysm. In this condition the reported findings have been left-axis deviation usually, and a definite pattern of left ventricular strain in a majority of cases. A few cases have shown additional changes suggesting the presence of coronary-artery disease. None of the reported tracings could be considered entirely normal, and yet changes definitely suggestive of an acute myocardial infarct have not been seen, even in cases in which the coronary arteries themselves were involved in the dissection.

The findings in our patient appear to fit well with this experience. The changes in the T waves in Lead 1 and 2 noted on the third day of illness are consistent. Later the tracing showed, besides some tachycardia, abnormal T and S waves, with widening of the T waves and prolongation of the QT interval. An electrolyte imbalance was suggested, as well as an interpretation to the effect that the pattern suggested coronary-artery disease with left ventricular strain. Certainly, some electrolyte disturbance existed, and if with the patient's azotemia there was associated a significant elevation of serum potassium, the widened T waves and increased QT interval may have been due to that. Also, I believe, some coronary-artery disease was present before the onset of the last illness.

CLINICAL DIAGNOSES

- Acute myocardial infarction
- Embolism to mesenteric artery
- Embolism to femoral artery, bilateral
- Acute pulmonary edema
- Congestive failure

isted Three days later the abdomen is described as distended and as having a doughy feel with peristalsis still audible. A guaiac test on the material passed by rectum is not mentioned. A positive guaiac test here would be of interest, and would tend to confirm the impression I get of this acute and progressive abdominal accident — namely that it represented mesenteric-vessel thrombosis with infarction probably extensive, of the bowel. Coming right on the heels of this process occurred another (an arterial) occlusion first in the left leg going on to gangrene and later in the right, without the development of gangrene.

This sequence of events could be well accounted for by a dissecting aneurysm of the aorta beginning either in the ascending or the thoracic portion and extending farther and farther down to include eventually both common iliac arteries in the same morbid process — namely, the creation of an artificial cleavage plane in the media, first of the aorta then of any of its branches to which the dissection extends with resulting marked narrowing of the true lumen and diminution or complete cutting off of the blood flow in the involved vessels. Such a process could also account for occlusion of one or both mesenteric arteries.

The diagnostic problem in cases of this sort is to differentiate dissecting aneurysm of the aorta and coronary thrombosis with myocardial infarction. In my opinion the first is the better diagnosis. I think so for several reasons: first, because almost every fact in the clinical history is consistent with such a diagnosis, and secondly because the sequence of arterial occlusions seems better explained this way. As far as my knowledge goes, the successive occlusion of two major aortic branches (three counting both iliacs) is a very rare event as a sequel to thrombosis on the endocardium, whereas it is very common with dissecting aneurysm. I think that if a very large myocardial infarct were the source of emboli from the heart, the probability of two successive arterial embolizations, both at their origins from the aorta, would be very small. Furthermore, one would have to postulate extensive myocardial damage, I think (in the absence of auricular fibrillation), and here the chances would be that endocardial thrombi would not be limited to the left side of the heart, we have no data on which to base a diagnosis of pulmonary embolism, it seems to me. Finally, I think that the location

of the patient's pain is more characteristic of dissecting aneurysm than of coronary thrombosis. Also with a myocardial infarction severe enough to cause this whole picture the characteristic electrocardiographic pattern should be seen, and it was not present here. For these reasons, I prefer the first diagnosis. The strongest objection to it is the apparent presence of congestive failure. We are led to think of a recent, severe myocardial accident to help explain it, since there is no evidence that failure existed prior to the present illness. As I shall indicate later however, I think it can be accounted for without this supposition. A third possibility is that the aortic dissection proceeded also in a retrograde direction to involve the mouth of at least one coronary artery. This not uncommon sequel may have been present here. I see no way of knowing but I doubt a large, recent myocardial infarction and I think that in any case the occlusive sequelae were in all probability due to dissecting aneurysm of the aorta.

To discuss certain details of the history in the light of a diagnosis of dissecting aneurysm of the aorta, let us consider first the question of the immediate cause of death. With this aortic lesion the terminal event is usually rupture of the aneurysm. This is found to occur into the pericardial sac, with cardiac tamponade into the mediastinum, frequently with hoarseness into one or both pleural cavities, and into the peritoneal cavity, in about that order of frequency. In this case, however, there is little in the clinical history to indicate such an event. Death, I believe, was due to bowel infarction with obstruction, distention, dehydration, azotemia and the presence of congestive failure. Very likely, some peritonitis was present.

Of course an acute abdominal episode of this type with bowel infarction is often precipitated by strangulation of the bowel, as in hernia or volvulus, or by infection in an abdominal organ tributary to the portal vein, as in appendicitis or pelvic infection. In such cases thrombosis usually involves the mesenteric veins. In this patient I believe mesenteric arterial occlusion, probably with thrombosis, is more likely, fitting in with the initial aortic lesion that I have postulated. One or both mesenteric arteries may be involved, if one alone, the superior mesenteric is the more apt to lead to infarction, because of the freer anastomosis

that occurs between the end vessels of the systemic arteries and the inferior mesenteric branches

The basal rales, extending on the left half way up the chest, in addition to the suggestion of bilateral pleural fluid and the finding of definite cardiac enlargement, point to congestive failure. This, I think, can be explained without postulating a further coronary occlusion in the present illness. I think the patient must have had hypertension. In the reported cases of dissecting aneurysm of the aorta this has been an invariable finding. We also are assuming that five years before this episode she suffered a myocardial infarction. The fact that no blood-pressure reading over 140 systolic is recorded during her hospital stay almost certainly is a reflection of the profound prostration going with intestinal infarction and obstruction. Thus, I think heart damage by coronary-artery disease and by hypertension manifested itself before the present illness. If tachycardia, fever and azotemia, possibly with increased serum potassium level, are added to this, cardiac decompensation is understandable. If further coronary occlusion did occur, the most likely mechanism would be a progression of the dissecting aneurysm in a retrograde fashion, as mentioned earlier.

The urinary findings are a good specific gravity of 1.020, a ++ test for albuminuria and frequent granular casts, rare red cells and 10 white cells per high-power field in the sediment. The serum nonprotein nitrogen was 64 mg per 100 cc. Except for the 10 white cells per high-power field in the sediment, there is nothing not entirely compatible with congestive failure and dehydration. Vascular nephritis of more than minimal degree I should doubt to have been present, with a good concentrating power. The moderate azotemia should be classed as pre-renal, I think, and the pyuria — if the leukocytes came from the bladder — could reflect the low-grade cystitis that is almost the rule in elderly women.

The fact that renal function was fairly well preserved does not throw out the diagnosis of dissecting aneurysm of the aorta. Frequently, the renal arteries are not involved, though the dissection extends distal to them, and in other cases when they are involved renal function has not appeared greatly impaired. The exact anatomical explanation for this is beyond my knowledge to discuss.

The description of the thyroid gland as bean-sized and hard is difficult to interpret. I cannot

see that the clinical history points to thyroid disease of any type. It would seem that the gland was perhaps smaller than normal and harder than normal. An adenoma may have been present, or perhaps this was an involuted gland in an elderly person.

The low serum protein of 5.8 gm per 100 cc is consistent with the patient's nutritional defect, combined with her age. The blood chloride value of 90 milliequiv per liter is somewhat below the normal range of 98 to 103 milliequiv and is consistent with the loss of chloride through vomiting and diarrhea. The white-cell count of 18,500 is characteristic of mesenteric thrombosis and bowel infarction.

Electrocardiographic studies in this patient are certainly consistent with the diagnosis of dissecting aneurysm. In this condition the reported findings have been left-axis deviation usually, and a definite pattern of left ventricular strain in a majority of cases. A few cases have shown additional changes suggesting the presence of coronary-artery disease. None of the reported tracings could be considered entirely normal, and yet changes definitely suggestive of an acute myocardial infarct have not been seen, even in cases in which the coronary arteries themselves were involved in the dissection.

The findings in our patient appear to fit well with this experience. The changes in the T waves in Lead 1 and 2 noted on the third day of illness are consistent. Later the tracing showed, besides some tachycardia, abnormal T and S waves, with widening of the T waves and prolongation of the QT interval. An electrolyte imbalance was suggested, as well as an interpretation to the effect that the pattern suggested coronary-artery disease with left ventricular strain. Certainly, some electrolyte disturbance existed, and if with the patient's azotemia there was associated a significant elevation of serum potassium, the widened T waves and increased QT interval may have been due to that. Also, I believe, some coronary-artery disease was present before the onset of the last illness.

CLINICAL DIAGNOSES

- Acute myocardial infarction
- Embolism to mesenteric artery
- Embolism to femoral artery, bilateral
- Acute pulmonary edema
- Congestive failure

DR QUINBY'S DIAGNOSES

Dissecting aneurysm of aorta
 Occlusion and thrombosis of mesenteric arteries,
 one or both
 Infarction and gangrene of bowel, probably both
 small and large intestine
 Peritonitis?
 Occlusion of left common iliac artery, total
 Occlusion of right common iliac artery, incom-
 plete
 Gangrene of left leg and foot
 Generalized arteriosclerosis
 Arteriosclerotic and hypertensive heart disease,
 with old coronary thrombosis and myocardial
 infarction, and ? recent coronary occlusion
 Adenoma of thyroid gland?
 Pulmonary edema
 Hydrothorax, bilateral

ANATOMICAL DIAGNOSES

*Coronary thrombosis, recent, left anterior descending
 branch*
*Myocardial infarction, left ventricle, recent, with
 mural thrombus*
*Embolization, multiple, of superior mesenteric and
 femoral arteries*
Gangrene of ileum
 Peritonitis, purulent, generalized
 Bronchopneumonia, lower lobes of lung
 Arteriosclerosis, generalized
 Nontoxic nodular goiter

PATHOLOGICAL DISCUSSION

DR DAVID G FREIMAN Upon opening the abdomen we noted that the omentum, loops of small bowel and portions of the large bowel were matted together by a thick yellow exudate, and a small amount of gray, murky fluid lay free in the pelvis. The jejunum and proximal third of the ileum were moderately dilated and congested. Beyond this

point the ileum became gradually less distended, pale and friable, and a few scattered patches appeared dark and necrotic. The lowermost portion of the ileum and the large bowel, though flabby, showed no obvious gangrene. The cause of the gangrene in the small bowel was a reddish-gray, adherent embolus in the superior mesenteric artery, which extended from the point of origin of the ileocolic artery distally for a distance of about 2 cm. Both inferior and superior mesenteric veins contained adherent laminated thrombi extending distally into the smaller tributaries. These were undoubtedly secondary to the intestinal necrosis. Emboli were also present in both femoral arteries extending distally from the level of the inguinal ligaments. That on the right was slightly adherent and encroached upon the profunda branch. Both arteries below the points of occlusion showed severe sclerosis to the point of marked narrowing, but the lumens were patent. Thus, practically all Dr Quinby's diagnoses relating to the abdomen were confirmed. The arterial occlusions were due, however, not to an aortic dissection but to an unusual multiple embolization, a source for which was found in the heart. A recent myocardial infarction involved the anterior apical and part of the adjacent lateral walls of the left ventricle, and a mural thrombus about 3.5 cm in diameter was adherent to the endocardium in the region of the apex. About 1.5 cm below the point of origin of the descending branch of the left coronary artery, a recent occlusion was present. The left circumflex and right coronary arteries were sclerotic to the point of marked narrowing in several areas, but were not occluded. The lungs showed marked congestion in the posterior and inferior portions of the lower lobes, and microscopical examination revealed bronchopneumonia in these areas. There was no pleural fluid. The thyroid gland contained several small cystic nodules.

MEDICAL EDUCATION AT MESA VERDE

ONE of the pictorial magazines recently presented a photograph of the governors of Utah, Colorado, Arizona and New Mexico, seated at a table placed over the exact spot where the boundaries of these four states meet. It would be of interest to know what they had to say to each other if anything, about medical education.

The ratios of the 1949 freshman medical students to the populations for these four states swing from the very highest to the very lowest in the United States. The ratios for all the states are shown in the September 3 issue of the *Journal of the American Medical Association*. Utah is the highest, with 10.5, New Mexico is the lowest, with 1.5, Colorado and Arizona are 7.6 and 3.1 respectively. Or one might similarly arrange a luncheon table at the point where the boundaries of Wyoming, South Dakota and Nebraska converge, the ratios for these three states being 2.6, 6.6 and 8.9.

In the same number of the *Journal* it was editorially suggested that these discrepancies had been noted in Washington, and it was pointed out that the bill for federal aid to medical schools now pending before the Senate provides, "No payments may be made to any school unless such school has filed an application therefor which contains adequate assurance, as determined by the Surgeon General that such school provides and will provide reasonable opportunity for the admission of out-of-state students." Under date of September 2 the American Medical Association also released a statement to the press under the caption "Residency Limitations by Medical Schools Held to be Disservice." In this statement it is pointed out that although tax-supported institutions might be expected to render their major services to the community that supports them, the exclusion of all nonresident students may not prove to be in the best interest of the community or the region of which the community is a part.

When the ratios quoted above are plotted geographically, it is plain that it is a regional problem, and could be more satisfactorily met by regional arrangements than if every medical school were prevailed upon to open wide its doors to all comers. At least it seems appropriate for a substantial majority of the medical students in the United States to be able to receive their professional training within a reasonable distance of their places of residence. There may be good reasons why certain persons want to cross the continent for purposes of study, and there may be good reasons for certain schools to want their students to be gathered from widely dispersed areas, but it is hard to believe that any state has five times as many qualified candidates as its next door neighbor. It is probable that the admission authorities of the medical schools are sensitive to and sympathetic with their regional needs, but the ultimate authority of tax-supported institutions may rest in governmental bodies. Regional consciousness is a difficult thing for politicians to acquire, particularly at what is known as the "state level." More dinners, or card games, or whatever it is that governors do when they meet at Mesa Verde might prepare them to carry back to their legislatures a far-sighted

point of view toward their whole region as well as their individual states. This kind of leadership would help.

In the meantime probably every medical school in the country would be doing itself a good turn if it were to encourage application from residents of the states with the lowest ratios of medical students to populations.

PEACETIME USO

MR. KARL K. VAN METER, executive vice-president of the United Service Organizations, consisting the YMCA, National Jewish Welfare Board, Salvation Army, National Catholic Community Service, YWCA and National Travelers Aid Association, points out the need for reactivating the USO now, in peacetime, and urges that funds be raised privately or through the agency of local community chests for this purpose.

With the present armed forces numbering over one and one-half millions, 70 per cent or more below the age of twenty-one, the desirability of some sort of benevolent civilian influence is evident, perhaps to an even greater extent than in wartime. Then the nearness of actual danger furnished incentive enough to serve. Military service in time of peace, however, directed as it is to warding off a more distant danger, leaves the individual service-man's incentive to be largely derived from the appreciative attitude of the public with whom he comes in contact. The responsibility of strengthening the armed forces has been rightly accepted, and with it goes the responsibility for their spiritual and social welfare.

It may be asked why this job should be done by volunteer workers on privately raised funds (the goal is twelve million dollars) rather than being included in the military budget, of which it would be an infinitesimal fraction, and it will come as a surprise to those who associate President Truman's name with the "Welfare State" to learn that a letter urging the former method appears in Mr. Van Meter's brochure over the signature of Harry Truman himself. Regardless of how efficient the military establishment has been, is now or may become, experience and common sense show that the

part of a soldier's morale that depends on his contact with his civilian background and surroundings cannot be supplied by military officialdom. The nation wants its sons efficiently trained and disciplined for national defense, but during their training at home or abroad it wants them "in contact with the normal and wholesome activities of civilian life" so they will not return "bitter and disillusioned, resentful of the treatment they have received from civilians." Furthermore "much of USO activity is of a religious and spiritual nature which no governmental auspices could appropriately provide."

Mr. Van Meter makes out so unanswerable a case for reactivating the USO now, four years after the ending of the war, that one cannot help wondering why so little has been done about it before.

POLIOMYELITIS GOES UNDERGROUND?

THE virus of poliomyelitis, according to a hypothesis recently advanced by L. E. Rector,* of St. Louis, may quite literally go underground. This hypothesis is based on the assumption that any single host or vector of poliomyelitis must fulfill certain criteria. It must be found throughout both the temperate and tropical zones, it must account for the frequently observed tendency of the disease to begin and to have a higher incidence in rural than in urban communities, it must account for the seasonal tendency of the disease in man, and it must be so inconspicuous as to have escaped consideration to date.

The ground mole, happy hero of all the creatures that people the damp and sunless habitations found in Kenneth Grahame's *The Wind in the Willows*, fulfills these requirements. Voracious, ever on the forage, the mole adapts the level of his burrowing to that of his natural quarry, the earthworm. In the winter his runs are deep in the earth, in the summer so shallow as barely to be covered by the roots of the overlying vegetation. If a true representative of the grass roots is wanted, it will be the mole. Persons lying on the ground in the summer, whether in park or pasture, may be cultivating the acquaintance of the mole to a degree that invites even the transfer of a virus.

*Rector, L. E. Mole as possible reservoir of poliomyelitis. *Arch. Path.* 47:366-377, 1949.

Because of the hypothetical possibility that the mole might be the host of poliomyelitis, moles from Forest Park, St. Louis, were made the subjects of an investigation into their susceptibility to the virus. A number having been injected intracerebrally with filtrates of infected mouse brains or with stool filtrates from child victims of the disease were kept under observation.

Various clinical signs were recorded, including anorexia, cardiac arrhythmias consisting of dropped beats and extrasystoles, and coming to the surface to die—an unnatural procedure for moles. At autopsy no lesions typical of poliomyelitis were found, but this lack of pathology is found also in rabbits subjected to inoculation with the virus.

In the unremitting search for the method of spread of infantile paralysis, each possibility must be explored. There is as yet no proof that the mole carries the virus of the disease, but there is also no proof that it does not.

RETIREMENT OF DR. FAXON

THE Massachusetts General Hospital's traditional "Ether Day" celebration was made this year the occasion for an inspired farewell party to the retiring director, Dr. Nathaniel Wales Faxon. Dr. Faxon's eminence as one of the country's leading hospital directors was emphasized by various speakers, and the fact was not lost sight of that he had begun his career as a country doctor in Stoughton, Massachusetts.

This breadth of experience is enough in itself to make the *Journal*, in wishing him a happy "retirement," hope that it will not be too retired. His services to the community as an elder statesman will be so valuable that he will, no doubt, not be permitted to become bored with idleness between his fishing trips.

Important advances are daily made in the dental art. Colleges, based upon the best and most thorough principles, are springing up in various sections of the States. Indeed, the progress of this science here is attracting much attention in England and on the Continent of Europe, and amongst those things in which we can boast a pre-eminence over the old world, may be safely enumerated dental surgeons.

Boston M. & S. J., November 7, 1849

NOTES FROM THE MEDICAL EXAMINER

USE OF BLOOD GROUPS IN CASES OF DISPUTED PATERNITY

The application of blood groups in cases of disputed paternity depends upon the fact that the laws of their inheritance are accurately known. Thus, neither antigen A nor antigen B will appear in the blood of a child unless it was present in the blood of at least one of the child's parents. In addition, 2 persons of Group O will never produce a child of Group AB. Conversely, 2 persons of Group AB will never produce a child of Group O. Table 1

TABLE 1 *Combinations Allowing an Alleged Father to Establish Nonpaternity**

PUTATIVE FATHER BLOOD GROUP	KNOWN MOTHER BLOOD GROUP	KNOWN CHILD BLOOD GROUP
O	O	A B
O	A	B AB
O	B	A AB
O	AB	AB
A	O	B
A	A	B AB
B	O	A
B	B	A AB
AB	O	O
AB	A	O
AB	B	O

*Impossible mother-child combinations are not included

shows the possible outcome of the various types of mating.

The application of these laws in forensic medicine is extremely simple. If a man is alleged to be the father of an illegitimate child, it is only necessary to test his blood, the blood of the child and the blood of the mother. If the mother is Group O, the alleged father Group O, and the child Group A and Group A antigen is not present in the blood of the alleged father or of the mother, it could not have come from the mother, it must have come from the real father of the child. Therefore, it may be concluded that the alleged father is not the natural father.

On the other hand, if the mother and the alleged father are Group A and the child is Group O, this does not prove that the alleged father is not the real father of the child, because persons of Group A sometimes produce children of Group O (Table 1). The O factor seems to act as a recessive in the presence of A or B. If these simple rules are kept in mind, little difficulty will be encountered in interpreting the results.

In performance of the tests it is naturally very important that the blood be correctly identified at the time it is taken. Sufficient blood may be taken by puncture of the finger or earlobe of the man and woman and put into physiologic saline solution. With very young children puncture of the great toe seems preferable.

The A and B antigens are not the only ones that may be applied to the investigation of paternity.

point of view toward their whole region as well as their individual states. This kind of leadership would help.

In the meantime probably every medical school in the country would be doing itself a good turn if it were to encourage application from residents of the states with the lowest ratios of medical students to populations.

MISCELLANY

AN APPEAL TO WHO

The editors of *Ärztliche Praxis*, a German weekly medical journal devoted to the interests of the general practitioner, have directed an open letter for help to Dr Brock Chisholm, director general of the World Health Organization

The appeal is based on the surplus of skilled physicians in the three western zones of Germany and their lack in many other parts of the world and the desire that the World Health Organization may facilitate the emigration of these trained physicians into less favored areas

CORRESPONDENCE

LAST REBUTTAL

To the Editor: Dr Allan M. Butler's letter in the October 13 issue of the *Journal* hints that Dr McManamy's aversion to "therapeutic" abortion, euthanasia and so forth is used as an "out" in avoiding difficult problems. It seems to me that euthanasia and "therapeutic" abortions are definite acts performed expressly to avoid difficult problems.

I suggest that Dr Butler should find out what "good Catholicism" means before he uses the term.

Unlike many things, the Fifth Commandment has no exceptions.

FRANCIS D. MCCARTHY, M.D.

Melrose, Massachusetts

BOOK REVIEWS

A Treatise on Obstetric Labor. By Richard Torpin, M.D. With a chapter on erythroblastosis fetalis and the Rh factor, by Edith L. Potter, M.D., and Philip Levine, M.D. 8°, cloth, 590 pp., with 187 illustrations. Augusta, Georgia: Augusta Obstetric and Gynecologic Book Company, 1949. \$7.00.

This treatise on obstetric labor is dedicated to the praiseworthy proposition that there are far too many operative deliveries and that a much larger percentage of labor should be normal. This, the author believes, can be accomplished by a judicious use of fluids, dextrose, transfusions, oxygen, sedation and rest, and in thousands of cases he has found these measures "far more profitable in saving life and preventing

disability of mother and fetus than surgical treatment immediately and ever so skilfully done."

In a series of 41 chapters and 73 selected illustrative case reports he undertakes to demonstrate this proposition. As a result of his experience, he has almost entirely eliminated from his practice haggling, extraction and version, though rather surprisingly he performs episiotomy in almost every case, including normal deliveries. This conservative attitude which he attributes to his early training by Culbertson and Heaney at Rush Medical College, is at least a refreshing contrast to much modern radical surgical obstetric teaching.

There is an authoritative chapter on erythroblastosis fetalis and the Rh factor by Dr Edith L. Potter and Dr Philip Levine. The work is illustrated with 187 admirable figures. Twelve hundred references to the literature are distributed in appropriate bibliographic groups at the close of the chapters.

Gynecologic Diagnosis. By Robert Tauher, M.D. 8° cloth, 275 pp., with 80 illustrations. New York: Thomas Nelson and Sons, 1949. \$5.00.

This monograph is intended to teach students correct methods of gynecologic diagnosis. The author first discusses history taking and interpretation, the various techniques of physical examination, the essential laboratory tests and the common diagnostic surgical procedures. He then presents what he terms a diagnostic clinic, a series of 33 cases in six groups, illustrating a number of frequent and a few rare pathologic conditions. At no time is the diagnosis stated, but the reader is supposed to make his own and then to refer to a list at the end of the book. There is an excellent final chapter on errors in diagnosis, and their avoidance. The work is admirably illustrated with eighty full-page figures by C. W. Brill, and has a brief bibliography of seventeen appropriate special references.

Die Kreuzschmerzen der Frau ihre Deutung und Behandlung. *Gynäkologische Orthopädie*. By Professor Dr Heinrich Martius, director of the University Women's Clinic, Göttingen. Third edition. 8°, paper, 136 pp., with 64 illustrations by Käthe Drosen. Stuttgart: Georg Thieme, 1947. Imported by Grune and Stratton, Incorporated, New York. \$2.75.

This third edition of a well known work, first published a decade ago, by the director of the Women's Clinic at Göttingen, presents an exhaustive survey of all the gynecologic conditions to which sacral pain in women is commonly attributed. Without denying the importance of these and of their appropriate treatment, the author believes that in all cases there is also an intrinsic postural element—that sacral, lumbosacral and sacroiliac pain in women is fundamentally an orthostatic symptom whose concurrent orthopedic treatment with a properly designed and adjusted girdle is essential, if satisfactory and total relief is to be obtained.

The book is well illustrated with 64 admirable black-and-white drawings by Käthe Drosen, and has an elaborate and valuable bibliography of 500 well selected references.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Surgery of the Eye. By Meyer Wiener, M.D., honorary consultant, ophthalmology, Bureau of Medicine and Surgery, United States Navy. Second edition. 8°, cloth, 426 pp., with 426 illustrations. New York: Grune and Stratton, 1949. \$12.00.

In this second edition a special illustrated work on surgery of the eye, first published in 1939 and long out of print, has been revised and brought up to date. The new material includes the preparation of sutures preliminary to the incision for cataract, Otto Barkan's improved technic for congenital glaucoma, Burch's method of implantation in exsiccation and Wiener's method of transplantation of the cornea by means of a mechanically obtained leveled edge. The text is not padded with redundant references to the literature. There is a good index. The work is intended to be a handy atlas of operating procedures for the ophthalmologist.

The inheritance of the M and N factors (Table 2), discovered in 1927, is equally well known

The rules of inheritance are somewhat simpler because there is nothing corresponding to Type O—that is, either antigen M or antigen N, or both, is always present in the blood. The interpretation of the test is otherwise exactly the same.

The Rh factors, discovered in 1940, have been investigated sufficiently so that they are being used by some workers in cases of disputed parentage. Eight genes are thought to be involved in the inheritance of the Rh factors, and since the resulting combinations of these genes, 2 at a time, give a pos-

sible 36 genotypes, not all of which can be distinguished by the use of the serums at present available or even by the use of any serums that may eventually be available, it is not so easy to summarize the interpretation of tests for the Rh factors in cases of disputed parentage. Weiner's summary of the situation is as follows:

Factors Rh₀, rh', rh'', hr' and hr'' cannot appear in the blood of a child unless present in the blood of one or both parents.

Parents of types Rh₁Rh₁ and rh'rh' cannot have children of types rh, Rh₀, Rh₂ or rh'', and parents of types rh, Rh₀, Rh₂ and rh'' cannot have children of types Rh₁Rh₁ or rh'rh'. Or, more simply, hr'-negative parents cannot have rh'-negative children, and rh'-negative parents cannot have hr'-negative children.

Parents of types Rh₂Rh₂ and rh''rh'' cannot have children of types rh, Rh₀, Rh₁ and rh', and vice versa. Or, more simply, hr''-negative parents cannot have rh''-negative children, and rh''-negative parents cannot have hr''-negative children.

*Five-year median

COMMENT

Diseases above the seven-year median for September were dog bite and poliomyelitis.

Diseases below the seven-year median were chicken pox, German measles, measles, mumps, salmonellosis, scarlet fever and whooping cough.

Poliomyelitis continued at a high level, exceeding all records for September except 1916. If only paralytic cases were counted, however, the figures this year were far below 1916.

Although chicken pox was unusually prevalent during the first half of this year, it fell to the lowest level for this month since 1939.

Measles also ran unusually high during the early part of this year, but the number of cases fell to the lowest September since 1937.

Scarlet fever, for the past three months, has been at the lowest levels ever recorded.

GEOGRAPHIC DISTRIBUTION OF CERTAIN DISEASES

Actinomycosis was reported from New Bedford, 1, total, 1.
Diphtheria was reported from Boston, 1, Chelsea, 1, Foxboro, 1, Lenox, 1, Malden, 1, Rockport, 1, Somerville, 1, total, 7.

Dysentery, amebic, was reported from North Andover, 1, total, 1.

Dysentery, bacillary, was reported from Boston, 4, Brookline, 1, total, 5.

Encephalitis, infectious, was reported from New Bedford, 1, Salisbury, 1, total, 2.

Lymphocytic choriomeningitis was reported from Springfield, 1, total, 1.

Malaria was reported from Medford, 1, total, 1.

Meningitis, meningococcal, was reported from Brockton, 1, Malden, 1, total, 2.

Meningitis, undetermined, was reported from Haverhill, 1, Worcester, 1, total, 2.

Poliomyelitis was reported from Abington, 1, Adams, 1, Amesbury, 2, Amherst, 3, Arlington, 11, Ashby, 3, Ashland, 1, Attleboro, 4, Auburn, 1, Ayer, 1, Barnstable, 2, Bellingham, 1, Belmont, 1, Berlin, 1, Beverly, 8, Billerica, 2, Boston, 87, Braintree, 6, Brewster, 1, Brockton, 5, Brookline, 10, Burlington, 1, Cambridge, 5, Canton, 3, Carver, 1, Charlton, 2, Chelsea, 7, Chicopee, 1, Clinton, 1, Cohasset, 1, Concord, 4, Dalton, 1, Dedham, 4, Dennis, 1, E Bridgewater, 3, Everett, 15, Fairhaven, 1, Fall River, 6, Framingham, 6, Framingham, 3, Franklin, 1, Great Barrington, 1, Groveland, 1, Hampden, 1, Haverhill, 2, Hardwick, 1, Hatfield, 1, Haverhill, 5, Hingham, 4,

THE GENESIS OF HEART SOUNDS

OSCAR ORIAS, M.D.*

CORDOBA, ARGENTINA

IT IS possible that the existence of the heart sounds was known to Hippocrates¹ and even that he made use of his knowledge for diagnostic purposes, but William Harvey² seems to have been the first to make specific reference to them. "With each movement of the heart as a quantity of blood is delivered from the veins to the arteries, a pulse takes place, which may be heard in the chest."

It is rather astonishing that the physicians of that time had thus far paid no attention to the heart sounds, but it is even more astonishing that their existence, when pointed out by Harvey, was soon denied. It was Parisanus³ who said, "Neither we, poor deafts nor any other doctor in Venice can hear them, but happy he is who can hear them in London."

Although Harvey placed beyond doubt the existence of sounds accompanying the heart's activity, Laënnec⁴ nearly two centuries later, gave the first precise description of the character of the sounds in normal and pathologic conditions and founded the art of auscultation.

Once the existence of the heart sounds was established, their cause was sought, and thus began an interminable series of investigations, controversies and theories, which have not ceased even at the present time. Theories on the causes of the heart sounds multiplied at such a rate that in 1881 Sandborg⁵ collected no less than forty, most of which were entirely without clinical or experimental basis and often revealed a complete ignorance of cardiac physiology on the part of their originators.

The first serious attempts to elucidate the exact causes of the heart sounds were made from 1835 on by various committees appointed by the British Association for the Advancement of Science.⁶ The problem was studied experimentally, and many of the findings have since become classic, such as the experiments on the part played by the ventricular muscle in the causation of the first sound. These studies were of the greatest value in that they clarified the whole problem, mainly by demonstrating the absurdities of most of the current theories of the day.

The advent of the graphic methods of recording soon made possible a more precise analysis of the different phases of cardiac activity and afforded a method that allowed one to ascertain the exact moments of production and other peculiarities of the heart sounds.

The time relations between heart sounds and cardiac events was an additional contribution to the elucidation of the causes producing the heart sounds.

It is now certain that at least four sounds may occur, under normal conditions, during the heart cycle. Two of them, the classic first and second sounds, are heard on any living person. A third heart sound may be heard during early diastole in many young persons after the second sound, and the fourth sound, also called auricular, takes place and may often be heard immediately before the first sound during auricular systole.

THE FIRST HEART SOUND

The first heart sound is certainly a complex phenomenon, and although there is no general agreement concerning the conditions that produce it, there is no doubt that they are numerous. In fact such a multiplicity of causes explains most of the discrepancies existing between the findings of different investigators. Each investigator, using some special technic, has taken account only of the factors that his own particular method revealed, and has ignored the existence of all that it was unable to detect. Here, as elsewhere in science, the existence of such discrepancies is a clear demonstration of incomplete knowledge of the subject, and this is due largely to inadequacy of the procedures employed. With improvement in technic a more objective study can be made, discrepancies gradually disappear, and knowledge of the subject becomes solid and well founded.

There is experimental and clinical evidence that the following events produce vibrations contributing to the formation of the first sound: muscular contraction and tension of the ventricular walls at the onset of ventricular systole (muscular factor), closure of the auriculoventricular valves (valvular factor), movements and distention caused by the

*Visiting professor in physiology, Long Island College of Medicine; director, Instituto de Investigacion Medica, Mercedes y Martin Ferreyra.

Critical Studies in Neurology By F M R Walshe, M.D., F.R.S., F.R.C.P., physician to University College Hospital, physician to the National Hospital for Nervous Diseases, Queen Square, and fellow of University College, London 8°, cloth, 256 pp., with 16 illustrations Baltimore Williams and Wilkins Company, 1948 \$4.50

The author has brought together in this small volume six papers originally published in *Brain* during the period 1942 to 1947, to which is added a paper published in the *British Medical Journal* in 1945. The series is preceded by an essay entitled "The Function of Criticism in Medicine." The reprinted papers comprise the anatomy and physiology of cutaneous sensibility, the giant cells of Betz, the motor cortex and the pyramidal tract, the mode of representation of movements in the motor cortex with special reference to "convulsions beginning unilaterally" (Jackson), the notion of the "discrete movement" in willed motion, the role of the pyramidal system in willed movements, and the integration of medicine. The publishing is well done. It is a convenience to have the scattered papers of Dr. Walshe brought together in one volume. It should be in the neurologic sections of medical libraries and available to neurologists.

Diseases of the Fundus Oculi With atlas By Adalbert Fuchs, M.D., co professor of ophthalmology of the University of Vienna. Translated by Erich Pressburger, M.D. Edited by Abraham Schlossman, M.D. First English edition 4°, cloth, 381 pp., with 81 illustrations and 44 tables Philadelphia Blakiston Company, 1949 \$30.00

It is a pleasure to note that this classic treatise of Professor Fuchs has been translated into English. The original German edition appeared in 1943, and in this edition in English the author has added many pictures and much material that had not appeared before either in German or in English, making it practically a new work. There are eighty figures in the text and the appended atlas consists of forty-four plates in color printed from the original plates in Vienna, and imported for inclusion in this volume. The plates are typical of the finest German work. There is a good index, and the type and printing are excellent. Dr. Fuchs is well known for his *Atlas of Histopathology of the Eye*, published in two volumes in 1923 and 1927. The edition is limited to 995 numbered copies. The price is not excessive for this type of book. The atlas should be in all eye collections in medical libraries and likewise available to all ophthalmologists.

NOTICES

COMBINED MEETING OF NEW ENGLAND SOCIETY OF PHYSICAL MEDICINE AND MASSACHUSETTS CHAPTER OF AMERICAN PHYSICAL THERAPY ASSOCIATION

A combined meeting of the New England Society of Physical Medicine and the Massachusetts Chapter of the American Physical Therapy Association will be held in the Bigelow Amphitheater of the Massachusetts General Hospital on Wednesday, November 16, at 8 p.m.

Dr. Eugene E. Record will speak on the subject "The Amputee and His Rehabilitation," with lantern slides, motion pictures and case presentations. Dr. Arthur L. Watkins will lead the discussion.

Physicians, physical therapists, occupational therapists and corrective therapists are cordially invited to attend.

94TH INFANTRY DIVISION LECTURES

The 94th (Bay State) Infantry Division is sponsoring a series of monthly lectures by prominent physicians in their respective specialties. The eighth lecture will be held in the auditorium of Boston University School of Medicine, 80 East Concord Street, Boston, on Thursday, November 17, at 8 p.m.

Dr. Elvin Semrad will speak on the subject "Common Pitfalls in Psychotherapy."

All interested physicians, whether reserve officers or not, are cordially invited to attend this carefully planned program. Reserve officers will be given one point credit if authorized by the instructor of their unit of assignment. Excellent films will also be shown during this period.

MASSACHUSETTS PUBLIC HEALTH ASSOCIATION

The annual fall meeting of the Massachusetts Public Health Association will be held at Simmons College, 300 Fenway, Boston, on Thursday, November 17. The section meetings, which begin at 4 p.m., will include sessions of the sections of health officers, laboratory, sanitation, maternal and child health and public-health nursing, health education and food and nutrition. The dinner session will be held at 6 p.m. The feature of the general session, beginning at 7 p.m., will be a panel discussion, led by Dr. John F. Conlin, on the subject "How John Q. Boston Was Persuaded To Be X-Rayed," which will emphasize the need of community participation in the attainment of public-health objectives.

NORFOLK DISTRICT MEDICAL SOCIETY

A meeting of the Norfolk District Medical Society will be held at the Boston Medical Library, 8 Fenway, Boston, on Tuesday, November 22, at 8 p.m. The following medical and surgical program by the Lahey Clinic, with Dr. Frank H. Lahey in charge, will be presented:

The Selection of Patients for Sympathectomy for Hypertension (Including Results after Operation) Dr. James A. Evans

The Management of Ulcerative Colitis Dr. Everett D. Kiefer

Blood Diseases Related to the Spleen, and Indications for Splenectomy Dr. John W. Norcross

Recent Advances in the Management of Thyroid Diseases Dr. Frank H. Lahey

There will be a short business meeting.

Subsequent meetings will be held on Tuesday, January 24, Tuesday, February 28, Tuesday, March 28 and Wednesday, May 3 (annual dinner).

JOINT MEETING OF ALPHA OMEGA ALPHA AND BOSTON CITY HOSPITAL HOUSE OFFICERS' ASSOCIATION

A lecture will be given under the joint sponsorship of the Harvard Chapter of Alpha Omega Alpha and the Boston City Hospital House Officers' Association in the auditorium of Building E, Harvard Medical School, on Tuesday, November 22, at 5 p.m.

The lecture will be on "Compound E in Arthritis" and will be delivered by Dr. Philip S. Hench, head of section in Division of Medicine, Mayo Clinic, and associate professor of medicine, The Mayo Foundation.

WORCESTER COUNTY CHAPTER, MASSACHUSETTS HEART ASSOCIATION

A panel discussion sponsored by the Worcester County Chapter of the Massachusetts Heart Association will be held at Dean Hall, Worcester, on Tuesday, November 22 at 8 p.m. The subject will be "The Problem of the Cardiac in Industry."

Howard B. Sprague, M.D., of Boston, president-elect of the American Heart Association, will be chairman of the panel. The panel speakers will include Eugene H. Giroux, chairman of the Massachusetts Industrial Accident Board, Karl Benedict, M.D., industrial physician, Norton Company, Worcester, who will speak on the subject "The Viewpoint of an Industrial Physician," and two members of the Worcester County Bar Association, who will present legal angles.

AMERICAN ACADEMY OF DERMATOLOGY AND SYPHILOLOGY

The eighth annual meeting of the American Academy of Dermatology and Syphilology will be held in Chicago from December 3 through December 8.

The principal sessions will be held at the Palmer House, with special courses in histopathology and mycology scheduled for Saturday and Sunday, December 3 and 4, at the medical schools of the University of Illinois and Northwestern University. Teaching clinics will be held at the University of Illinois College of Medicine in Chicago on the afternoons of December 5, 6 and 7.

(Notices concluded on page xvii)

of the valvular factor for the production of the heart sounds

No matter how obvious it seems to consider the vibrations of the valves as a main cause of the heart sounds, dissident views have also appeared. Just as an example of how positive a man can be in affirming or denying the role of the heart valves in the production of the heart sounds Kassatkine,²¹ a Russian investigator considered himself justified in concluding that "the tendency to consider the heart sounds as a valvular sound is a mistake." He believes that the view of those who attribute the origin of the sounds to the vibrations of the heart walls and of the walls of the aorta and pulmonary arteries adjacent to the valvular orifices is more convincing.

Vascular Component

Even in the earliest writings on the subject, the idea was expressed that vibrations due to the opening of the semilunar valves took part in the formation of the first sound (Cruveilhier,²² in 1841, and Ceradini,²³ in 1872).

Bamberger,²⁴ by simple auscultation, had concluded that during systole, when the first sound is heard, four sounds, which are superimposed and usually heard as two, are produced — namely, the tricuspid and mitral sounds, and those caused by distention of the pulmonary artery and aorta.

The pioneer records of the heart sounds taken by Einthoven and Geluk²⁵ showed a delay of about 0.06 second for the first sound recorded at the base of the heart, as compared with the same sound recorded at the apex, they therefore thought that the first sound at the base was due to the opening of the semilunar valves.

The part played by a vascular component in the genesis of the first heart sound was denied on the basis that this sound did not spread to any extent during the ejection phase of ventricular systole. This can no longer be doubted after phonocardiographic observations in animals (Wiggers and Dean²⁶) and in man (Schütz,²⁷ Weber²⁸ and Caeiro and Orías²⁹).

My own experience has shown that in human phonocardiograms obtained from the chest, it is extremely common to find that the first sound is composed of two principal groups of vibrations (Orías and Braun-Menéndez,²⁹ Orías³⁰ and Caeiro and Orías³¹). The records demonstrate clearly that one of these corresponds to the systolic isometric phase and the other to the ejection phase of ventricular systole. If the heart sounds are explored from different sites it is always possible to show this division appearing in at least one such area of auscultation either constantly or else during certain moments in the respiratory cycle (Caeiro and Orías³¹).

In fact, from the careful study of a large number of phonocardiographic tracings we are convinced

that vibrations of vascular origin form an important and as yet not sufficiently recognized proportion of the first sound as heard over the precordial area in normal conditions.

When, by reason of favorable circumstances the separation of the components of the first heart sound occurring during the isometric and the ejection phases of the ventricular systole is more accentuated, a true splitting of the sound may be recognized by auscultation and recorded by the phonocardiograph.

Auricular Component

The idea that vibrations of auricular origin contribute to the formation of the first heart sound has suffered many vicissitudes. The earliest records made of the first sound showed that this began 0.02 to 0.04 second before ventricular systole, which led some workers like Hürthle,³² Pawlinsky,³³ Weiss³⁴ and Roos³⁵ to believe that the initial vibrations were of auricular origin.

Later records showed that, although the earliest vibrations of the first sound sometimes preceded ventricular systole, they appeared *after* auricular systole (Battaerd³⁶ and Wiggers and Dean²⁶). This observation, together with the fact that when a separate clearly auricular sound existed, as in cases of gallop rhythm, these auricular vibrations preceded those of the first sound by a longer interval, led Wiggers³⁶ to deny the possibility of auricular participation in the formation of the normal first sound. In his opinion the small and slow initial vibrations that precede ventricular systole had not received an adequate explanation.

When more sensitive recording devices were used, especially in cases of delayed auriculoventricular conduction (incomplete, partial and complete auriculoventricular block) and in cases of transitory nodal rhythm it was shown that late manifestations of auricular activity contribute to the formation of the first heart sound.

Braun-Menéndez and Solari³⁷ by recording the heart sounds direct from the ventricular wall in dogs with auriculoventricular block, found that auricular contraction can produce sound vibrations persisting 0.20 second after the beginning of auricular systole and forming two groups of vibrations in the sound record. The first group of vibrations coincides with auricular contraction but the second group appears during full auricular diastole.

These facts satisfactorily meet Wiggers's objection that the auricular sound, when present, does not merge into the first sound. What happens is that when the first component of the auricular vibrations is sufficiently strong to be recorded, a clear auricular sound is observed, well separated from the first heart sound. In ordinary conditions it is the delayed components (second group) that contribute to, and so reinforce, the first sound.

ejection of blood from the ventricles into the arteries (vascular factor), and residual vibrations due to the preceding auricular contraction (auricular factor)

Before each one of these factors is analyzed it should be mentioned that sounds of the type observed in semiocluded arteries (Korotkow sounds), which may be produced by the action of the ventricular muscle on the coronary arteries, have also been suggested as an additional cause of the first heart sound (Laurell⁷)

It should also be emphasized that the factors mentioned above have not been listed in order of their relative importance. This will be considered below, for it varies according to the conditions and with the site of auscultation. However, almost everyone will agree that the valvular factor is the most important of all

Muscular Component

The existence of a muscular component in the first heart sound was debated for a whole century and is still a matter of dispute

In 1835-1840 the Committees appointed by the British Association for the Advancement of Science⁶ showed that a muscular factor was responsible for a great part of the first heart sound, for this could still be heard after closure of the auriculoventricular valves had been prevented by the introduction of a finger into the auriculoventricular orifice. Ludwig and Dogiel,⁸ in 1868, arrived at similar conclusions by placing ligatures in the auriculoventricular groove in dogs so as to prevent the free movement of the valves. They assumed that the sound still heard in such conditions was due to friction between muscle fibers at the beginning of systole. Yeo and Barrett,⁹ in 1885, Krehl,¹⁰ in 1889, Kasem-Beck,¹¹ in 1890, and Hess,¹² in 1920, repeated the experiments and confirmed the results of Ludwig and Dogiel

A dissident view appeared in 1933, when Dock¹³ interpreted his experiments, which followed the Ludwig and Dogiel pattern, as indicating that the first heart sound disappeared when the valvular motion was prevented. Subsequent experiments, however, along the same line have led Smith¹⁴ and Smith, Gilson and Kountz¹⁵ to the conclusion that elements initiated by the heart wall contribute to the production of the first sound

Eckstein¹⁷ approached the problem from another point of view. To ascertain whether or not myocardial tissue from a mammal's heart produces a sound during contraction, he removed the heart from a cat immediately after death and perfused the coronary vessels from a cannula placed in the aorta. While the heart continued to beat, the right coronary and the left circumflex branches were ligated. All the ventricular musculature was then cut away except a V-shaped strip surrounding the left ramus descendens. The weight of this strip averaged

about 6 gm. After ligation of the small vessels, the strip continued to beat, and with the occasional help of epinephrine the beat could be made forceful. When a receiver was sewed to such a strip of ventricular muscle devoid of valves, chordae tendineae and ventricular chambers, vibrations were still heard and recorded during contraction. The vibrations increased in amplitude and number after epinephrine, and this showed that they depended upon the vigor of contraction. That skeletal muscle produces a sound when it contracts has been known since the classic demonstration of Wollaston¹⁸ in 1810

The muscular factor may not be essential for the production of the first heart sound, but until further evidence is available it would be incautious to deny that muscular contraction per se is able to originate sound vibrations

Apart from the muscular sound discussed above, which is assumed to be due to the friction of the fibers against each other, it has been suggested that vibrations due to sudden tension of the ventricular walls also contribute to the formation of the first sound. This idea was put forward in 1895 by Geigel¹⁹ and shared by Goldscheider,²⁰ Frank and Hess²¹ and Hess.²² It has been expressed with slight variations by Frey,²³ Schütz²⁴ and Weber.²⁵

Current discussions of the causes of the heart sounds do not neglect the possibility of a muscular component in the first heart sound. In one of the latest reviews on the subject Rappaport and Sprague²⁶ state that "in spite of conflicting experimental evidence, it appears likely that contraction of the ventricle produces vibrations in the absence of valve closure. These (vibrations) contribute to the early part of the first sound"

On the clinical side, White,²⁷ in his well known textbook on diseases of the heart, says, "the first sound, loudest at the apex, is produced by closure of the mitral and tricuspid valves, plus an element of muscular contraction"

Valvular Component

Rouanet,²⁸ in 1832, seems to have been the first to regard the closure of the auriculoventricular valves as an important, or indeed the only, factor in the origin of the first heart sound. Obviously, of all the cardiac structures the valves seem the most likely to produce a sound by their closure. Said Rouanet: "They are thin, resistant, and inextensible, and pass suddenly from flaccidity to a state of very great tension," and this process explains the mechanism of production of the sound

Bayer,²⁹ in 1869, and Giese,³⁰ in 1871, showed that if, in a dead heart with artificial circulation, the auriculoventricular valves were suddenly placed in tension, a sound was produced

The changes in the characteristics of the heart sounds following valvular defects created by disease are further proof of the paramount importance

the auricles (Bridgman⁷⁴), and the friction of the auricle against neighboring structures

Once auricular contraction itself is finished, there is a possibility of residual vibrations in the above structures, and of new vibrations (Melik-Gulnasarian⁷⁵) owing to the movement of apposition of the auriculoventricular valves at the end of auricular contraction

All these factors probably combine in different proportions to produce the auricular sound, and account for its complexity in phonocardiographic records when it occurs separate from the first sound as in cases of auriculoventricular block (Braun-Menéndez and Solari⁷⁷)

The intensification of the auricular sound under special pathologic conditions implying myocardial damage, as in some cases of gallop rhythm, is further evidence of a muscular component in the genesis of the auricular sound

SUMMARY

There is experimental and clinical evidence pointing to four factors as contributing to the formation of the first heart sound: muscular contraction and tension of the ventricular walls at the onset of ventricular systole (muscular factor), closure of the auriculoventricular valves (valvular factor), movements and distention caused by the ejection of blood from the ventricles into the arteries (vascular factor), and residual vibrations due to the preceding auricular contraction

The second heart sound is due to vibrations produced by the closure of the semilunar valves on the valves themselves, in the walls of the arteries (pulmonary and aorta) and also in the blood column

The third heart sound is caused by vibrations of the ventricular walls due to their sudden distention by the inrush of blood from the auricles in the final moments of rapid ventricular filling

Muscular contraction and distention, passage of blood through the auriculoventricular orifices, distention of ventricular walls by the inrush of blood from the auricles and friction of the auricle against neighboring structures are the underlying factors accounting for the auricular sound

DISCUSSION

DR WILLIAM DOCK.* Dr Orias has given an excellent historical and critical review of the heart-sound problem to which I have nothing to add. However, I should like to do some subtraction and to recapitulate my heresies, already incorporated in two papers and presented to the sophomores each year until Dr DiPalma decided that it was not advisable to continue confusing the class in physical diagnosis.

Of the animal experiments the crucial one is that of Macleod and Cohn,⁷⁶ who inserted a piezoelectric device into dogs' hearts through the carotid artery or the jugular vein, to record the pressure synchronously with the electrocardiogram. Such a system records sound vibrations if they are intense and the records show clearly that the first sound is intense only at the auriculoventricular orifice, although vibrations are recorded, synchronous with the first sound and

with ejection, at the aortic orifice. The second sound is intense only at the aortic orifice. These observations seem to me to show that the dog's aorta, unlike its brachial and femoral arteries, does not give off a pistol-shot sound when the pulse wave enters it; they show that the first sound originates in the auriculoventricular, and the second in the semilunar valves. No vibrations of audible frequency were recorded from either the auricular or the ventricular walls with which the pick-up came in contact; the vibrations became attenuated rapidly a few centimeters away from their points of origin. In a continuous medium — air, water or steel — sound is attenuated according to the usual square of the distance formula, in discontinuous mediums — cork, rubber, air full of rain or snow, plasma full of red cells or muscle — sound is attenuated very quickly. Fibrous structures or crystalline structures such as bone and tendon, transmit sound fairly well. The aorta and pulmonary-artery walls are better sound conductors than the ventricles, and the aortic and pulmonary sounds are loudest at the points where the vessels come closest to the thoracic wall, not where the stethoscope is closest to the valves. The auriculoventricular valves insert into the annulus close to the great arteries, and the first sound is transmitted to and along these vessels. First sounds, greatly attenuated, also pass out to the chest wall through the ventricular muscle mass. With a stethoscope, one can hear the heart sounds of a mouse or a horse, when the heart is exposed and in the hand, even if the ear is placed fairly close; no heart sounds in dogs', calves' or horses' hearts are detected. If the muscle itself vibrated, the sound should be intense at the surface. A violin string plucked so as to set up vibrations as intense as those recorded at the auriculoventricular valve by Macleod and Cohn⁷⁶ when in contact with the recorder could be heard many meters away in air. It is not remarkable that the heart sounds — damped by blood and meat, lung and adipose tissue — were unheard so long, even after Harvey.

I agree with Dr Orias that the auricle, when it begins to contract, causes audible vibrations loudest next the esophagus, as shown by Taquini.⁷⁷ I think this sound is due to the sudden tensing of the valves of Vieussens and Thebesius, guarding the coronary venous orifices, which are just next to esophagus. This sound is never heard and rarely recorded from the surface of the body.

I agree that there is a pair of little clicks at the end of auricular systole, even when this occurs in mid-systole of the ventricles with the auriculoventricular valves firmly closed. This is believed to be due to the snapping back and forth of the interauricular septum as systole dies out first in one auricle and then in the other and venous blood surges in. During all the rest of auricular systole, there is dead silence — muscular contraction and interfibrillar friction occur, but what sound is produced is quenched before reaching the cavity or the surface of the auricle.

During ventricular systole there is dead silence except for a brief snap as intraventricular pressure begins to rise. Here, also, all sound due to motion and friction is quenched at its source. If the heart is empty, or if it contracts early in diastole before isometric relaxation has ended and ventricular filling begins, there is dead silence as one may observe in early ectopic beats. Here a contraction only a few thousandths of a second later in diastole, when the heart is filling but so empty that the weak beat fails to open the semilunar valves, causes a very loud first sound. In heart block, auricular fibrillation and ventricular tachycardia one regularly observes that beats occurring late in relation to phases of ventricular filling cause weak first sounds; those near the peak of a wave of filling cause loud sounds even when, as in ventricular tachycardia, the patient is pulseless and the second sound absent in the same beat.

Caudal to the third rib the first sound is almost purely valvular, but at the base vascular elements enter into it and the peak intensity may occur 0.02 to 0.04 second later than at the apex. First sounds at the base vary in intensity less than at the apex in the conditions named above. Rarely, the ear can detect splitting at the base in first sounds not split at the apex, so that the vascular element is distinct from the valvular element. Both elements arise in fibrous structures suddenly made taut by rising pressure, but even in anemia and aortic insufficiency the first sound at the base, in spite of the vigorous pulse wave and the closeness of the great vessels to the chest wall, is less intense than the apical first sound. Even at the base, the vascular vibrations may

*Director, Department of Medicine, Long Island College of Medicine

THE SECOND HEART SOUND

The origin of the second sound is much simpler than that of the first, and was well understood even by the very earliest investigators of the heart sounds.

The connection of the second heart sound with the closure of the semilunar valves was first precisely proposed and demonstrated by Rouanet²⁸ in 1932. He found that sudden stretching of an elastic membrane is always accompanied by a more or less distinct "snap," and on the basis of this simple experiment he could demonstrate what happens when the second sound is produced.

He inserted a vertical tube into the upper portion of an excised aorta, and into the other end, below the valves, another tube connected to a rubber balloon filled with water, which was compressed rhythmically. Each time that by decompression of the rubber balloon the reflux of the column of liquid was stopped by the semilunar valves, a sound could be heard if the ear was applied to the tube. Rouanet's explanation was adopted by Billing,⁴⁸ Carlisle⁴⁹ and Bouillaud.⁵⁰ His experiments were repeated and confirmed by the British Committee.

All the later anatomic, clinical and experimental observations have adduced new proofs in favor of the idea that the closure of the semilunar valves is the essential cause of the second sound, which is the acoustic expression of vibrations set up at this moment in the valves, in the walls of the artery and also in the blood column itself (Webster⁵¹).

In the ordinary conditions in which auscultation is made, the sounds originating in the aorta and the pulmonary artery, respectively, are heard as only one sound owing to summation. In cases of asynchronous closure of the semilunar valves, a reduplicated or split second sound is the result. The asynchronous closure of the semilunar valves as a cause of the split second sound was expressed without any objective basis before the phonocardiographic era but is now supported by experimental facts (Katz⁵² and Braun-Menéndez and Solari⁵³).

THE THIRD HEART SOUND

Many hypotheses have been proposed to explain the origin of the third sound. Here also, to a greater or lesser extent either the valves or the heart walls, or both, have been held responsible for the vibrations originating the sound.

Einthoven⁵⁴ thought that the third sound was caused by vibrations set up by sudden tension of the semilunar valves, but without definite statement of why this phenomenon should occur.

Gibson⁵⁵ and Hirschfelder⁵⁶ attributed the third sound to a transient and sudden closure of the auriculoventricular valves after the rapid filling of the ventricles. Gallavardin,⁵⁷ Benjamins⁵⁸ and Bridgman⁵⁹ supported this view. The study of venous pulse tracings optically recorded simul-

taneously with phonocardiograms eliminates, however, the possibility of any such valvular movement occurring at the moment at which the third sound is produced (Braun-Menéndez and Orías⁶⁰). Nor could Dean,⁶¹ by experiments in dogs, verify the existence of a valvular apposition at the time when the third sound is produced.

The third sound is produced in the final moments of the rapid ventricular filling as shown by its very constant relation with the last portion of the descending limb of the V wave (Ohm⁶² and Braun-Menéndez and Orías⁶⁰). From this observation the hypothesis has been advanced that the third heart sound is caused by vibrations of the ventricular walls that are due to their sudden distention by the inrush of blood from the auricles in the final moments of rapid ventricular filling. This conception was proposed by Ohm⁶² and has been supported by Frey,²³ Lian,⁶⁴ Gubergritz,⁶⁵ Melik-Gūlnasarian,⁶⁶ Leonhardt,⁶⁷ Schütz²⁴ and Braun-Menéndez and Orías.⁶⁰

By the term "ventricular walls" no distinction is implied between muscular and tendinous structures or valves. Furthermore, although the cause given above is stressed as the principal one, subsidiary factors should not necessarily be excluded.

The intensification of the third heart sound under special pathologic conditions implying myocardial damage as happens in some cases of gallop rhythm is further evidence of a muscular component in the genesis of the third sound.

Boyer⁶⁸ has presented experimental evidence to show that vibration of the ventricular wall produced in the quiescent heart by a very feeble impact gives rise to a sound very like the normal third sound in frequency, amplitude and duration.

On the clinical side, White²⁷ states "The third sound is probably the result of the vibration of the ventricular walls and auriculo-ventricular cusps caused by the inrush of blood every diastole."

CAUSES OF THE AURICULAR SOUND

One of the most important contributions made by the graphic method to the study of the acoustic manifestations of the heart's activity has been the recognition that, even in normal conditions, auricular contraction produces vibrations having the properties of sounds that are undoubtedly often heard at the surface of the chest in healthy persons, even under the ordinary conditions of auscultation.

During auricular activity various phenomena may produce a sound. Acoustic vibrations may be produced during auricular contraction by the muscular contraction itself as pointed out by Krehl,¹⁰ Roos,⁴⁴ Weber and Wirth,⁶⁹ Benjamins,⁵⁸ Reid,⁷⁰ Mond and Oppenheimer⁷¹ and Fogelson⁷², the tension of the auricular walls, the passage of blood through the valvular orifices (Kahn⁷³), the distention of ventricular walls by the inrush of blood from

THE PHYSIOLOGIC COMPONENTS OF THE URINARY BLADDER*

Their Clinical Significance

S RICHARD MUELLNER, M D †

BOSTON

THE study of bladder function by cystometry has led to the conclusion that the bladder acts as a single unit. This was inevitable, since the cystometer registers the summation of changes in intravesical pressure resulting from detrusor contraction, without disclosing how such changes are brought about. Observation of the bladder during micturition under the fluoroscope, however, makes it quite clear that this concept is not entirely correct.

There are two functional units of the bladder that, by their synergism under normal circumstances, comprise the total detrusor function. These two units, which consist of the bladder base and of the dome, have a separate embryologic origin. The dome of the bladder develops from the cloaca, and is thus entodermal in origin, and the base is formed from the wolffian ducts and therefore stems from mesodermal tissue.¹ The base of the bladder is thicker than the dome, and this fact is of physiologic significance.² The function of the dome and of the base of the bladder can become separated under certain pathologic conditions, with the result that the dome will seriously hamper the action of the bladder base, and micturition then becomes inefficient. This pathologic state is more easily understood if the sequence of events in normal micturition in man is kept in mind.

In a previous paper³ it was pointed out that man has a distinct voluntary mechanism with which he starts and stops micturition. This mechanism uses the pubococcygeus, a large, paired, striated muscle with a somatic nerve supply, which, when relaxed at will, causes the region of the internal sphincter to drop downward. It is the displacement of the internal sphincter that precipitates the reflexes of micturition. The reflex for the ensuing detrusor contraction starts at the vesical neck and then propagates symmetrically and bilaterally to the base, to the sides and lastly to the dome of the bladder, so that at the beginning of micturition, after the downward tug on the internal sphincter, one can see quite clearly the contraction of the base followed by the rather marked contraction of the sides of the bladder. The bladder dome is thus raised, and at this moment the vertical diameter of the bladder becomes considerably greater, whereas the transverse diameter becomes smaller. At the moment micturition is deliberately stopped, the vesical neck becomes sharply elevated by the contraction of the levator ani muscles (including the pubococcygeus), the internal sphincter is shut, and first the base, then the sides and gradually the dome can be seen to relax, so that the vertical diameter of the bladder becomes smaller, and the transverse diameter larger (Fig 1). It will thus be clear that the bladder neck is the site at which the stimulus for the contraction of the detrusor originates, and from which the signal

†Instructor in urology, Harvard Medical School; assistant visiting urologist, Beth Israel Hospital.

be less intense and record only as small late oscillations, with the peak of intensity synchronous at base and apex.

Dr Orías has properly stressed the contribution made by the vascular vibrations in determining the character of the first sound at the base. Most split first sounds, even at the base, are due to a synchrony of events on the two sides of the septum, not to separation of valvular and vascular elements. I am not aware of any clinical significance attached to detectable variations in the first sound as heard at the base, but such correlations may be noted in future by those who study these two factors at the bedside or in records of the sounds.

The auricular element recorded as blending into the first sound seems related to presystolic gallop. It might be called a belated, weak presystolic gallop, or fourth sound. These sounds, whether protodiastolic and due to early passive filling or late and caused by auricular systolic ejection, are not the result of tension in the ventricular walls. Apical records and border motion records made with the x-ray apparatus show that further filling follows the protodiastolic gallop or third sound, so that the ventricle could not be taut like a blown-up paper bag. Actually, the diastolic ventricle is never taut in that sense. If one prevents outflow in a dog's heart by clamping the aorta or inducing ventricular fibrillation, it balloons up to twice the volume normally reached in diastole, if the pericardium is then cut away it nearly doubles in volume again. In diastole the muscle is a jelly, capable of being drawn out to twice or thrice its usual diastolic column. If a Valsalva experiment is performed on a normal person with third sounds the heart shadow is far larger than during normal diastoles in which third sounds were recorded. The third and fourth sounds and the gallops occur when pressure between auricle and ventricle become equalized, the apex and lateral wall move basalward at this time, blood moves toward the auricle, and the valves may be drawn taut so quickly as to cause a sound louder than the first sound. If the patient has mitral-valve disease, and has a systolic murmur, the gallop, like the first sound, may be followed by a murmur, as Rydand has clearly demonstrated. Therefore, it is concluded that all sounds heard between the second sound and the true, or aortic-ventricular, first sound are due to tension of the valves at the end of a wave or rapid inflow.

To summarize, the apical first sound and all the third and fourth sounds and gallops are due to tension of the aortic-ventricular, and the second sound to tension of the semilunar valves. The basal first sound may contain elements, or rarely a distinct split sound, owing to the shock in the wall of the great arteries, usually, in man the pulse wave causes no sound in the aorta, and in dogs, in which brachial and femoral vessels have normally a pulse sound, the aorta has none, or a very feeble one. Most split first sounds are due to ventricular asynchrony.

The ventricular muscle is a good sound damper, as in the blood itself. The great vessels transmit sound fairly well.

The views expressed by Levine and Harvey⁷⁸ differ from those of White,⁷⁷ just as mine do from those of Dr Orías. Whether cardiologists live in the same town or in different hemispheres, clinical experience and honest careful study of their own and their colleagues' observations may lead them to diametrically opposed or deviant views. If this leads to further study, the profession has a future, when it leads one to believe his own or someone else's dogma, and stops experiment, the profession is dead.

larger quantity of urine (Fig. 2) A bladder that has thus become quite large and overstretched loses much of its contractile power, and if micturition is possible at all, it will be accompanied by large residua. This loss of efficiency, however, may be only temporary, and the detrusor can recover much or all of its contractile power after the removal of an obstruction or after rehabilitation by means of drainage or other appropriate therapeutic measures in neurogenic vesical dysfunctions.

The shape of the bladder dome in obstructive conditions will vary, depending on the degree and the rate of development of the obstruction. The dome can hypertrophy evenly with the rest of the bladder, and the bladder configuration on the cystogram, except for the thickened bladder wall, may then resemble that of the normal organ. On the other hand, the bladder base may hypertrophy to twice the thickness of that of the dome so that with increasing failure of the detrusor to empty, the thin dome may balloon out considerably and assume a cystographic silhouette, as shown in Figure 3. In

FIGURE 3 *Urinary Bladder in a Case of Benign Prostatic Hypertrophy*
Note the enormous dilatation of the dome

neurogenic vesical disturbances that lead to a big and overdistended bladder with large residua, the dome may become distended to enormous proportions (Fig. 4). When the dome has become markedly overdistended by whatever cause, it fails to assist the bladder base in the expulsion of urine. When the patient is still able to elicit a contraction wave from the bladder neck to the base upward, this wave tends to dissipate toward the dome, and the resulting slight increase in intravesical pressure may balloon out the dome somewhat further. It is under

such circumstances that the patient literally "voids into the dome of his bladder." In neurogenic vesical dysfunctions when the contraction of the detrusor has become enfeebled by overstretching, a large, dilated and therefore quite useless bladder dome may nullify the efforts of the detrusor to void. An overdistended noncontractile bladder dome therefore fails the detrusor in two respects. Being overdistended and noncontractile, it does not propagate or enhance the peristaltic wave, and by the same

FIGURE 4 *Urinary Bladder in a Tabetic Patient (Oblique View)*
Arrows point to the markedly dilated bladder dome

token, it wastes the increase in hydrostatic pressure that results from the contraction of the base and of the sides of the bladder, by directing much of that force upward toward the dome instead of downward toward the bladder neck.

To improve the efficiency of micturition under such circumstances it is necessary to correct these anatomic and physiologic changes of the bladder. In most cases this can be readily accomplished. If these changes, however, prove to be permanent, mere concentration on the vesical neck, or on means to stimulate the detrusor, will not restore adequate micturition. Under such circumstances improvement can be achieved if the useless bladder dome is excised. The resultant small bladder, which consists essentially of the bladder base and of its sides, can become a surprisingly efficient expulsive organ. In a previous communication,⁴ the beneficial results of such an operation in certain cases of prostatism was pointed out. Moreover, this procedure ought to be of value whenever the bladder dome irrevocably becomes a useless pouch. Resection of the bladder dome, however, is reserved only for patients in whom its permanent uselessness is demonstrated, and it ought not to be undertaken if its contractility can be restored by conservative means. The indication for this operation, therefore, must be carefully

for its relaxation spreads. The bladder base with its thicker musculature is therefore the primary expulsive motor force, and the dome facilitates the uninterrupted emptying of the bladder by contract-

in pathologic conditions. The study of bladder behavior in obstructive and in various neurologic dysfunctions was helpful in an interpretation of the events in the normal person.

FIGURE 1 Urinary Bladder in a Normal Male

A = bladder at rest (note the shape of the bladder base, and its relation to the symphysis pubis)

B = bladder during micturition (note the shape and the descent of the bladder base, the vertical diameter is now larger, and its horizontal diameter is smaller compared to its shape during the resting stage)

C = bladder immediately after deliberate cessation of micturition (The base and the dome have resumed the contour shown in A)

ing progressively and thus serving an important auxiliary function. It is the contraction of the dome that directs downward toward the internal sphincter

The thinner structure of the dome and its greater motility make it particularly suited to take up unusual pressure and volume changes of the bladder

FIGURE 2 Urinary Bladder in a Case of Cancer of the Prostate

the increased hydrostatic pressure, resulting from the contraction of the base. The foregoing remarks are based on about 200 careful fluoroscopic observations of the function of the bladder in normal and

in certain obstructive or neurogenic vesical disturbances. Under such circumstances the dome and also the sides of the bladder can become markedly overdistended to accommodate the considerably

skin cancer are seen, and many more persons consult physicians for relatively insignificant growths on the skin in comparison with conditions twenty or twenty-five years ago

Thus, the five most common diagnoses include 1057 cases, or 50 per cent, the next ten diseases 1439, or 72 per cent, and fifteen diseases 1558, or 78 per cent. Many of these conditions are common to many ages and not necessarily restricted to this particular age group (see Table 2)

Not included in this group are conditions commonly occurring in older persons — that is, con-

rosacea, impetigo, pityriasis rosea, scabies, intertrigo, erythema induratum, molluscum contagiosum and pediculosis. As a matter of fact, they can occur at any age, but they are much more frequent below sixty. Rosacea was seen more often in women than in men (this condition is usually more apparent among patients thirty to fifty years of age). Erythema induratum, of course, is more frequent on the legs of female patients between ten and thirty, although 2 cases were seen in this group. Impetigo

ditions that would be found on a general examination in a large group, such as dry skin, atrophy, pigmented areas, graying of hair, thinning of hair, brittle nails and small tumors of various types. Many questions are asked on these subjects by patients being examined for other cutaneous disturbances.

In addition to this group, there was a group of relatively common dermatoses, which occurred less

TABLE 2 Most Common Skin Diseases

frequently among elderly patients. Table 3 demonstrates the diseases observed next in frequency. These are not particularly caused by increasing age but appear in the general population.

In Table 4 are listed relatively unusual dermatoses observed in this group. These usually occur at a somewhat younger age, but they have been noted in this series of older persons. Rare or unusual diseases were present in less than 5 per cent of this series.

More commonly observed in younger persons — that is, in those under sixty — are such diseases as

occurring in the older age group is often more obstinate than that seen in children. In certain cases it has responded very slowly, but such cases have been more responsive to penicillin than to some of the older antiseptic drugs previously used. Other diseases in this group were not seen very frequently.

It has been a surprise to us that there have not been more cases of certain diseases in these 2000 cases. There were only 2 cases of varicose ulcer and 13 cases of an eruption due to drugs, though it is possible that some of the cases of toxic erythema were drug eruptions. Leukoplakia would be thought

to occur more often in this age group, and kraurosis vulvae, of which only 1 case was observed, is described much more frequently at this age. It is also surprising that more persons do not present themselves for graying or loss of hair. These items are expected perhaps as a part of growing old, although the advertisements of newspapers and magazines

established on an individual basis, and in conjunction with other measures calculated to remove obstruction and to enhance detrusor tonicity

SUMMARY

The urinary bladder in man is made up of two integrated functional units, which consist of the bladder base and dome. These two units have a separate embryologic basis and differ in their physiologic function. The bladder base is the primary motor force in micturition, and the bladder dome acts in an auxiliary manner. Under certain pathologic conditions, the bladder dome can become

permanently overdistended and noncontractile. When this occurs, the dome interferes with the expulsive efforts of the base, and micturition becomes inefficient. Excision of the useless dome remarkably increases detrusor efficiency.

GERIATRIC DERMATOSES*

C. GUY LANE, M.D.,† AND ETHEL M. ROCKWOOD, M.D.‡

BOSTON

DISEASES of the aged are becoming increasingly important in the economic, social and medical life of the country. Whereas in 1910 only 4.3 per cent of the population were sixty-five or over, in 1950, 7.9 per cent of the population will be in this age group, and in another ten years, 10 per cent of the population will have reached this age. Thus, the diseases of this group require and will continue to require greater attention on the part of all physicians. In addition, the infirmities accompanying the aging process are apt to be slower in responding to treatment or to become more chronic so that more individual medical attention is required.

From the medical standpoint the diseases of this age group affect many systems of the body, and it is seldom that only one system is involved. The skin and its accessories participate in the changes of advancing years, but little attention has been paid to the part that these cutaneous disturbances may play in the life of the person affected. Many of these manifestations on the skin persist because of some other disease or condition, such as a circulatory abnormality, nutritional deficiencies, lack of proper care, failure to realize implications of a relatively insidious onset and often a real neglect. Thus, the disturbances on the skin must be considered in the light not only of the age of the patient and his general medical condition but also of various other factors.

Since comparatively little attention has been given specifically to the skin disturbances of this age group it seemed of interest to review the records of 2000 private patients over sixty years of age for the pur-

pose of determining the diagnosis of their diseases and discussing them.

This survey was made several years ago and included many records of the late Dr. Arthur M. Greenwood, as well as our own records. Of these 2000 cases, 785 (40 per cent) were in men, and 1215 (60 per cent) in women. The proportion of women to men in these figures is much higher than that in Massachusetts or in the country at large, although it is a fact that after sixty years of age the proportion of women to men is somewhat greater. We do not believe that these figures indicate that women have a higher percentage of disease in this age group, but rather that women are more apt to seek the advice of a physician.

So far as ages are concerned, 1145 patients (57.25 per cent) were between sixty and sixty-nine, 677 (33.85 per cent) between seventy and seventy-nine, 170 (8.5 per cent) between eighty and eighty-nine, and 8 (0.4 per cent) over ninety years of age. A characteristic distribution according to age and sex among 1000 patients is shown in Table 1.

Table 2 presents data concerning the most common skin diseases found in this group.

Although these figures do not indicate the frequency with which the diagnoses would be observed in patients given a general examination in this age group, it will be seen that senile keratosis (the precursor of epithelioma), epithelioma, seborrheic keratosis, eczema and contact dermatitis were the most common conditions for which older patients consulted a dermatologist, or at least the most common conditions found on examination by a dermatologist. One wonders if the relatively large number of cases in the first three groups was due mainly to campaigns against cancer carried out over a period of years. Certainly, far fewer neglected cases of

‡Dermatologist, Massachusetts General Hospital.

ing down the scaling and crusting over a considerable period in the very superficial type. If infiltration developed, or actual ulceration, it was probable that a malignant change had already developed, and the lesions were treated as basal-cell epithelioma.

SEBORRHEIC KERATOSIS

Seborrheic keratoses, sometimes spoken of as senile flat wart or verruca seborrheica, were in general quite different. They were usually on covered parts of the body, such as the upper back, over the shoulders and over the chest. They were found, however, on the face, hands and abdomen. In general, these were sharply outlined, oval, slightly elevated, usually slightly pigmented and perhaps slightly greasy lesions. In certain persons there was often difficulty in distinguishing some of these lesions from the senile keratoses, but in general a distinction could be made. A definite hereditary factor was indicated by the fact that the lesions were seen in certain members of a family over two or three generations, or that such a history could be obtained.

In view of the fact that they seldom became malignant their removal was not necessary except for cosmetic reasons. They were destroyed in various ways as seemed necessary.

ECZEMA

Eczema and dermatitis are, of course, the most common diseases of any age group. It is a question whether there should be much distinction between cases of eczema and those of dermatitis. Both terms refer to an inflammatory reaction in the skin. The term "eczema," perhaps, will not disappear, but its use has decreased much in dermatology, and the term "dermatitis," either acute, subacute or chronic, has become more widely employed for simple inflammations of the skin, whether of external or internal origin. In this older age group the term eczema has been used for cases of inflammation of the skin that were not definitely due to an external contact, and in many cases no single factor could be assigned as a cause. The skin disturbance seemed more intractable than in younger persons, a fact that was particularly true when the lower legs were affected. We believed that there was often a circulatory factor, although not always associated with obvious varicosities. Many of these cases started with a pruritus or perhaps a mild dermatitis, with exaggeration thereafter by the trauma of scratching or rubbing, perhaps by low-grade secondary infection, sensitization to some therapeutic agent and stasis — that is, being on the feet too much for the circulatory system of the particular patient and so forth. Etiologic factors were often multiple. There were found in the cases in this group various degrees of itching and discomfort, and varying amounts of redness, swelling, excoriations, scaling, crusting, infiltration, pigmentation and so forth. Much patience was often required to obtain an account of the onset and course of the disease from

these older people and their relatives, and to ascertain something of earlier treatments and the results of such therapy.

Recently Guy et al* discussed geriatric nutritional eczema in patients past middle life with an eruption of the lower legs associated with varying degrees of edema. Hypoproteinemia was a main factor, and edema was abolished when an adequate supply of protein was given. These patients were usually amenable to a six-point plan of treatment: adequate mastication, a diet rich in proteins, administration of protein hydrolysates, concentrates and vitamins, correction of hypochromatic anemia, dilute hydrochloric acid with meals, and local care in keeping with the status of the inflammatory process. The additional factor of possible focal infection was brought out in the discussion of this report.

Treatment often had to be individualized, and careful, preferably written, directions given for the regime that was prescribed. Much time was often consumed in the details of treatment of acute, subacute and chronic types. Suffice it to say that soothing combinations, such as a modified calamine lotion and a zinc oxide or calamine, starch and vaseline ointment were usually prescribed at first. With much oozing and much redness and swelling, boric acid or weak potassium permanganate compresses were often well tolerated. Occasionally, an oil as a cleansing agent seemed preferable. In many cases in which the leg was affected it was essential that the patient keep off his feet, or wear a linen-mesh bandage properly applied.

A rather high percentage of these cases of contact dermatitis among older persons seemed to be associated with the soap that was used. There were a few cases due to nail polish, a few to plants, a few to nickel, and a few to paint solvent, and there were 1 or 2 cases of a large number of different agents with which the patient had been in contact. A great many of these cases involved the hands. Detection of the offending agent and its elimination were important for therapy but often difficult to achieve.

PRURITUS

Pruritus was a very troublesome symptom. It is hardly necessary to emphasize the disastrous effect that a mild but persistent itch can have on the life and general condition of the older patient. And a severe pruritus, if unrelieved, will prevent the sleep the patient needs, interfere with appetite and general nutrition, depress him mentally and in general greatly affect the general health.

About 50 per cent of the cases were of the so-called senile type, with very few or no demonstrable skin lesions except for the excoriations produced in an attempt to relieve the itching by scratching. Of the remainder, localized perianal and vulval itching

*Guy, W. H., et al. Geriatric nutritional edema. *Arch. Dermat. & Syph.* 57:822-827, 1948.

may lure them when the dermatologists' pessimistic prognoses fail

Before the more common dermatoses noted in this group are discussed it is hardly necessary to emphasize that senile cutaneous changes do not develop at any particular age. The onset of such changes is just as variable as the beginning of senile changes in the ear, eye, joints and arteries, and the rate of alteration varies greatly in different persons. In the general examination of older patients the physician finds that as the years pass the subcutaneous fat is lessened, the skin becomes less elastic and thinner, more wrinkling develops, the color may become grayish or yellowish, perhaps with pigmented or depigmented areas, and there may be a variable amount of dryness and scaling, especially in cold weather. There is also the appearance of gray and white hair, as well as the thinning and possibly entire lack of hair on the vertex in men. In addition, the physician will find in many older people hyperpigmented areas, especially on exposed surfaces, with varying degrees of pigmentation, including depigmentation, small capillary tumors or angiomas, small pedunculated fibromas, small verrucae, keratoses and so forth, many of which have been present so long or have developed so gradually that they are accepted by the patient as a part of the aging process.

EPITHELIOMA

In this series it will be noted that skin cancer, or epithelioma, and its precursor, keratosis senilis, constitute the largest group of cases observed in this series—574, or 28.7 per cent of the total number of cases. In fact, in many cases epithelioma and keratoses of both types were found in the same person. The number of women with epithelioma was very much larger than the number of men. In one of our groups the number of women with epitheliomas was almost twice that of the men. In that same series the proportion of brunettes was very much larger than blondes. The nose and cheeks accounted for more than half the cases. Cancer of the skin was found in two clinical types. The milder type—the basal-cell epithelioma—was usually a pearly nodule or ulcer with a pearly border and central crust, though there was considerable variation in its appearance. The more serious type—the squamous-cell epithelioma, which was less frequent—developed more rapidly, had more ulceration, was a deeper process and tended to metastasize.

When seen early these lesions were treated very satisfactorily with x-rays or radium, occasionally, desiccation was used, or excision advised. The dose of radium or x-rays was varied with the size and depth of the individual lesion, but an adequate border about the lesion was included and the dosage was sufficient to produce necrosis of the area. Excision must be wide enough to remove any possible extension of the tumor mass, and desiccation

in the same way should include enough area to eradicate any fingerlike processes from the main tumor.

Cancer is a serious disease, but cancer limited to the skin does not have the relatively serious prognosis of cancer of the other organs. This abnormal process on the skin is external and visible or palpable, or both, and if treated properly and early in its development can be absolutely eradicated. In fact, it can be stated that mortality from skin cancer can be absolutely prevented by the co-operation of the patient in presenting himself for diagnosis at the earliest possible moment and by the co-operation of the physician in early diagnosis and complete eradication. However, if one considers in this group cancer on the lip and tongue and oral cavity, the seriousness of prognosis is greatly increased, and early diagnosis is of far greater importance.

The campaign against cancer has been most helpful as far as skin cancer is concerned, but perhaps more emphasis should be placed on this form of cancer. Much disfigurement and perhaps even death might be prevented by any form of lay campaign by medical or public-health groups emphasizing the desirability of reporting for examination of even minor, localized changes in the skin as the patient becomes older. In any such campaign at the same time physicians need to be reminded of possible malignant changes developing in apparently insignificant lesions in persons over sixty years of age. Of course, basal-cell carcinoma has been seen in the teens and twenties, but in the older age group it is much more frequent. The tumor clinics established in many hospitals, with a surgeon, radiologist and dermatologist in attendance, have been important factors in many communities in education about cancer in this age group, as well as furnishing diagnostic and therapeutic centers.

SENILE KERATOSIS

As with epithelioma, the figures in this series indicate that these keratoses appear more frequently in women than in men. Senile keratoses are real precancerous lesions. They occur chiefly on exposed surfaces, and they are seen more commonly in persons much exposed to the sun and wind and in those of blond or "sandy" complexion. They may occur anywhere on the face, more frequently (in this series) on the forehead, upper cheeks, nose, ears, sides of the neck and dorsal surfaces of the hand. They are usually red, slightly scaly and quite sharply outlined, often with slightly or even tightly adherent crusts, which are sometimes dark, dry and often hard. These crusts frequently come off but soon re-form.

These lesions were destroyed by desiccation, radium or x-rays, or by trichloroacetic acid adequately applied. A mild salicylic and sulfur ointment, 2 to 4 per cent of each in white vaseline or cold cream, was often helpful in removing or keep-

Women had a higher incidence of epithelioma and keratosis, as well as other diseases, and men a higher proportion of inflammatory diseases, such as eczema and contact dermatitis and fungous infection.

Relatively few unusual diseases were noted.

It is important that minor changes in the skin be examined early to prevent later extensive involve-

ment, and that apparently insignificant growths be examined to determine if malignant lesions exist and to provide adequate therapy. The relief of itching and discomfort is quite important.

In older patients it is especially necessary that the patient as a whole, and not merely his cutaneous disturbance, be considered and treated.

REACTIONS FROM THE USE OF BENZODIOXANE (933 F) IN DIAGNOSIS OF PHEOCHROMOCYTOMA*

VICTOR A. DRILL, Ph.D., M.D.†

DETROIT, MICHIGAN

PHEOCHROMOCYTOMA is a known cause of hypertension that is being more frequently diagnosed.¹ This tumor produces epinephrine or an epinephrine-like substance that is responsible for the observed increase in blood pressure. Pharmacologically the dioxane group of drugs (883 F, 933 F, 1164 F and others) prevent or reverse the hypertension produced by epinephrine in animal experiments.^{2,3} The compounds 883 F and 933 F do not have any significant effect on the blood pressure of dogs or rats with renal hypertension.^{4,5} Thus, the benzodioxane group of drugs would be expected to prevent the effects of circulating epinephrine produced by a pheochromocytoma, and thus to reduce blood pressure, but would be without effect in the patient with other forms of hypertension. Recently, a test for hypertension due to circulating epinephrine has been devised, on the basis of the adrenolytic effect of benzodioxane derivatives.⁶

The use of such drugs to block the effects of epinephrine will provide a more specific test in the diagnosis of pheochromocytoma. However, such agents as the benzodioxane derivatives can produce many side reactions that have not been sufficiently emphasized. The present paper reports the occurrence of severe side reactions resulting from the injection of a benzodioxane derivative in 2 patients with suspected pheochromocytomas.

METHOD OF ADMINISTRATION

The benzodioxane derivative used was 933 F (piperidino-methyl-benzodioxane). It was administered by the technic and in the dose utilized by Goldenberg, Snyder and Aranow.⁶ The patient received an intravenous infusion of 5 per cent glucose, and with the infusion running control determinations of blood pressure were taken each minute for approximately twenty minutes. When the patient was adjusted to this procedure 933 F

was injected into the infusion tubing for two or three minutes in a dose of 10 mg. per square meter of surface area.

CASE REPORTS

CASE 1 A 51-year-old woman was admitted to the hospital complaining of severe headaches, blurred vision, nerv-

FIGURE 1 Zero Time (Control Infusion Started)
Injection of 933 F at A. Complaint of nausea and headache at B.

ousness and weight loss. These symptoms had begun 3 years previously, with anorexia and headache. This was followed by a gradual onset of fatigability, attacks of dizziness, nervousness and palpitation. The headaches became worse, and 2 months before admission she complained of blurred vision and yellow spots before the eyes. The weight loss during this period was 36 pounds.

formed the largest group. In many cases both areas were involved. Only 6 per cent of these cases were of diabetic origin. The diagnosis of pruritus particularly a generalized pruritus, called for a careful detailed examination to prove conclusively that there was no general causal factor. Such itching is, of course, associated with diabetes not infrequently, the lesions of the lymphoblastoma group, liver conditions and other diseases. In the same way, localized pruritus called for investigation, both for a local causal factor and for general factors. In the northern part of the country numerous cases of pruritus of the generalized type appear in older persons with the onset of cold weather and clear up in the spring—the “winter itch,” or pruritus hiemalis. The neurogenic factor was a more difficult one to evaluate in both the general and the local type, but in cases of perianal, vulval and scrotal pruritus in which only the results of rubbing and scratching were apparent, with no other lesions to account for the itching, a neurogenic factor was given serious consideration.

Treatment of these cases was often difficult. It is imperative that all possible causal factors found on general examination be eliminated so far as practically possible. Frequently, in the general type, the kind of soap seemed important, and the use of a so-called superfatted soap or of less soap, or perhaps no soap at all, in bathing, followed by some mild emollient, often provided considerable relief. The treatment of the localized pruritic areas in older patients is often a severe test of the physician's therapeutic skill. Phenol is still the best single antipruritic agent, and menthol and camphor can be useful in treatment, but careful observation is required to be sure that these agents do not act as sensitizers. Whether some of the new antihistaminic agents will prove useful in these cases still remains to be proved. The itching was often an individual problem and can hardly be discussed in general without an individual case for consideration. Mild sedation was a helpful ally in many cases but was discontinued as soon as possible. Fractional x-ray therapy was used in carefully selected cases. It is to be deprecated that x-ray therapy has been employed to such a degree that numerous cases of atrophy and telangiectasia, with the resulting sequelae, appeared as the result of such radiation of localized pruritus. It is essential that a limit be set upon the amount of treatment to be given the individual area, and when that limit is reached the patient should be informed that his particular quota has been reached and it is inadvisable to continue further with such treatment. It is, of course, essential that every attempt be made to maintain accuracy of dosage if radiation is prescribed.

DISCUSSION

Space does not permit the discussion of the other diseases noted in this series. In addition to the

diseases mentioned above there were many diseases in which only 1 to 4 cases have been listed. Thus, there are many diseases of the skin with which the older patient can be afflicted and for which he will seek relief.

In the care of these patients it is well to remember that the older skin is drier and that less soap or perhaps a so-called super-fatted soap is frequently helpful. In addition, in colder weather the use of a thin oil or grease often gives considerable relief. Additional protection from cold weather gives relief in many cases, although wool seems to have an effect of producing itching in some.

In many older persons there was need to compromise with the usual directions given for the care of some skin diseases. There was the need to compromise with a strict diet if such diet seemed as if it would interfere with the daily routine of life that had been carried on over many years. Although it was essential to give very careful directions, perhaps in writing, it was necessary to compromise on some of the details to avoid complicating the life of the patient or family too much. Some of these patients were extremely meticulous, others very carefree, and others very forgetful, so that such directions varied with the individual patient. Relief of itching, especially of generalized itching, was of prime importance in many of these cases. Much consideration had to be given to procedures that were *essential*—treatment of skin cancer, remaining off the feet and so forth—as compared with measures not absolutely essential. In many cases improvement or relief was brought about by unusual methods or unacceptable proprietary applications, and it often seemed best to go along with such methods for a while without too sudden changes, with a gradual shift to methods and agents that should really have done better for the patient. It was often a difficult matter to decide whether to accept and go along with preconceived ideas or to attempt to alter them to a more generally accepted method. In other words, it was often especially necessary to treat the patient with the disease and in relation to his other diseases and not simply the cutaneous disease with which he was afflicted.

SUMMARY

The case records of 2000 patients over sixty years of age with diseases of the skin are reviewed.

The most common diseases observed in this age group are discussed.

Fifty per cent of these patients received a diagnosis of one of five diseases,—senile keratosis, epithelioma, seborrheic keratosis, eczema or contact dermatitis,—and in 79 per cent the diagnosis was one of fifteen other diseases.

Senile keratosis and epithelioma—that is, premalignant and malignant disease—accounted for 28 per cent of the cases.

and tachycardia⁷ The hypertension and tachycardia caused by 933 F is a sympathomimetic effect that is not seen in the anesthetized animal The effect of epinephrine on the heart rate is not abolished by 933 F, on the contrary the drug increases the tachycardia produced by epinephrine Thus, side effects of this nature may be expected in some patients when 933 F and related compounds are used

The effect of the benzodioxane derivatives in lowering the blood pressure of patients with pheochromocytoma⁶ has been confirmed⁸ In such studies it was found that the usual response produced by 933 F in patients with essential hypertension was an increase in blood pressure⁶ Normal subjects also showed a rise in blood pressure after injections of 933 F, but less so in comparison with patients with essential hypertension Other side reactions were noted, such as flushing, palpitation, nervousness, cold and clammy extremities, hyperpnea, mild headache, fright, sighing and dizziness These reactions were seen chiefly when the injection of 933 F was made in thirty seconds and were noted much less with an injection time of two minutes

In the 2 cases reported above, 933 F produced a marked rise in both systolic and diastolic blood pressure That this is a central effect of the 933 F is seen by the simultaneous increase in pulse rate Other side effects were nausea, headache, dizziness and flushing, and 1 patient complained of severe precordial pain

The central-nervous-system stimulation caused by 933 F, as reflected in the marked increase in blood pressure and the tachycardia, is a dangerous side reaction, and is an inherent property of such

compounds that apparently becomes more manifest in patients with hypertension that is not due to pheochromocytomas A different type of adrenolytic drug, dibenamine hydrochloride, that may also stimulate the central nervous system has recently been reported The use of dibenamine in the diagnosis of a case of pheochromocytoma has recently been described⁹

SUMMARY

An adrenolytic drug, 933 F (2-piperidino-methyl-1, 4 benzodioxane), was administered to 2 patients with suspected pheochromocytomas

The injection of 933 F produced an immediate and marked rise in systolic and diastolic blood pressure, and 1 patient complained of severe precordial pain The possible toxic effects of such compounds are discussed

DEFINITION

Until recently, the only abnormality detectable in laboratory animals deficient in vitamin P was an increased capillary fragility, and substances that could correct this abnormality were described as having vitamin P activity. The term has acquired a broader meaning and is used to describe agents that increase the strength of capillaries of normal animals. Because of the unreliability of tests of capillary strength, other procedures have been suggested to demonstrate vitamin P activity. Thus, pulmonary hemorrhages have been produced in mice by sudden reduction in atmospheric pressure. It has been claimed by some²¹ but denied by others²² that vitamin P reduces the severity of this type of hemorrhage. Other suggested bases for biologic assay are the reduction in bleeding time in normal guinea pigs²³ and the increased resistance of erythrocytes to hypotonic saline solution,²⁴ both of which are effected by vitamin P. It is obvious, then, that the term vitamin P has exceeded the usual limits that one associates with the word "vitamin."

CHEMISTRY

The many types of vitamin P have a similar structure. They may all be regarded as derivatives of flavone proper (phenyl gamma benzo pyrone) or its variations.^{25 26}

When the double bond between carbon atoms 2 and 3 is saturated, the compounds are called flavonones, examples of which are hesperidin and eriodictin (eriodictol). When a hydroxyl group is attached to the third carbon atom, the structure is known as a flavonol, of which rutin is representative. Derivatives of these three variants of the flavone nucleus are collectively referred to as flavones. Rutin, for example, is the rhamnoglucoside of 3, 5, 7, 3', 4' pentahydroxy flavone.

Flavones

The flavones are a group of yellow, plant dye-stuffs that are widely distributed in nature, being

found in citrus fruits, tobacco plants and buckwheat. The last is the present commercial source of rutin. The existence of the flavones was known long before their vitamin P activity was appreciated. Hesperidin, for example, was discovered in 1828.² More recently isolated types of vitamin P are the flavins²⁷ and coumarins,²⁸ represented by *d*-epicatechin and esculin respectively. In the former, the ketone group on the fourth carbon atom of the flavone nucleus is reduced, and the double bond between the second and third carbon atoms is saturated. The coumarins show the greatest divergence from the flavone nucleus. The phenyl ring is lacking, the pyrone ring is reduced, a double bond lies between the first and second carbon atoms, and ketone groups are attached to the third and fourth carbon atoms.

D-epicatechin and esculin are among the most potent types of vitamin P, having an activity at least five hundred times that of citrin. Catechins are extracted from vegetables and kola nuts, and esculin is derived from chestnuts.

IDENTIFICATION OF VITAMIN P COMPOUNDS

Spectrographic analysis is the only certain method for the identification of individual vitamin P compounds. Various colorimetric procedures are available but they are all group specific.^{27 29 30} Since not all flavones or catechins are endowed with vitamin P activity, the results of colorimetric procedures need not be synonymous with vitamin activity.

METABOLISM

Very little is known of the fate of vitamin P after its ingestion. The little information available deals only with the soluble type of compound. As yet no one has traced the pathway of insoluble compounds like rutin given by mouth. When soluble compounds are injected parenterally, a variable portion may be recovered in the urine and bile for a period extending over several hours or days.^{31 32} The amount excreted depends, in part, on the previous body store of vitamin P. Other factors that govern excretion, the fate of the unrecovered fractions and the intermediary metabolism in the body have all to be worked out.

PHARMACOLOGY OF VITAMIN P

Different types of vitamin P have different pharmacologic properties.³³ Some, like eriodictol, are inert when injected intravenously. Others like

MEDICAL PROGRESS

THE BIOCHEMISTRY AND CLINICAL APPLICATION OF VITAMIN P*

BENJAMIN A. LEVITAN, M.D., M.Sc.†

DURHAM, NORTH CAROLINA

THE term vitamin P was proposed by Armentano and his co-workers¹ to denote a group of compounds distinct from ascorbic acid that maintained the physical strength of capillaries. This concept grew out of investigations to determine why crude sources of vitamin C controlled hemorrhages in vascular purpura whereas purified ascorbic acid was ineffective. From the ascorbic-acid-free residue of the mother substance, a faintly yellow crystalline material, which was found to exert the so-called vitamin P activity, was extracted. Because of its derivation from citrus fruits, this active powder was called citrin. Various analyses revealed that citrin was a mixture of different flavones, and several of these were subsequently isolated.² Their potency has been the subject of considerable debate. Opinions also differ concerning whether these compounds actually function as vitamins. The original claims^{3, 4} that vitamin P prolonged the lives and reduced the severity of the symptoms of scorbutic guinea pigs failed to stand up to independent investigation,^{5, 6} and even Szent-Gyorgyi⁷ could not confirm the initial results.

Early investigations were hampered by the difficulty of preparing a diet completely free of flavones. In addition, because of the similar natural distribution of flavones and ascorbic acid, diets that excluded sources of flavones were also deficient in vitamin C. Animals maintained on such regimes developed scurvy, which masked possible effects of vitamin P deficiency. It remained for Zacho⁸ to achieve a pure vitamin P deficiency state in his animals by adding pure ascorbic acid to their flavone-free diet. The only abnormality that developed in such animals was a capillary weakness, which responded specifically to vitamin P. This claim has been well substantiated.^{9, 10} Scarborough^{11, 12} has described a vitamin P deficiency in human beings characterized by capillary weakness, spontaneous perifollicular hemorrhages and rheumatic pains in the legs and shoulders. Again, a specific, rapid response to vitamin P was claimed, whereas ascorbic acid was ineffective. Although Scarborough's work seemed to be well controlled, his findings could not be con-

firmed by Lazarus and his co-workers,¹³ who maintained that neither vitamin P nor ascorbic acid remedied the capillary weakness in scurvy. From this welter of conflicting evidence, it is impossible to arrive at any definite conclusions. Possibly, the use of injectable preparations might lead to more uniform results.

Regardless of their acceptance as vitamins, the flavones have attained an important position in clinical medicine because they appear to exert a nonspecific, stabilizing effect on capillaries. This applies to a wide variety of pathologic conditions in which capillary defects are present. In addition, as pointed out below, evidence that vitamin P stabilizes ground substance opens new avenues of investigation into the relation between vitamin P and the numerous diseases to which ground substance falls prey.

When capillaries that are subjected to physical stresses rupture excessively and form petechiae, they are said to display increased fragility or decreased resistance. The physical stresses are either an increased intracapillary pressure obtained by the application of a blood-pressure cuff to the upper arm or a negative external pressure obtained by the application of a suction cup to the skin.

These tests have recently been reviewed in detail.¹⁴ The numerous modifications to which they have been subjected clearly indicates that they leave much to be desired. There is no correlation between positive and negative pressure. When performed at the same time the tests may yield entirely divergent results.¹⁵ Influences on capillary resistance due to age,¹⁵ sex,¹⁶ season, time of day, emotions,¹⁷ trauma¹⁸ and hemorrhage, render the interpretation of these tests most difficult. The confusion has been compounded by the failure of many investigators to heed the warning¹⁹ that tests repeated at intervals of less than three weeks may yield false-negative results.

The term "increased capillary permeability" is also used loosely to indicate a weakness of capillary walls. Capillary permeability is gauged by the extent of transudation following venous stasis¹ or by the degree and rate of streamer formation following the intradermal injection of the dye patent blue.²⁰ In contrast to the fragility measurements, the permeability tests have had a limited application

increase the strength of capillaries,⁴⁷ and the parathyroid hormone to increase the resistance of the connective tissue.⁴⁸ Thus, vitamin P is visualized as regulating capillary resistance by an endocrine mechanism based on the ability of epinephrine to mobilize the pituitary gland and its target glands. It is not yet known whether adrenochromes can emulate this action of epinephrine on the endocrine system. Since adrenochromes are devoid of most of the properties that limit the administration of epinephrine, such information might be of considerable practical as well as academic interest.

The Direct-Action Theory

A theory commendable for its simplicity is that of Lenaz and Alborn.⁴⁹ It was based on their finding that blocks of agar in citrin solution absorbed considerably less fluid than those in a control medium. The results were interpreted according to the postulate of Gellhorn that colloid hydrophilia was a function of colloid permeability. Since citrin decreased the hydrophilia of the agar blocks, it was concluded that it had done so by reducing the permeability of this colloidal material.

In conclusion, it is apparent that little is known about the mechanism of action of vitamin P. These substances are administered and the end results observed. There is a vast gap in knowledge concerning what transpires between these two points.

THE CLINICAL SIGNIFICANCE AND VITAMIN P THERAPY OF CAPILLARY-FRAGILITY STATES

Several types of vitamin P have been employed in diseases in which capillary weakness has been demonstrated or suspected. By controlling the capillary factor with vitamin P it has been possible at times to arrest a train of events that, if uninterrupted, would have imposed a serious burden upon the patient. The significance of the capillary weakness and results of vitamin P therapy are discussed below.

Allergic States

An increased capillary fragility has been found in allergy, this weakness and the vascular derangements, such as angioneurotic edema⁵⁰ and allergic purpura,⁵¹⁻⁵² have responded favorably to vitamin P therapy. No information is available on the nonvascular aspects of allergy in human beings. A report by Rapaport and Klein⁵³ on the value of vitamin P in correcting capillary fragility in allergic children makes no mention of the effects of vitamin P, if any, on the allergic diseases from which these children suffered.

Animal studies indicate that pretreatment with vitamin P fails to inhibit the acquisition of the hypersensitive state,⁵⁵ and most observers agree that it does not suppress the antigen-antibody

reaction.⁵⁵⁻⁵⁴ The claims that vitamin P prevents anaphylactic death in normal animals⁵⁵ have not been substantiated. However, it appears that vitamin P does stabilize certain peripheral substrates against the action of metabolites released during the antigen-antibody reaction. Thus, vitamin P could partially offset the action of histamine when the capillary wall was the substrate.⁵⁶ When smooth muscle of bowel, bronchus or vascular tree was the effector organ, no antihistamine power could be demonstrated.⁵⁵⁻⁵⁵⁻⁵⁶ Even with relatively tremendous doses of rutin, no antihistamine activity could be elicited in intact rabbits when the effector organ was the smooth muscle of the pulmonary-artery tree.⁵⁶ In summary, it is generally agreed that there is a capillary weakness in allergic states that may be corrected by vitamin P. The cause of the capillary dysfunction is unknown. Possibly, the weakness is due to excessive activity of trypsin, which is said to be capable of digesting interendothelial cement.⁵⁷

Natural Hemorrhagic Diathesis

Although coagulation disturbances are generally considered to be the prime cause of bleeding in conditions such as thrombopenic purpura, leukemia and aplastic anemia, Roskam,⁵⁸ in 1921, and subsequently others⁵⁹ have regarded the platelet factor as secondary in importance to a capillary defect. Even in hemophilia,⁶⁰ it has been suggested that a capillary disturbance may be of importance as well as the hypocoagulability of the blood. In animals, experimental thrombopenia fails to produce bleeding. Capillary damage must also be present.⁶¹ After splenectomy in thrombopenic purpura, it has been claimed that cessation of bleeding paralleled recovery from the capillary defect more closely than restoration of the platelet count.⁶¹ McFarlane⁶² has shed some light on the nature of the capillary factor. He has described structural changes in capillaries of adults suffering from vascular and thrombocytopenic purpura. In normal persons closure of capillaries was found to be an important factor in arresting capillary bleeding. In the above conditions, post-traumatic capillary closure failed to occur. It would be of interest to know if this capillary contractility returned after splenectomy, but no mention was made of this.

In vascular purpura¹ and hereditary hemorrhagic telangiectasia,⁶³ vitamin P has been able to arrest bleeding. In these conditions a simple mechanical weakness seems to operate, and may be reinforced by vitamin P. In thrombocytopenic purpura,¹⁻⁶⁴ in which a multiplicity of factors are involved, vitamin P has proved to be of no value. The compounds used so far do not stimulate capillary contractions. In view of McFarlane's findings of capillary atony, it would be interesting to try the catechins in this disease since they strongly stimu-

quercitrin and quercetin derivatives of rutin, produce a depressor response attributed to arteriolar dilatation. Intravenous administration of rutin itself has little or no effect on the blood pressure of cats³⁴ and dogs³⁵.

The catechins are unique in their ability to stimulate capillary vasomotion.³⁴

All types of vitamin P inhibit the oxidative destruction of epinephrine.³³ Some of them also partly simulate the action of that substance. For example, rutin and its aglycone, quercetin, both relax the guinea-pig colon.³³

TOXICITY

The only evidence of possible toxic manifestations of vitamin P is the depressor response that dogs exhibited after the intravenous injection of some of these compounds, and the depressor response that a patient with malignant hypertension experienced when 300 mg of hesperidin methyl chalcone was injected intravenously.³¹ The latter compound has been administered to human beings in oral doses up to 15 gm without any detectable adverse effects. Solutions of rutin have been injected in animals in amounts up to 500 mg per kilogram of body weight without any evident acute toxicity.³⁶ Rats fed diets containing naringin, hesperidin or rutin in amounts up to 1 per cent for as long as two hundred days did not show any signs of toxicity. On histologic examinations of the organs of the rats fed hesperidin and rutin, the tissues appeared normal.³⁷ Rutin in doses up to 500 mg daily has been administered to human beings orally, and no toxic signs could be ascribed to this therapy.³⁸

Evidence suggests that vitamin P, in addition to being free of toxic characteristics, reduces the toxicity of protoplasmic poisons such as heavy metals³⁹ and thiocyanates.¹⁹

MECHANISM OF ACTION

Capillary-Vasomotion Theory

The mechanism of the regulation of capillary resistance and permeability by vitamin P is, as yet, poorly understood. The first theory, proposed by Parrot and Lavollay,⁴⁰ was that vitamin P substances affected the capillaries indirectly by inhibiting the oxidative destruction of circulating epinephrine. The authors found that flavones inhibited the oxidation of epinephrine in vitro and that they prolonged the action of epinephrine on the colon and seminal vesicles of the guinea pig.³⁴ The claim that the flavones had no direct action on the guinea-pig viscera was subsequently disproved, but the epinephrine-sparing action of vitamin P has been substantiated.³³

Adrenochrome Theory

The epinephrine theory was modified⁴⁰ when it was found that a latent period of ten to thirty

minutes elapsed before a rise in capillary strength could be detected after the injection of this hormone into guinea pigs and human beings. This was in contrast to the usual promptness of the classic action of epinephrine, and it was postulated that the capillary changes were mediated by one of the early products of epinephrine metabolism, such as adrenochrome. This viewpoint was strengthened by the findings that various nonpressor adrenochromes⁴¹ increased capillary resistance in normal human beings and normal and scorbutic guinea pigs. Although the capillary-vasomotion theory was thus rejected, it was recently revived by others,⁴¹ who found that the catechins markedly stimulated capillary contractions. However, this theory still appears to be untenable since purified *d*-catechin, which stimulated capillary contractions, was, in the hands of others, shown to be devoid of vitamin P activity.

The adrenochrome theory was later expanded to include histamine as its chemical antagonist. This seemed plausible, particularly when antihistaminics were found to increase capillary resistance. Scorbutic guinea pigs demonstrated an increased sensitivity to histamine that could be restored to normal by vitamin P. However, in normal animals, vitamin P failed to neutralize the effects of histamine on the intact animal or the isolated colon. Thus, it was concluded that vitamin P did not directly antagonize histamine but that it reacted with the tissues so as to prevent histamine from increasing their permeability.⁴² The failure of vitamin P to demonstrate antihistamine activity in the normal animal does not correspond with the increase in capillary resistance observed in normal persons after the administration of vitamin P or adrenochrome. This casts considerable doubt on the histamine aspect of the theory, as does the observation that histamine is not a physiologic regulator of capillary permeability.⁴³ The increased susceptibility of vitamin P deficient animals to histamine is probably a reflection of a generalized nonspecific increase in tissue permeability that these animals acquire. In such animals, even an inert substance such as saline solution, when injected intradermally, diffuses more extensively than normally.⁴⁴ If a physiologic antagonist of vitamin P does exist, a more likely suggestion is hyaluronidase.⁴⁵

Epinephrine-Pituitary-Target-Gland Theory

Another mechanism has suggested itself on the basis of the epinephrine-sparing action of vitamin P. This theory suggests that the ultimate factors acting on the tissues are the hormones of the adrenal cortex and, possibly, the parathyroid glands. It is known that epinephrine causes a discharge of the anterior pituitary gland that, in turn, leads to an increased output from the various target glands.⁴⁶ The adrenocortical hormones have been shown to

increase the strength of capillaries,⁴⁷ and the parathyroid hormone to increase the resistance of the connective tissue.⁴⁸ Thus, vitamin P is visualized as regulating capillary resistance by an endocrine mechanism based on the ability of epinephrine to mobilize the pituitary gland and its target glands. It is not yet known whether adrenochromes can emulate this action of epinephrine on the endocrine system. Since adrenochromes are devoid of most of the properties that limit the administration of epinephrine, such information might be of considerable practical as well as academic interest.

The Direct-Action Theory

A theory commendable for its simplicity is that of Lenaz and Albori.⁴⁹ It was based on their finding that blocks of agar in citrin solution absorbed considerably less fluid than those in a control medium. The results were interpreted according to the postulate of Gellhorn that colloid hydrophilia was a function of colloid permeability. Since citrin decreased the hydrophilia of the agar blocks, it was concluded that it had done so by reducing the permeability of this colloidal material.

In conclusion, it is apparent that little is known about the mechanism of action of vitamin P. These substances are administered, and the end results observed. There is a vast gap in knowledge concerning what transpires between these two points.

THE CLINICAL SIGNIFICANCE AND VITAMIN P THERAPY OF CAPILLARY-FRAGILITY STATES

Several types of vitamin P have been employed in diseases in which capillary weakness has been demonstrated or suspected. By controlling the capillary factor with vitamin P it has been possible at times to arrest a train of events that, if uninterrupted, would have imposed a serious burden upon the patient. The significance of the capillary weakness and results of vitamin P therapy are discussed below.

Allergic States

An increased capillary fragility has been found in allergy, this weakness and the vascular derangements, such as angioneurotic edema⁵⁰ and allergic purpura,⁵¹⁻⁵² have responded favorably to vitamin P therapy. No information is available on the nonvascular aspects of allergy in human beings. A report by Rapaport and Klein⁵³ on the value of vitamin P in correcting capillary fragility in allergic children makes no mention of the effects of vitamin P, if any, on the allergic diseases from which these children suffered.

Animal studies indicate that pretreatment with vitamin P fails to inhibit the acquisition of the hypersensitive state,⁵⁵ and most observers agree that it does not suppress the antigen-antibody

reaction.⁵⁵⁻⁵⁴ The claims that vitamin P prevents anaphylactic death in normal animals⁵⁵ have not been substantiated. However, it appears that vitamin P does stabilize certain peripheral substrates against the action of metabolites released during the antigen-antibody reaction. Thus, vitamin P could partially offset the action of histamine when the capillary wall was the substrate.⁵⁶ When smooth muscle of bowel, bronchus or vascular tree was the effector organ, no antihistamine power could be demonstrated.⁵³⁻⁵⁵⁻⁵⁶ Even with relatively tremendous doses of rutin, no antihistamine activity could be elicited in intact rabbits when the effector organ was the smooth muscle of the pulmonary-artery tree.⁵⁶ In summary, it is generally agreed that there is a capillary weakness in allergic states that may be corrected by vitamin P. The cause of the capillary dysfunction is unknown. Possibly, the weakness is due to excessive activity of trypsin, which is said to be capable of digesting interendothelial cement.⁵⁷

Natural Hemorrhagic Diathesis

Although coagulation disturbances are generally considered to be the prime cause of bleeding in conditions such as thrombopenic purpura, leukemia and aplastic anemia, Roskam,⁵⁸ in 1921, and subsequently others⁵⁹ have regarded the platelet factor as secondary in importance to a capillary defect. Even in hemophilia,⁶⁰ it has been suggested that a capillary disturbance may be of importance as well as the hypocoagulability of the blood. In animals, experimental thrombopenia fails to produce bleeding. Capillary damage must also be present.⁶¹ After splenectomy in thrombopenic purpura, it has been claimed that cessation of bleeding paralleled recovery from the capillary defect more closely than restoration of the platelet count.⁶¹ McFarlane⁶² has shed some light on the nature of the capillary factor. He has described structural changes in capillaries of adults suffering from vascular and thrombocytopenic purpura. In normal persons closure of capillaries was found to be an important factor in arresting capillary bleeding. In the above conditions, post-traumatic capillary closure failed to occur. It would be of interest to know if this capillary contractility returned after splenectomy, but no mention was made of this.

In vascular purpura¹ and hereditary hemorrhagic telangiectasia,⁶³ vitamin P has been able to arrest bleeding. In these conditions a simple mechanical weakness seems to operate, and may be reinforced by vitamin P. In thrombocytopenic purpura,¹⁻⁶⁴ in which a multiplicity of factors are involved, vitamin P has proved to be of no value. The compounds used so far do not stimulate capillary contractions. In view of McFarlane's findings of capillary atony, it would be interesting to try the catechins in this disease since they strongly stimu-

late capillary vasomotion. In a single case of hemophilia, Raunert⁶⁵ claimed that two intravenous injections of citrin given several hours apart were followed within twenty-four hours by cessation of bleeding, whereas the usual measures had been ineffective over a four-week period. However, as in all cases in which multiple therapy is given, the question of which agent produced the clinical response is problematic.

Radiation Disease

Over a period of years, it has become evident that hemorrhage following radiation may be due to at least three factors: thrombopenia,⁶⁶ capillary damage⁶⁷ and the presence of a heparinoid substance in the circulation.⁶⁸ The role of thrombopenia has been discounted because bleeding does not necessarily coincide with reduction in platelet counts.⁶⁸

Mathewson⁶⁸ was the first to use vitamin P for the control of radiation hemorrhage. Severe retinal hemorrhages developed in a patient receiving irradiation by spray technic for multiple myeloma. After vitamin P therapy the retinal bleeding stopped, as did hemorrhages from the nose and bladder, the latter antedating the x-ray therapy. Bleeding recurred when vitamin P was withdrawn and stopped again when the vitamin therapy was resumed. Mathewson stressed the importance of the capillary factor in x-ray therapy and suggested the prophylactic use of vitamin P to reduce the danger of hemorrhage from this type of treatment. Experimental confirmation of this suggestion has been brought forth by Reckers and Field.⁶⁹ Fifty dogs were subjected to a single exposure of 350 r. Twenty-five served as controls, and of these, 16 (64 per cent) died in thirteen to thirty days. All 16, as well as 3 of the survivors, showed widespread hemorrhagic phenomena. The other 25 dogs were treated with rutin orally, 50 mg three times a day beginning one week before radiation. Of this treated group, only 3 (12 per cent) died. All the survivors of the rutinized group, as well as 1 of the 3 that died, were relatively free of petechiae and ecchymoses during the post-radiation period, and when autopsied at forty to sixty days. In addition, several rutinized dogs survived a severe leukopenia lasting from ten to fourteen days. The authors stated that in their previous experience, spontaneous recovery from severe radiation leukopenia of this duration was extremely rare. In mice⁷⁰ rutin failed to prevent death from radiation, but it must be noted that, in this species,⁷¹ hemorrhages are frequently difficult to find and are not an important cause of death. It therefore seems that the protective action of rutin, as in other instances, is largely confined to the vascular tree.

After the explosion of atomic bombs, three types of energy are liberated: blast, heat radiation and

ionizing radiation.⁷² The last is said to induce pathologic changes identical to those resulting from overdosage of irradiation. At Hiroshima and Nagasaki,⁷³ the exposed persons who survived the blast and heat effects developed an illness similar to that which Shouse and his co-workers⁷⁴ and Reckers et al.⁶⁹ had produced in dogs with overdosage of x-rays. All the formed blood elements were reduced, mostly owing to destruction of bone marrow. Terminally, petechiae appeared in the skin, and blood oozed from the body orifices. At autopsy, hemorrhages were found in the tissues and viscera, including the brain, meninges, kidneys and gastrointestinal tract.⁷⁵ Of the 125,000 deaths resulting from the atomic explosions it has been estimated that from 8 to 20 per cent were due exclusively to radiation effects.⁷² In view of the importance of hemorrhages as a cause of death in these cases, the ability of rutin to inhibit radiation-induced bleeding is of obvious significance. In addition, it has been shown that rutin accelerates the recovery of tissues burned by overdosage of x-ray.⁷⁶ Several investigators⁷⁶ found that the degenerated bone marrow of many of the survivors retained a regenerative capacity, and they stated that if advantage had been taken of this feature, the death rate from ionizing radiation would have been much lower. These findings suggest a possible prophylactic value of vitamin P in persons subjected to ionizing radiation for therapeutic or other purposes. The findings are of such potential significance that ample confirmation of these observations is eagerly awaited.

Dicumarol Therapy

The occurrence of hemorrhage after administration of Dicumarol does not necessarily parallel the prolongation of the prothrombin time. Bleeding has occurred with only moderate depression of prothrombin activity, and conversely, when the prothrombin has been excessively prolonged, expected hemorrhages have frequently failed to materialize. For this reason, factors other than hypocoagulability of the blood have been sought that might have a bearing on bleeding. Wright and Prandoni⁷⁷ have shown that, even when Dicumarol produces hemorrhage, there is no increase in capillary fragility. However, in dogs given Dicumarol, Bingham, Meyer and Pohle⁷⁸ found marked dilatation of capillaries, small arteries and veins. This suggested a vascular component for the institution of bleeding—a viewpoint that has been stressed by Quick.⁷⁹ McLean and Brambel⁸⁰ gave rutin to patients receiving Dicumarol, but since none of the controls bled, the effects of rutin could not be judged. Clark⁸¹ administered sufficient Dicumarol to rats to induce bleeding and found that rutin given orally failed to prevent the hemorrhages. Since in these experiments the rats may have succumbed before

the latent period of rutin activity expired, Levitan and Schwager⁵² carried out similar experiments in rabbits, using esculin, which is a potent, quick-acting type of vitamin P. Like rutin, esculin failed to prevent the hemorrhages. Neither rutin nor esculin produces capillary contractions. In view of the pathological evidence of vascular engorgement in Dicumarol poisoning, it would be of interest to test the catechins in this condition since they are said to stimulate vasomotor activity.

Degenerative Vascular Disease

As arteries degenerate, newly formed capillaries appear about the atheromatous plaques in the intima.⁵³ These intimal capillaries⁵⁴ are distinct from the vasa vasorum, which lie in the outer half of the artery wall, and appear only after arteriosclerosis has progressed to a moderate degree. Their role in the pathogenesis of coronary and cerebral thrombosis has been established by Paterson⁵⁴ and confirmed by others.⁵⁵ When the capillaries rupture, an intimal hemorrhage that leads to the development of a thrombus in the adjacent lumen is formed. The suggestion that a similar mechanism operates in cerebral hemorrhage⁵⁶ apparently stimulated Griffith and Lindauer^{19, 33} to study the role of capillary fragility in cerebral and retinal hemorrhages complicating hypertension. They confirmed Levrat's⁵⁷ finding that the incidence of such complications was considerably greater when an increased capillary fragility was present. Numerous studies since 1872^{58, 59} have shown that capillaries deteriorate in arteriosclerosis, and hence the finding of an increased fragility in such circumstances reflects a diffuse vascular degeneration. The correlation between positive fragility tests and a high incidence of vascular accidents thus becomes apparent. Griffith and Lindauer³³ claimed that they could correct the capillary weakness in 75 per cent of such cases by the use of rutin, and concomitantly, the incidence of cerebral and retinal hemorrhages was reduced. Unfortunately their control group consisted of the 25 per cent whose capillary defect failed to respond to rutin, because of either insufficient or intermittent dosage. This choice of a control group complicates an evaluation of their findings. Other investigators,⁶⁰ in smaller series of cases and over relatively short periods of observation, have obtained varied results. Final conclusions regarding the effects of rutin on the vascular complications of hypertension cannot be made from the data available at the present time.

Diabetes Mellitus

Numerous workers have found a high incidence of increased capillary fragility in this disease, par-

ticularly when retinopathy is present.^{61, 62} This is partly due to the premature development of arteriosclerosis. The retinopathy, however, depends on factors in addition to arteriosclerosis. Changes in plasma proteins that were more pronounced in cases complicated by retinopathy have been found.⁶³ An endocapillary layer of protein has been described by Danielli⁶⁴ as an integral part of the capillary wall that regulates pore diameter. A disturbance of this layer secondary to the changes in plasma proteins might contribute to the retinopathy by increasing the size of the pores so as to allow the escape of blood constituents that go to form the hyaline plaques.

Several types of vitamin P have been used to control the retinopathy. The results have not been dramatic.^{1, 91, 92} Objective improvement has not been attained, but it appears that the degenerative process has been arrested in patients whose capillary fragility returned to normal. According to Rodriguez and Root,⁹¹ this may not be achieved until many months of intensive therapy have elapsed. It appears, then, that little can be expected from vitamin P therapy in diabetic retinopathy unless large doses are administered indefinitely.

Frostbite

The capillary damage that occurs in this condition prompted Fuhrman and Crismon⁹⁵ to study the effects of rutin in frostbite. Large doses of rutin administered to rabbits prior to or shortly after the extremities were subjected to low temperatures markedly reduced the extent of subsequent gangrene. However, these effects of rutin were not reproducible when the ears were the test object.

Albuminuric Diseases

Dunn⁹⁶ states that Cohnheim originated the idea that damage to peripheral capillaries was important in the development of renal edema. Some support for this concept is afforded by the findings of Göthlin⁹⁷ that capillary resistance is decreased in albuminuric conditions. Although the cause of this change is unknown, two possibilities are present. Glomerulonephritis and its variant, lipoid nephrosis, are believed by many to develop on the basis of an acquired sensitivity to streptococcal toxin, and as was previously shown, capillary fragility is increased in allergic conditions. Thus, an increased capillary fragility and permeability of an allergic nature may explain the early formation of edema, before plasma proteins are significantly reduced. The loss of albumin through visibly damaged glomeruli might also contribute to the capillary damage by disrupting the endocapillary layer.

Several authors have used vitamin P in various nephritides. Again the results are contradictory.^{1 98, 99} Further work is required, particularly with injectable preparations.

Dermatologic Conditions

Goldfarb¹⁰⁰ has used citrin therapy in psoriasis, based on Wertheim's description of morphologic capillary alterations in this disease. Of 45 patients treated 30 were said to have improved on the basis of diminution in the infiltration of the lesions and a decrease in scaling. In only 2 patients did the lesions completely disappear. In a variety of dermatologic conditions, crude hesperidin and hesperidin methyl chalcone administered for ten days to three weeks have proved to be of little value.¹⁰¹

Miscellaneous

Several reports have appeared on the use of rutin in bleeding of obscure origin. Schwager⁹² administered rutin, 20 mg three times a day, to a five-year-old girl with a history of epistaxis recurring three to six times weekly for several months. The only abnormal finding was an increased capillary fragility. After a month of rutin therapy, the capillary strength became normal, and the bleeding stopped. During an eighteen-month follow-up period, only one nose-bleed occurred, in the course of an upper-respiratory-tract infection. Shanno⁹⁴ reported 2 cases of hemoptysis, and Zfass¹⁰² 1 case of hematemesis of obscure etiology that responded favorably to rutin. In both reports the capillaries were excessively fragile prior to rutin therapy.

FIELDS FOR FUTURE STUDY

In spite of the widespread application of vitamin P, there remain several commonly occurring diseases in which it has yet to be applied. These include schizophrenia, cryptogenic epilepsy, migraine and Ménière's syndrome, in all of which capillary disorders appear to be of importance.

Capillary microscopy has revealed bizarre morphologic abnormalities in schizophrenia, and the weakness of these vessels is borne out by their directly observed tendency to rupture spontaneously.¹⁰³ An increased capillary permeability has also been detected by the technic of blister formation.¹⁰⁴ The possibility that recurring episodes of petechial hemorrhages in the brain substance contribute to the mental deterioration and the possible interruption of this process by vitamin P makes interesting speculation.

In cryptogenic¹⁰⁵ and deteriorated types¹⁰⁶ of epilepsy and in migraine,¹⁰⁶ which is genetically related to epilepsy, structural abnormalities of capillaries have been described. During attacks of migraine an actual increase in capillary permeability has been observed,¹⁰⁷ as indicated by blurring of capillary outlines. Similar changes have occurred premenstrually,¹⁰⁷ at which time migraine

attacks are prone to occur. Migraine is frequently precipitated by emotional conflict, which is also said to increase capillary fragility. These considerations, as well as the claim that vitamin P prevents the increased fragility that occurs in emotional stress,¹⁷ suggest a trial of vitamin P therapy in these diseases.

In Ménière's disease,¹⁰⁸ edema of the labyrinth has been implicated, and in view of the probable capillary basis for the edema, this syndrome merits a trial of vitamin P therapy.

The more recently discovered types of vitamin P, such as the catechins and esculin, also deserve further clinical application particularly in view of their potency, moderate solubility in water and rapid absorption from the gastrointestinal tract. Both may be given parenterally in aqueous solution. Rutin, the current popular type of vitamin P, is practically insoluble in water and must be dissolved in alkali alcohol, pyridine or propylene glycol for parenteral use. Clinically, rutin has been given only by mouth. Its absorption and excretion have not as yet been studied, and except for clinical response, there is no proof that it is absorbed from the gastrointestinal tract. Although it is possible that the long latent period observed in the clinical use of rutin is due to the nature of the pathologic condition being treated, it may also be referable to poor absorption from the intestines. Further work is required to clarify this point. The capillary vasomotor stimulation that the catechins alone exhibit³⁴ suggests their application in diseases such as thrombocytopenic purpura in which capillary atony is said to be an important factor in the genesis of bleeding.⁶²

Although almost all the investigations carried out to date are concerned with capillaries, recent evidence suggests that vitamin P is concerned with the stability of the system of ground substance of which that present in capillaries is only a small part. The ability of spreading factors to increase the permeability of connective-tissue ground substance has been reduced by vitamin P^{44 109} and enhanced by anti-vitamin-P factor.⁴⁴ The significance of this observation lies in the number of diseases to which ground substance falls prey. Abundant data have been accumulated¹¹⁰ indicating that the spread of infections and malignant growths is partly determined by the degree of permeability of ground substance. The stabilizing effect of vitamin P^{44 109} is thus of obvious significance. Ground substance is probably present in the erythrocyte membrane, and its stabilization by vitamin P is suggested by the increased resistance that erythrocytes treated with vitamin P demonstrate when exposed to hypotonic saline solution.²⁴ This observation raises the problem of a possible relation between vitamin P and hemolytic and aging processes of the red blood cell. Ground substance is present in the artery wall,^{89 111} and in experimental arteriosclerosis it has been

clearly shown that alteration or damage of this ground substance takes place before lipoids are deposited in it.¹¹² That vitamin P stabilizes arterial ground substance is suggested by the claims that rutin reduces the incidence of cerebral hemorrhage in hypertension.²⁵ Although this study was undertaken on the assumption that intramural capillary hemorrhage might determine the occurrence of cerebral hemorrhage, such a mechanism has never been clearly demonstrated in this type of vascular accident. It is generally believed that cerebral hemorrhage is due to an elevated arterial pressure rupturing the entire thickness of a weakened vessel wall. Since little or no change in blood pressure has been observed in such cases treated with rutin, the beneficial effects appear to be due to local stabilization of the vessel wall. With these considerations in mind, I attempted to study the effects of rutin on the prevention of experimental arteriosclerosis in rabbits. Uncontrollable factors twice reduced the number of surviving animals so as to preclude definite conclusions, but some protection seemed to be afforded by rutin. There is ground substance present in intervertebral disks, probably hyaluronic acid.¹¹³ The interesting hypothesis has been advanced that disk degeneration is due to disease of the ground substance of the disk and, as such, reflects a widespread ground-substance degeneration, possibly owing to repeated infections caused by hyaluronidase-producing organisms.¹¹⁴ If this is true, the ability of vitamin P to stabilize ground substance against the action of hyaluronidase^{115, 116} is again of obvious importance.

Increasing attention is now being directed to the role of mucus in the prevention of peptic ulcer and chronic ulcerative colitis. Meyer and his co-workers^{115, 116} have shown that the enzyme lysozyme, which is capable of digesting mucus, is present in high concentration in the gastric juice of patients with peptic ulcer and in the stools of patients with chronic ulcerative colitis. They have suggested that dissolution of the mucin coating by lysozyme activity exposes the bare gastrointestinal mucosa to the eroding action of hydrochloric acid and indigenous bacteria. The protective action that gastric mucin affords the gastric mucous membrane has been clearly demonstrated. The mucosin sulfuric acid of gastric mucin is closely related to the hyaluronic acid and chondroitin sulfuric acid of connective-tissue ground substance.¹¹³ The ability of vitamin P to stabilize the ground substance raises the question whether a similar effect might be exerted on gastrointestinal mucin. In this connection, it may be more than coincidental that cabbage juice, which has been claimed to accelerate the healing of peptic ulcer,¹¹⁷ is a rich natural source of vitamin P. Other conditions that suggest themselves for vitamin P studies are the collagen diseases and amyloidosis.

In conclusion, vitamin P studies have been made in numerous diseases in which capillary defects appear to play a role. The purpose of this paper is to review these findings and to direct attention first to other diseases in which capillary factors appear to be of importance and secondly to diseases of ground substance that might provide interesting material for future vitamin P investigation.

CASE 35461

PRESENTATION OF CASE

A sixty-three-year-old laborer entered the hospital complaining of epigastric pain.

He had been well until eight years before admission, when he developed burning epigastric pain. There was no relation to meals. His physician prescribed a "white stuff," which relieved the pain but caused constipation. A gastrointestinal series at that time was negative. The pain disappeared after a few weeks and did not return until two years later, when there was a similar attack. The third episode occurred six months before admission. The pain usually came on when he was hungry, beginning in the midepigastrium and radiating toward both flanks. It occurred daily, one to four hours after meals, and was relieved by food, milk and the white medicine. His worst attack began three weeks before admission, the pain was more severe than ever, but was still relieved by food and sometimes by the passage of flatus. There had been no nausea, vomiting, change in bowel habit, melena or grossly bloody stools. There had been little weight loss, the weight on admission being 165 pounds, one year previously, it had been 170 pounds.

Physical examination revealed a well developed and well nourished, muscular man in no discomfort. The anteroposterior diameter of the chest was increased. The lung fields were hyperresonant. The heart was normal. There was slight tenderness without spasm in the midepigastrium. The costo-

vertebral angles were slightly tender. No masses other than what appeared to be feces in the colon were palpable.

The temperature was 99°F, the pulse 74 and the respirations 20. The blood pressure was 138 systolic, 78 diastolic.

Laboratory studies revealed a red-cell count of 5,000,000, with 14 gm of hemoglobin, and a white-cell count of 9600, with a normal differential count. Urinalysis was normal. The total protein was 7.4 gm, the nonprotein nitrogen 29 mg, and the fasting blood sugar 81 mg per 100 cc. A stool was guaiac negative.

A gastrointestinal series revealed a deeply penetrating ulcer in the midportion of the posterior wall approaching the greater curvature. It measured 2 cm in width and 3 cm in depth. About the ulcer there appeared to be a good deal of soft-tissue swelling. Barium passed the pylorus without hesitancy, filling the duodenal bulb to its normal contour.

A gastroscope was introduced, and normal, rather active peristaltic waves were seen passing over a normal-appearing antrum. Just proximal to the angulus of the greater curvature, an ulceration, sharply punched out and measuring 1.5 cm in diameter, was noted. The margin was sharp and surrounded for a distance of 2 cm by a flat, plateau-like area in which no rugae were present. The lesser curvature, from a distance of about 2 cm above the ulcer down to the pylorus, was rigid and shortened. Not enough barium passed into the duodenum to fill out the duodenal bulb to normal contour. No barium left the stomach by way of any anastomosis.

A fasting gastric aspiration failed to produce free acid, but free acid was present after histamine. The patient was kept virtually pain free by hourly feedings. The temperature and white-cell count fell to normal. The morning gastric residual fluid was reduced from 300 to 75 cc during the first week. On the seventeenth day, gastroscopy revealed a constantly deformed and rigid-appearing angulus. Its outline was irregular and slightly nodular. No peristalsis was visible. The ulceration seen at fluoroscopy was out of the range of the gastroscope.

Three days later, an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. CLAUDE E. WELCH* We may as well start by seeing the x-ray films to get all the data

CLINICAL DIAGNOSIS

Gastric ulcer

DR WELCH'S DIAGNOSIS

Benign gastric ulcer

ANATOMICAL DIAGNOSIS

Benign gastric ulcer, greater curvature

PATHOLOGICAL DISCUSSION

DR CASTLEMAN On the posterior surface along the greater curvature, 9 cm from the proximal resection edge, was a perforated ulcer, partly walled off by the adjacent mesocolon, omentum and pancreas. When the stomach was opened the lesion was sharply punched out, and its grossly benign appearance was confirmed microscopically.

CASE 35462

PRESENTATION OF CASE

First admission A fifty-seven-year-old housewife was admitted to the hospital because of vomiting and a spontaneous black eye.

She was apparently well until four weeks before entry, when she developed a severe lumbosacral pain radiating at times to the left leg, not relieved by strapping and continuing intermittently until she entered the hospital. She also noted blood in the stool as well as some blood on the nightgown. Three weeks prior to admission she entered a community hospital for vaginal bleeding, the first since her menopause ten years previously. No diagnosis was made, and she was discharged after three days. One week before entry a rash appeared on the medial aspects of both legs and thighs. Four days before admission she developed mild vomiting and anorexia. There was no blood or bile in the vomitus.

The past history revealed an episode of pain in the right upper quadrant, with vomiting and jaundice, two years prior to admission. A cholecystostomy was performed, with the removal of several gallstones. The patient had been known to have mild diabetes for an indefinite period.

Physical examination revealed a well developed, moderately obese woman who was not acutely ill. There was a fading papular rash over both posterior thighs and lateral aspects of the knees. There were right periorbital and scleral areas of ecchymosis. The lungs were clear. The heart was slightly enlarged to the left, and a Grade II, harsh systolic murmur was audible at the apex. Abdominal examination showed slight diffuse tenderness referred to the upper quadrant and some tenderness in both costovertebral angles. Pelvic and rectal examinations were negative. Examination of the fundi showed a few flame-shaped hemor-

rhages, with arteriolar narrowing and blurring of the disk margins, without papilledema. There was a questionable slight left facial weakness. Tendon reflexes were hypoactive throughout, but there was no asymmetry. Ankle jerks were absent bilaterally. Both plantar responses were down or absent. There was no weakness of the extremities. Sensation was intact, co-ordination was accurate.

The blood pressure was 140 systolic, 95 diastolic. The pulse was 85, and the respirations 20.

Urinalysis revealed a specific gravity of 1.020, a ++ test for albumin and intermittent green in the sugar reactions. A catheterized specimen showed 30 white cells per high-power field but no red cells or casts in the sediment. There was no bile or Bence-Jones protein. Examination of the blood revealed an initial hemoglobin of 11 gm, slowly falling to 8 gm. The white-cell count was within normal range, the platelets were adequate. Repeated determinations of the clotting time, prothrombin time, capillary fragility, bleeding time and platelet counts were within normal limits, as were the serum nonprotein nitrogen, the carbon dioxide combining power, the total protein, the calcium, the phosphorus, the amylase, the cholesterol and the cholesterol esters. The blood sugar ranged between 200 and 250 mg per 100 cc. The bromsulfalein test showed 36 per cent retention of the dye in forty-five minutes. The van den Bergh reaction rose from normal to 1.6 mg per 100 cc. The urine urobilinogen was 1.2 Ehrlich units in two hours. The thymol-turbidity and the cephalin-flocculation tests were negative. A blood culture was negative. An electrocardiogram revealed changes consistent with coronary-artery disease. An electroencephalogram was within normal limits. X-ray films of the chest were unremarkable except for some strand-like increase in density. Films of the spine, ribs, pelvis, hips and shoulders showed peculiar scattered areas of bone density. The second lumbar vertebra was denser than normal. Skull films were normal. A gastrointestinal series revealed no abnormalities. An intravenous pyelogram was normal except for a double pelvis in the right kidney. A bone-marrow aspiration showed marked stimulation of red-cell production. A vaginal smear was negative for tumor cells. A lumbar puncture revealed an initial spinal-fluid pressure equivalent to 400 mm of water, falling after fifteen minutes, relaxation to 300 mm. Three cubic centimeters of clear spinal fluid was removed, the total protein was 104 mg per 100 cc, no cells were present.

During the two-week period in the hospital the vomiting cleared and the ecchymoses of the skin and the right orbit faded somewhat. No new symptoms appeared. The diabetes was mild and was controlled without insulin. It was decided to observe the patient rather than to perform a craniotomy because of the symptoms of increased intra-

DR RICHARD SCHATZKI In addition to what is reported in the record I think I see something else that might be of significance. It seems to me that in these three films the lesser curvature is stiff over an area 5 cm in length. The crater may be seen in profile in this film. In this next film the crater cannot be seen because there is too much barium. This stiffness, which I assume to be present, is the ulcer. There is marked swelling around the ulcer.

DR ALFRED KRANES Are you able to tell that the wall is stiff without fluoroscopying the patient?

DR SCHATZKI I certainly prefer fluoroscopy. On the other hand several films may allow some judgment. The normal stomach changes constantly in shape, and an area that does not change is usually rigid. We have not many films here, and I would like to have my hands on the patient's stomach.

DR WELCH I do not know what disease this patient had, but, as an academic exercise, we shall recount the methods of differentiating benign and malignant ulcer. In the first place, patients in the older age group who have a long story of gastric distress are more likely to have benign than malignant lesions. The patient with a short history is rather likely to have cancer. On this basis, we are slightly inclined toward ulcer in this case. The position of the ulcer is of importance. Almost all ulcers on the greater curvature are malignant. Those on the anterior or posterior walls carry about a 20 per cent chance of malignancy according to our figures in this hospital. Since this ulcer was on the posterior wall close to the greater curvature, the diagnosis is indeterminate from that criterion. The determination of free hydrochloric acid is not of great importance. If it is absent, one is inclined toward a diagnosis of a malignant lesion, but if free acid is present, cancer cannot be excluded.

Another method of differentiation is by the rate of healing. No evidence is offered in this case since the patient was observed in the hospital for only eight days. Another method is afforded by the type of pain, but, in this patient, who had a deeply penetrating lesion of the pancreas with tenderness in the epigastrium, pain is sure to have been present regardless of the diagnosis of ulcer or cancer.

A final bit of evidence is offered by the cytologic smear of the gastric contents. If the specimen obtained is in good condition and cancer cells are not seen, the differential diagnosis is still dubious because about a third of the carcinomas of the stomach do not shed cells. However, if cancer cells are reported from our laboratory, the chances of error are almost zero.

Whether or not such an examination was made is not mentioned in the protocol.

There is some additional evidence that this patient had ulcer rather than cancer. He had no weight loss in spite of the fact that the lesion was large. Also, examinations for occult blood in the

stool were negative, and carcinoma is more likely to demonstrate this type of blood loss than is benign ulcer. The gastroscopic examination introduces a rather disturbing feature in that no peristalsis was observed around the margin. This is uncommon for ulcer and more typical of cancer, but in this particular patient, we have an element of pancreatitis superimposed because this lesion had perforated into the pancreas.

Considering all these features, the evidence is in favor of benign ulcer in this patient. The evidence is also strongly in favor of operation. An operation designed for cancer rather than an operation for benign lesion should be carried out.

DR WALTER BAUER I am trying to get Dr Kranes to bet on the possibility that this was not benign. I want to bet that it is benign.

DR SCHATZKI I do not like to bet in a case like this because I think the evidence is not conclusive. If I were to take a chance, I would say cancer.

DR MILFORD SCHULZ It is not a deeply penetrating ulcer. Considering that ulcer occurs following necrosis in a spindle-cell tumor, would Dr Schatzki like to say something about that and why he does not think it is one of that type?

DR BENJAMIN CASTLEMAN You mean an intramural extramucosal tumor?

DR SCHULZ Yes.

DR SCHATZKI From the evidence I would rather say no, but probably that is just what it is going to turn out to be. May I say one word about a statement Dr Welch made that an ulcer on the greater curvature is almost always malignant. I think that statement is based on surgical statistics, and roentgenologic statistics vary a bit because it depends on what one calls an ulcer of the greater curvature in one's statistics. In cases with any kind of ulceration of the greater curvature, there is an overwhelming number of cancers. If those that are grossly malignant are excluded and only the grossly benign lesions considered, the percentage of benign ulcers will go way up. I remember at least 3 or 4 ulcers of the greater curvature in this hospital that turned out to be benign. Statistics will vary among hospitals. In an active hospital the number of benign cases will go up because many more benign lesions will be operated on, it also depends considerably on the x-ray interpretation.

DR CHARLES MIXTER, JR A cytologic smear was made, but it was unsatisfactory. At the time of operation the lesion was grossly benign. It was close to the greater curvature and appeared to invade the pancreas and transverse mesocolon. In view of the position of the lesion and because of apparent invasiveness we treated it as carcinoma and therefore elected to take out the tail of the pancreas and also a part of the transverse colon.

vertebra, and I believe there is an area of destruction in the margin of the second lumbar vertebra with slight compression of the body of this vertebra. Small radiolucent areas are seen in the lower ribs. Examination of the chest, made on the first admission, shows a strand-like increase of density throughout both lung fields and small nodules in the peripheral lung fields. A film made on the second admission shows only a slight increase in the strand-like and nodular densities in both lung fields.

The films of the skull show one or two small radiolucent areas over the vertex having the appearance of venous lakes. The density extending across the parietal bones is due to a braid of hair. The sella turcica is normal in size and smooth in contour. There is no evidence of lesions in the skull. The calcified pineal body is in the midline.

DR BALBONI: Is there anything abnormal about the duodenum? There is no widening?

DR McCORT: There is no widening and no evidence of intrinsic involvement of the duodenal wall. The liver, as I mentioned previously, seems somewhat larger than normal.

DR BALBONI: Are the kidneys normal?

DR McCORT: Yes, the double kidney on the right is of no pathological significance.

DR BALBONI: It is rare but not impossible for metastases from a single tumor to be both osteoblastic and osteolytic. Is that the situation here?

DR McCORT: The changes in the bone are both osteoblastic and osteolytic.

DR BALBONI: With the help of the x-ray studies, the picture seems to be clearing a little bit. She had an x-ray picture of metastatic cancer, widespread throughout the skeleton, of both osteoblastic and osteolytic lesions and also lesions in the lung. The liver, which was not enlarged clinically, was slightly enlarged by x-ray study. There was abnormal function of the liver as manifested by the bromsulfalein retention. This was the only liver-function test that was abnormal, and it is consistent with involvement of the liver by tumor. I assume that part of the liver was destroyed by metastases but that the remaining liver cells were functioning normally and capable of performing all functions of the liver except excretion, which was somewhat reduced as evidenced by the bromsulfalein test and the van den Bergh reaction, which rose to 16 mg per 100 cc.

The common tumors that metastasize to bone are tumors of the breast, the prostate, the kidney and the bronchus. The only one I am sure was not involved here was the prostate, but there is little to suggest any of the others. The question of multiple myeloma in the bone, spreading widely through the pelvis, ribs and spine, has to be considered when one is confronted with lesions of this multiplicity, but such lesions are almost invariably osteolytic. Furthermore, at this stage of the game in multiple myeloma one would expect an elevated

serum protein, and sometimes an elevated serum calcium. The absence of Bence-Jones protein in the urine is not against the diagnosis because it only occurs in about 50 per cent of cases of multiple myeloma.

Osteoblastic lesions are usually very slowly growing lesions such as may be seen in tumors of the pancreas. It is difficult to locate the primary site of the cancer. We know that she had previous gall-bladder disease, and she could have had a malignant lesion that developed in the gall bladder. Usually, in that situation, a mass is palpable in the region of the gall bladder. This woman apparently had none. I cannot locate the source of the tumor but I think she died of metastatic tumor involving the brain, the spine, the pelvis, the lungs and the liver. It would be unusual to have this a granulosa-cell tumor of the ovary that became malignant and spread, but in view of the fact that she had vaginal bleeding and an estrogen effect in the vaginal smear and in view of the fact that she had not taken any estrogen orally that diagnosis has to be considered. I would also seriously consider the gall bladder and pancreas as the primary site for the cancer.

A PHYSICIAN: Is the elevated blood sugar significant?

DR BALBONI: She was known to have diabetes for a good many years, and I would think that the elevated sugar was consistent with her diabetes, which was aggravated by the surgical procedures she was subjected to.

DR GREENE FITZHUGH: The diagnosis on the Medical Service was metastatic cancer. Our opinion was that we should biopsy that mass in the pelvis before having a neurosurgeon see her because of the brain lesions, but she got worse so rapidly that we transferred her to the neurosurgeons in the hope that they might be able to prolong her life.

CLINICAL DIAGNOSES

Disseminated neoplastic disease, unidentified
Metastatic carcinoma of brain and lung
Diabetes mellitus

DR BALBONI'S DIAGNOSES

Metastatic cancer involving brain, spine, pelvis, lungs and liver
? Granulosa-cell cancer of ovary, ? cancer of gall bladder, ? cancer of pancreas

ANATOMICAL DIAGNOSES

Carcinoma of gall bladder, with extension to extrahepatic bile ducts and peripancreatic nodes, and metastases to lungs and bones
Cholelithiasis, with obstruction of ampulla of Vater
Arteriosclerosis, generalized

cranial pressure On the fifteenth hospital day she was sent home to be followed in the Out Patient Department

Final admission (six days later) After a very short stay at home the patient was readmitted because of increasing back pain and recurrence of the vomiting

The neurologic examination remained unchanged The fundi, however, revealed advanced papilledema and recent hemorrhages Sensory changes were equivocal Her mental state, which had been extremely poor, was unchanged

On the fifth hospital day bilateral anterior temporal burr holes were made to rule out subdural hematoma The right side revealed a thickened dura but no subdural fluid Bleeding during the procedure was very profuse and difficult to control On the following day she had a left hemiparesis of the face and upper extremity Re-exploration revealed a recent operative blood clot in the right frontal burr hole After enlargement of the incision no subdural accumulation of fluid was discovered Dural and bone bleeding was controlled, but during the evening after operation oozing was noted over the bandage Gradually, the patient became more comatose, and the blood sugar ranged from 350 to 450 mg per 100 cc On the eighth hospital day a right subtemporal decompression was performed because of jerking movements of the left arm and hand, suggesting possible subdural hematoma, but none was found A repeated x-ray film of the chest showed an increased number of nodular densities

During the following days the patient progressively deteriorated She became very pale, the blood pressure dropped, and she died on the twentieth hospital day

DIFFERENTIAL DIAGNOSIS

DR VICTOR G BALBONI* We are dealing with a woman in late middle age who a month before entry developed severe back pain At about the same time, she had vaginal bleeding and then vomiting, for which she was admitted to the hospital She was found to have ecchymoses about the eye, and a rash, which may have been a purpuric rash although the record is not clear on that The vaginal bleeding, the rash, the ecchymoses about the eye and the fact that later on she developed signs of an intracranial lesion raise the question of whether she had some form of bleeding tendency or purpura However, the bleeding time, the clotting time, the prothrombin time and the tourniquet test were all within normal limits Therefore it seems untenable to entertain seriously a diagnosis of purpura to account for the clinical course of this patient The leg rash, I cannot explain The ecchymoses about the eye, I think, may be explained on the basis of rupture of normal or slightly arterio-

sclerotic vessels while she was vomiting for four days She had mild diabetes and was entitled to some vascular disease

Vaginal bleeding is a much more important symptom, and in any woman of this age means cancer of the genital tract until proved otherwise Pelvic and rectal examinations were negative We are told that she had a previous hospital entry for three days, and I wonder if dilatation and curettage were done at that time It would seem like a logical thing to do on a woman who was bleeding, but we have no information about that A functioning ovarian tumor, a granulosa-cell tumor, may cause resumption of vaginal bleeding any time after the menopause, but granulosa-cell tumors are rarely malignant Later on there is evidence that she had a malignant tumor with widespread metastases Granulosa-cell tumors can become malignant and metastasize, but usually they do not The vaginal smear showed no evidence of cancer cells That is fairly good evidence against a malignant lesion of the uterus It does not completely rule it out, however Sometimes in reports of vaginal smears, the presence or absence of an estrogen effect in the cells is noted I wonder if it was in this case

DR JOHN W LITTLEFIELD Yes, there was a marked estrogen effect in the smears

DR BALBONI That raises another question A not uncommon cause for vaginal bleeding in a woman of this age is oral or parenteral estrogenic medication

A PHYSICIAN There was no history that she had been taking estrogenic medication

DR BALBONI The fact that she showed an estrogen effect in the vaginal smear indicates that she had been taking estrogenic substances or that she had a functioning tumor of the ovary—a tumor making estrogen

Later in the clinical course signs of increasing intracranial pressure developed, and the questionable right facial paralysis she showed on entry became very definite In other words, she apparently had a lesion within the skull, and it probably was getting larger The x-ray films show lesions in many of the bones and in the lung and from the description I gather that they were osteoblastic metastases We might well review the films now

DR JAMES J MCCORT On the intravenous pyelogram a double kidney is seen on the right side The liver edge is lower than normal A study of the gastrointestinal tract discloses a normal esophagus, stomach and duodenum No widening of the duodenal loop is seen The colon was examined on two occasions and shows no intrinsic abnormality On the films made of the colon it is noted that there are small densities present throughout the bones of the lower ribs, the lumbar spine and the pelvis These densities are irregular and of varying size, extending up to 2 cm in diameter There is also increased density of the second lumbar

THANKSGIVING

THAT historic Thanksgiving in Plymouth Bay Colony, before the gobbling of turkeys was heard through the land, and when only a few handfuls of parched corn were available for the feast, has been succeeded by an era of plenty — at least for the prosperous.

Thanksgiving has not been the expression of a universal emotion, however. This country, even if less sharply than others, is also divided between the haves and the have nots, and many of the haves, apprehensive lest they lose what they hold, or discontented by nature, seem to find little enough for which to be thankful.

Thankfulness results from an appreciation of comparative values. On this basis nearly everyone has something to be thankful for, particularly in America. Most Americans, if they are not utterly derelict, can be thankful for enough to eat and a

place to sleep. They can be thankful for freedom of speech under most circumstances, for freedom of action if it does not offend the majority or more powerful interests, and for freedom in selecting the type of medical care that is most suited to their needs.

They can be thankful for freedom to worship — to a less degree for freedom from religious intolerance. They can be thankful for many liberties, although all of them must be constantly protected against the inroads of bureaucracy. They can be thankful for the preservation, to date, of free enterprise, and for having been spared such reigns of terror as have become the lot of many other countries of the world.

BANNER WITH A STRANGE DEVICE

AMONG the activities associated with the United Nations the World Health Organization stands out as one of the most promising. Its program is reasonable and reminiscent of the good old days before 1914 when the civilized nations united in all sorts of mutually beneficial activities, such as uniform postal rates, copyright laws, weather reports, public-health regulations, the gold standard and hydrographic surveys, and global war had not been heard of since Waterloo except in the nightmares of H. G. Wells. If all nations could really agree on the importance of achieving world health, most other problems would be solved for nothing is unhealthier than war and its sequelae.

Medical knowledge has kept pace with the technical advances that have marked a century of progress. This is what the chief of the American delegation to the second World Health Assembly, held in Rome from June 13 to July 2, may have had in mind when he declared in his report: "Unless we move forward to improve the health of mankind it is impossible for mankind to move forward." The statement suggests a pleasing slogan: *Gesundheit et excelsior!* What might the nations accomplish if united under a banner with such a device?

Of course there is the risk that when mortal disease is abolished man will propagate so unrestrainedly that the world will be overpopulated in a few generations and that people will then die off, in

Operative scars cholecystostomy, old, frontal burr holes, recent, subtemporal decompression, recent

PATHOLOGICAL DISCUSSION

DR TRACY B MALLORY Autopsy on this patient disclosed a small, extremely firm, shrunken gall bladder, with thickened walls and some palpable excrescences of the mucosa. There was obvious tumor tissue extending down the length of the common duct, surrounding it completely, and extending into the region of the head of the pancreas. It was the impression, however, that the tumor nodules were lymph nodes around the head of the pancreas rather than in the pancreatic tissue and that the probabilities were all in favor of a primary carcinoma of the gall bladder that had spread to the pancreas rather than in the reverse direction. It is frequently very difficult to decide in this group of tumors which spot is primary. The tumor, extraordinarily enough, had not infiltrated the liver although it was in the lymphatics of the gall-bladder wall. Usually, carcinoma of the gall bladder invades the liver very widely and very early. In the lung the lesions were so small that they could not be picked up grossly, but microscopically the lymphatics throughout the pulmonary tissue were filled with tumor emboli.

One of the very unusual findings of the case was an obvious polyp of the endometrium, which on microscopical section showed metastatic cancer in the lymphatics within the polyp. The explanation of the central-nervous-system symptoms remains rather doubtful. I have to ask Dr Kubik to tell us what he found.

DR CHARLES S KUBIK No explanation for the cerebral symptoms has been found. Both explorations were negative for subdural hematoma,

and at the second operation the brain itself was explored, with a negative result. On post-mortem examination there were numerous ecchymoses and small extravasations of blood on the inner surface of the dura, not only near the sites of the operations but also at considerable distances from them. This is almost surely a late development, which did not account for the cerebral symptoms. The conditions were probably explained by the surgical procedures and also perhaps by a hemorrhagic tendency, for which there was considerable clinical evidence, in spite of the negative blood studies. The patient did have ecchymoses of the skin and probably a hematoma of the orbit. There was little or no flattening of the convolutions, the ventricles were not enlarged, and there were no pressure cones. Aside from the mental status, papilledema, a spinal-fluid pressure equivalent to 400 mm of water and a protein of over 100 mg per 100 cc. were very real abnormal findings, and it is remarkable that nothing was found to explain them.

DR MALLORY I neglected to mention one finding that may have had some significance. There was embedded in the ampulla of Vater a small gallstone, so that she had definite cause for obstruction in the biliary tract—two causes, both carcinoma and the gallstone. In a certain number of cases of liver disease, this type of bleeding is seen when platelets, prothrombin time and everything else are normal, nevertheless, the patient bleeds extensively.

DR ALFRED KRANES She did not have liver disease?

DR MALLORY She had extrahepatic biliary-tract disease of severe grade without, however, clinical jaundice. The liver showed only insignificant changes.

THANKSGIVING

THAT historic Thanksgiving in Plymouth Bay Colony, before the gobbling of turkeys was heard through the land, and when only a few handfuls of parched corn were available for the feast, has been succeeded by an era of plenty — at least for the prosperous

Thanksgiving has not been the expression of a universal emotion, however. This country, even if less sharply than others, is also divided between the haves and the have nots, and many of the haves, apprehensive lest they lose what they hold, or discontented by nature, seem to find little enough for which to be thankful

Thankfulness results from an appreciation of comparative values. On this basis nearly everyone has something to be thankful for, particularly in America. Most Americans, if they are not utterly derelict, can be thankful for enough to eat and a

place to sleep. They can be thankful for freedom of speech under most circumstances, for freedom of action if it does not offend the majority or more powerful interests, and for freedom in selecting the type of medical care that is most suited to their needs

They can be thankful for freedom to worship—to a less degree for freedom from religious intolerance. They can be thankful for many liberties, although all of them must be constantly protected against the inroads of bureaucracy. They can be thankful for the preservation, to date, of free enterprise, and for having been spared such reigns of terror as have become the lot of many other countries of the world

BANNER WITH A STRANGE DEVICE

AMONG the activities associated with the United Nations the World Health Organization stands out as one of the most promising. Its program is reasonable and reminiscent of the good old days before 1914, when the civilized nations united in all sorts of mutually beneficial activities, such as uniform postal rates, copyright laws, weather reports, public-health regulations, the gold standard and hydrographic surveys, and global war had not been heard of since Waterloo except in the nightmares of H. G. Wells. If all nations could really agree on the importance of achieving world health, most other problems would be solved for nothing is unhealthier than war and its sequelae.

Medical knowledge has kept pace with the technical advances that have marked a century of progress. This is what the chief of the American delegation to the second World Health Assembly, held in Rome from June 13 to July 2, may have had in mind when he declared in his report: "Unless we move forward to improve the health of mankind it is impossible for mankind to move forward." The statement suggests a pleasing slogan: *Gesundheit et excelsior!* What might the nations accomplish if united under a banner with such a device?

Of course there is the risk that when mortal disease is abolished man will propagate so unrestrainedly that the world will be overpopulated in a few generations and that people will then die off, in

great batches, of suffocation and starvation. But this is not a serious threat at the moment.

The report referred to above points out that in the war-torn countries nonmilitary deaths per thousand have dropped in France from 15.2 in 1937-1939 to 10.5 in 1948, in Austria from 14.2 to 11.8 and in Japan from 17.3 to 12.0 (30 per cent less than any death rate previously recorded), and that before 1946 the death rate from malaria in Ceylon was 20 to 22 per thousand — a thorough dusting with DDT brought it down to 14.3 per thousand.

From the long-range point of view it would be more realistic to include the military deaths and the mortality among displaced persons, and to take some account of the psychiatric, moral and spiritual casualties of the past decade, but perhaps these are not germane to the subject. It is hoped that the old saw may be trusted — that when all men have sound bodies, sound minds will result.

At any rate, one cannot but agree with the American chief delegate that the United States may well increase its contribution to WHO from five to seven millions of dollars.

SHALL THE LADIES JOIN US?

MEN, by and large, have one broad outlet for ministering to the health of their fellow beings. This is the profession of medicine, with its ramifications. Women, more subtly, have various methods of accomplishing the same purpose. The first, patently, is nursing, in which they reign supreme, casting into shadow men's efforts in this field. As medical secretaries, as technicians and in the research laboratory women perform subsidiary but invaluable services.

Other ways in which the more resourceful sex can contribute to the health of the community are illustrated by two interesting letters to the editor, to be found in this issue of the *Journal*. That from Dr. Edith Varney suggests the indomitable courage with which a young woman nearly sixty years ago, emulating Trotula, Rebecca and Constanza, the medical "ladies of Salerno," became one of the notable group of women physicians of this country.

The other, from the pen of the president of the Woman's Auxiliary to the Massachusetts Medical Society, gives intimations of the way in which women have guided the affairs of nations since the world began. As Esther to Ahasuerus, so may the women of the Auxiliary further the projects of their husbands and direct them into the most fruitful channels.

The Auxiliary is now a thousand strong, with the approval of its aims and the encouragement to join that will inevitably come to every wife from every husband in the Society, its enrollment should soon double and even triple. Fellows of the Society, however, must not wait for the moment when their wives will consult them on the desirability of membership, but urge them to join at once!

IT MIGHT HAPPEN HERE

THE comparisons that have frequently been made between British Medicine under the National Health Service Act and what might happen in this country were similar circumstances to prevail can never be entirely to the point. Socialism in England is, at the moment, an accomplished fact. It is the result of conditions that have been long in the making. It is a system that has been accepted, however willingly or unwillingly, by a people whose traditions, social cleavages and economic problems are peculiarly their own.

It goes without saying that England's current system of medical practice is at present undesired in this country. The present Congress recognizes the fact, even as Congress, most of the medical profession and a majority of the people believe that improvement in the quality and distribution of medical care can and must and shall be made.

The British deserve credit for being among the most reasonable people on earth, with a wholesome respect for authority, once authority has been granted. Thus with Britain's minister of health, whose insistence on the acceptance of the present Health Act by Britain's medical profession caused so much unhappiness a year ago, Mr. Bevan's authoritative utterances on matters of health are now received unquestioningly, and duly appear in the British medical press.

In the section on Medical Notes in Parliament, in the *British Medical Journal* of August 6, 1949, following a request from Mr Bevan that x-ray films be used economically, and a refusal by him to agree to a proposed transfer of the South-Western Hospital to St Thomas's Hospital, there appears a decision from the minister regarding the toxicity of ducks' eggs. Ducks' eggs, according to this statement, are eaten most safely after being baked or fried or boiled for ten minutes provided they have not been preserved in water glass.

As an example of extreme co-operation on the part of the profession, the *Lancet* of May 28 refers to the hospital surgeon who wrote on a case paper "This patient requires a hernia for his truss."

Among the 240 idiots described by the Commissioners to the Legislature of Massachusetts, 7 seem to have been made so by their mothers' trying to procure abortion by using very powerful drugs. Although these unborn children were not thus quite killed, yet they were irrecoverably stupefied and malformed to the lowest degrees of both mental and animal idiocy and weakness.

Boston M & S J, November 14, 1849

MASSACHUSETTS MEDICAL SOCIETY

DEATH

SCHOLZ — Samuel B Scholz, M D., of Jenkintown, Pennsylvania, died on March 4. He was in his seventy-second year.

Dr Scholz received his degree from Denver and Gross College of Medicine in 1905. He was medical director of the Penn Mutual Life Insurance Company of Philadelphia and was a fellow of the American College of Physicians and the American Medical Association and a retired member of the Massachusetts Medical Society.

His widow and a son survive.

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

PROJECT FOR DENTAL RESEARCH

Under the provisions of Section 1, Chapter 473, of the *General Laws* of the Commonwealth, the Department has instituted a research project, which has been approved by the Massachusetts Dental Society, to evaluate the feasibility of expanding the training of auxiliary dental personnel. Under the law, the project is limited to a period of five years,

the first two years being devoted to the training of female personnel and the last three representing an effort to determine the quantity and quality of dental service that can be rendered by auxiliary personnel to help overcome the wide disparity between dental needs and existing facilities. The project will be conducted at the Forsyth Dental Infirmary for Children. A representative group of students will be selected from the first-year class of the Forsyth School for Dental Hygienists, eventually to qualify as dental hygienists under the laws of Massachusetts.

Dr Howard M. Marjerson and Dr Charles E. Hatch, both members of the staff of the Infirmary, will be, respectively, director and clinical supervisor of the project. Dr William D. Wellock, of the Dental Division of the Department, will act as liaison officer between the Department and the Infirmary, and Dr William H. Griffin, dental director of the City of Boston Health Department and member of the State Health Department Public Health Council, is chief consultant. Other consultants appointed include leaders in dentistry and public health. In the near future, the commissioner, with the advice of the Massachusetts Dental Society and other interested groups, will appoint an advisory committee of dentists, public-health officers, social workers and other professional groups and civic leaders, to review periodically the reports of the project.

Every effort will be made to keep the dental profession informed of the progress of the project.

CORRESPONDENCE

NEVER UNDERESTIMATE THE POWER OF A WOMAN

To the Editor The following two letters, which have been in my possession for many years, may prove of interest to the readers of the *Journal*, particularly as the first women to be admitted to Harvard Medical School are entering on their final year.

Harvard University,
Cambridge, September 22, 1890

My dear Dr Bowditch,—

I regret to say that there is as yet no provision for the medical education of women either in Harvard University or by the Society for Promoting the Collegiate Education of Women. Please excuse the delay in replying to your note of September 13th. It was first forwarded to Mount Desert and then returned to Cambridge.

Very truly yours,

Dr Henry I. Bowditch

Charles W. Eliot

Peterborough
Sept. 24, 1890

Miss Varney
Dear Madam

I am not surprised at the tenor of President Eliot's reply, which I enclose. I deem the position of Harvard in regard (to) the education of women, one of which essentially the University will be thoroughly ashamed.

Even the word "Annex," which is connected with the Academic Department shows its low estimate of women. I never can think of it save with a certain contempt for the proud self-sufficiency evinced by the term. The Corporation virtually says "You women shall not join in the

great batches, of suffocation and starvation. But this is not a serious threat at the moment.

The report referred to above points out that in the war-torn countries nonmilitary deaths per thousand have dropped in France from 15.2 in 1937-1939 to 10.5 in 1948, in Austria from 14.2 to 11.8 and in Japan from 17.3 to 12.0 (30 per cent less than any death rate previously recorded), and that before 1946 the death rate from malaria in Ceylon was 20 to 22 per thousand—a thorough dusting with DDT brought it down to 14.3 per thousand.

ERYTHROBLASTOSIS FETALIS

V The Value of Blood from Female Donors for Exchange Transfusion*

FRED H ALLEN, JR., M.D.,† LOUIS K. DIAMOND, M.D.‡ AND JOSEPH B. WATROUS, JR., M.D.§

BOSTON AND NEW YORK CITY

IN reviewing the data from 208 cases of erythroblastosis fetalis treated by exchange transfusion, we were surprised to note that although the mortality was over 15 per cent in the whole group, there were no deaths in a group of 42 babies who happened to receive blood from female donors exclusively. This prompted the examination by statistical methods of available data in this large

bank records, and the sex of the donor was thus determined for almost all the babies in our series. Lately, we have been using blood from females only, but up to this time the selection of blood had been completely random as far as the specificity of sex of the donor was concerned. This report includes no cases in which female blood was selected deliberately, except for the parenthetical

TABLE 1 Relation of Outcome to Sex of Baby and of Blood Donor in 179 Babies with Erythroblastosis Treated by Exchange Transfusion*

SEX OF BABY	SEX OF BLOOD DONOR	LIVING PATIENTS		DEAD PATIENTS					SURVIVAL RATE

*Including all erythroblastic babies treated with an exchange transfusion of more than 150 cc

series, which showed that this finding has true significance.

It should first be noted that the sex of the blood donor was included in our data only as an afterthought, our interest being turned in this direction by our recent finding¹ that female babies with erythroblastosis fetalis do significantly better than male babies, especially with regard to the incidence of kernicterus. It was relatively easy to find out which donors were female by search of the blood-

statement that, since the use of blood from female donors only, we have treated 13 babies with exchange transfusion, with no deaths.

Table 1 shows the results of erythroblastosis fetalis in 205 consecutive babies, treated by the method of exchange transfusion using the umbilical vein as described by Diamond,² in which 150 cc or more of blood was given to the baby. This figure (150 cc) was picked arbitrarily, but it represents at least twice the amount that would be given in a single transfusion to a newborn baby, and certainly one could not consider that a successful exchange transfusion had been done with a smaller amount. Only 3 babies in our series were omitted from consideration in Table 1, because they received less than 150 cc of blood. One of these 3

*From the Blood Grouping Laboratory of Boston Children's Medical Center, Boston, the Boston Lying-in Hospital and the departments of Pediatrics and Obstetrics, Harvard Medical School.

†Instructor in pediatrics, Harvard Medical School; associate director of the Blood Grouping Laboratory.

‡Associate professor of pediatrics, Harvard Medical School; director of the Blood Grouping Laboratory.

§Formerly house officer in obstetrics, Boston Lying-in Hospital and associate of the Blood Grouping Laboratory.

Academic Rule because you are inferior to us, but as you want to learn something, we will have a small center connected with our University, an "Annex" and the professors, who choose to do so, are allowed to teach you in certain departments. But in this Department of Medicine in certain courses of which woman is fitter than man to practise the art—we will never teach you.

Thank Heaven! other Universities in this country and in Europe have higher ideals in regard to women.

I regret that I cannot help you, but if you think (of) any further counsel I can give you I hope you will write again.

Respectfully yours,
Henry I Bowditch

Boston University took me in, from which I graduated in the Class of 1893. I interned at what is now Massachusetts Memorial Hospitals from January 1894 to 1895, then went abroad and spent a year studying at Vienna and other medical centers. I practiced in Lynn for fifty years, retiring four years ago.

EDITH C VARNEY, M.D.
Newfields, New Hampshire

ORGANIZED HELPMATES

To the Editor: A well known physician telephoned me recently to solicit aid from the Woman's Auxiliary to the Massachusetts Medical Society in a particular matter. As a result of the conversation I was sure that this doctor had no idea who made up the membership of the Auxiliary, and what its objectives are.

Perhaps other *Journal* readers are unaware that there has been a national organization of doctors' wives since 1922, and that this society grew from a small reception to physicians' wives at the home of Dr. McReynolds of Dallas, Texas. In 1917 while Mrs. McReynolds was greeting a guest she asked her how she liked Dallas. The guest replied "I like Dallas very much. I have lived here for thirty years."

The wife or widow of any fellow in good standing in the Massachusetts Medical Society, who is not herself a physician and a fellow, is eligible for membership in her own district. We have a comprehensive twenty-point program and hope, with the help of our medical advisers, to have the whole state fully organized by 1950. Massachusetts has been far behind the other states in forming an auxiliary, but in our first year, under the leadership of Mrs. Leighton Johnson, we acquired a thousand members.

My message to the fellows of the Massachusetts Medical Society is "Doctor, does your wife belong?"

ELIZABETH C AYERS, President
Woman's Auxiliary to the
Massachusetts Medical Society

Worcester, Massachusetts

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

The 1948 Year Book of Endocrinology, Metabolism and Nutrition Endocrinology Edited by Willard O Thompson, M.D., clinical professor of medicine, University of Illinois College of Medicine, attending physician (senior staff), Henrotin Hospital, and attending physician, Grant Hospital of Chicago. *Metabolism and Nutrition* Edited by Tom D Spies, M.D., chairman, Department of Nutrition and Metabolism, Northwestern University School of Medicine, and director, Nutrition Clinic, Hillman Hospital, Birmingham, Alabama. 16°, cloth, 544 pp., with 87 illustrations. Chicago Year Book Publishers, Incorporated, 1949. \$4.50.

Contribución de la vitamina K a la terapéutica de la alergia By Dr. E. F. Llovet. 12°, paper, 85 pp. Montevideo Editorial "Montevideo," 1949.

Haematologica Archivio Vol 32, 1948. 8°, paper, 508 pp. Pavia Tip "La Bodoniana," 1948.

NOTICES

ANNOUNCEMENTS

Dr. Robert H. McCarter announces the opening of an office at 65 Bay State Road, Boston, for the practice of psychiatry.

Dr. Irving H. Steinberg announces the opening of his office for the practice of internal medicine at 146 Chestnut Street, Springfield.

NEW ENGLAND CONFERENCES ON ALLERGY AND RELATED SUBJECTS

A number of programs on allergy and related subjects, open without charge to all interested, is planned for the coming year. These are to be presented under the auspices of the Department of Medicine of Boston University School of Medicine, Courses for Graduates, Harvard Medical School, and the Postgraduate Division, Tufts College Medical School.

The first meeting will take place on Wednesday afternoon and evening, November 30. The afternoon program, consisting of the presentation and discussion of cases with special emphasis on the use of the antihistaminic drugs, will be held in the lower Out Patient Department amphitheater of the Massachusetts General Hospital, Fruit Street, Boston, from 3:00 to 5:00 o'clock.

The evening program will take place in the Sheraton Room of the Copley Plaza Hotel, Copley Square, Boston, at 8:30 o'clock. Dr. Earl R. Loew will speak on the subject "The Role of Histamine in Anaphylaxis and Allergy in the Light of Experience with the Antihistaminic Drugs."

All members of the medical profession are cordially invited to both the afternoon and the evening meetings.

NEW ENGLAND PEDIATRIC SOCIETY

The next meeting of the New England Pediatric Society will be held in Boston on Wednesday, December 7.

The afternoon and evening meeting will be devoted to a discussion of ACTH.

A detailed program will be published at a later date.

NEW ENGLAND SOCIETY OF ANESTHESIOLOGISTS

The December and January meetings of the New England Society of Anesthesiologists will be as follows:

A regular meeting will be held in the Auditorium of Building A, Boston University School of Medicine, Boston, on Tuesday, December 13, at 8 p.m. Dr. Emanuel M. Papper, executive officer and professor, Department of Anesthesia, Columbia—Presbyterian Medical Center, New York City, will speak on the subject "Diagnostic and Therapeutic Nerve Blocks."

A regular meeting will be held in the Auditorium of Building A, Boston University School of Medicine, Boston, on Tuesday, January 10, at 8 p.m. Dr. Edward F. Bland will speak on the subject "The Appraisal and Preparation of Poor Risk Patients for Surgery."

94TH INFANTRY DIVISION LECTURES

The 94th (Bay State) Infantry Division is sponsoring a series of monthly lectures by prominent physicians in their respective specialties. The ninth lecture will be held in the auditorium of Boston University School of Medicine, 80 East Concord Street, Boston, on Thursday, December 15, at 8 p.m.

Dr. Eugene R. Sullivan will speak on the subject "Crush Syndrome and Related Conditions."

All interested physicians, whether reserve officers or not, are cordially invited to attend this carefully planned program. Reserve officers will be given one point credit if authorized by the instructor of their unit of assignment. Excellent films will be shown during this period.

(Notices concluded on page xv)

* $\chi^2 = 2.80$

Babies who received blood from female donors are compared with all the others This is probably unfair, since in cases in which blood from both male and female donors was used there was no note on the record to indicate which blood was used first and then washed out by the other blood χ^2 (4.94) for the data in Table 3 is still statistically significant,

since a figure of this value would occur less than once in 20 times by chance alone

Since, as previously reported,¹ the sex of the infant has an important effect on mortality this was next analyzed with relation to the sex of the donor whose blood was used In Table 4, the mortality in male babies receiving blood from male donors is seen to be 22.5 per cent as compared to no mortality in the female babies receiving blood from female donors With Yates's correction for small series, χ^2 for the data in Table 4 is only 2.80, which is not significant However, when this is added to the similar χ^2 for Table 5, a significant

compared with previous data¹ indicating the relatively favorable prognosis for female babies Table 6 indicates a chance tendency (not statistically significant) to select blood from female donors for transfusion of male babies in this series This may account in part for the generally more favorable outcome in male infants in our series than would have been expected on the basis of our earlier reports Also on the basis of this previous experience, we have thus selected, by chance, a group of babies with somewhat less favorable prognosis in which to use blood from female donors This increases the value of the data in Table 2

The remainder of the statistical analysis considers only the 179 babies included in Table 2, cases in which the sex of the donor could not be ascertained or in which bloods from both male and female donors were used being eliminated. The data in Table 7 and 8 demonstrate that no other factors, chance or otherwise, can be held responsible for the benefit of blood from female donors. Table 7 and 8 compare the results, based on the sex of the blood donor, with the severity of illness, the infant's red-cell count, the mother's titer, the ratio between mother's titer and baby's titer, the length of gestation, the amount of blood given, the baby's age when the transfusion was started, the age of the blood used and, finally, the chronological period.

First, the figures for severity of disease at birth (Table 7 and 8) indicate that more than chance selection was involved in the giving of blood from

sicker babies are considered, the beneficial effect of blood from female donors is still striking, χ^2 being 4.58 (Table 8). The significant selection of blood from male donors for sicker babies does not, therefore, discredit the use of the female donor.

Since the severity of erythroblastosis fetalis is not easy to judge in the newborn baby, since in our series some babies were considered "sick" because of intrauterine anoxia or atelectasis even though the red-cell count was high and since in some babies with low red-cell counts the disease was considered "mild" because of their excellent condition otherwise, it was thought desirable to analyze for other data involved in the determination of "severity of disease." Eight other tables similar to Table 7 were made, and the essential information from them is presented in Table 8, with the essential data from Table 1 and 7 included for comparison. Analysis of the red-cell count at

female donors to a larger percentage of mildly affected babies than to the sicker babies, and it is believed that there was a greater tendency to select bloods with higher packed cell volume (almost invariably from male donors) when the baby was very sick. A tabulation of donors by sex in the two blood banks from which most of the blood was obtained shows that in one bank (Boston Lying-in Hospital), where blood from female donors constitutes about 28 per cent of the total, such blood was chosen in only 22 per cent of the cases, and at the other bank (Children's Medical Center), where blood from female donors constitutes about 24 per cent of the total, it was chosen in only 21 per cent of the cases. This confirms our recollection of having chosen bloods with higher cell volume when other factors (amount and freshness) were equal. The selection of blood from male donors for "sicker" babies has statistical significance, χ^2 being 4.76, and it obviously decreases the value of the data in Table 2. However, when only the

or shortly after birth shows again a significant (χ^2 of 4.64) tendency to use blood from male donors for sicker babies. Again, however, the beneficial effect of blood from female donors is most striking in the group of babies with low red-cell counts, the χ^2 of 3.75 being on the borderline of statistical significance.

When the mother's anti-Rh titer is taken into account (Table 8) there is again a tendency (not statistically significant) to use blood from male donors for babies who would be expected to have more serious disease (born to mothers with high titers).² The ratio of mother's titer to baby's titer, which has been found to have a closer statistical relation to prognosis than the baby's titer alone,¹ was next considered. The figures show no tendency to selection of blood from male donors for babies with worse prognosis (Table 8).

There is known to be a highly significant relation between immaturity (gestation of less than thirty-eight weeks) of the baby and an unfavorable prog-

nosis in erythroblastosis fetalis.³ Table 8 shows a chance tendency (χ^2 of 3.58 not quite significant statistically) to use blood from female donors for immature babies. This partly balances the statistically unfortunate tendency to use blood from

others with siblings with erythroblastosis or with mothers given transfusions of Rh+ blood, 8 died, and of 60 with no history of erythroblastosis fetalis among siblings or transfusion of Rh+ blood in the mother, 12 died. There is thus no

†Table 1 was source of data.

‡Table 7 was source of data.

male donors in babies with unfavorable signs and symptoms at birth.

Analysis of the amount of blood given, the age of the baby when the transfusion was started and the chronologic period (Table 8) shows no tendency to use blood from male donors more frequently in the groups with higher mortality, but in each case there was a significant (by χ^2) benefit from blood from female donors in the groups with higher mortality. No significant differences in mortality dependent on the age of the bank blood could be shown (Table 8). Table 9 shows no significant relation between sex of donor and the later need for additional small transfusion in babies having an exchange transfusion, although the percentage is somewhat higher in the group of cases in which blood from female donors was used.

Table 10 gives the most important clinical and laboratory data available in babies treated by exchange transfusion of blood from female donors. In 11 cases there was a previous death from erythroblastosis fetalis, and in an additional 9 there was an erythroblastotic baby or a transfusion of Rh+ blood at some time in the mother's past history. Both these factors have been shown² to have serious implications toward the survival of later infants. The comparable figures for babies receiving blood from male donors are as follows: of 37 with siblings dying of erythroblastosis, 7 died, of 40

significant difference in the two groups with respect to the past history. The table is arranged in order of severity as judged by the red-cell count. It can be seen that, although there is a distinct tendency to milder anemia in this group as compared with the group receiving blood from male donors,

there is included a fair number of babies with marked anemia, and a few were desperately sick. Infant B41343 was very pale, edematous and limp, with grunting respirations and a tense and bulging abdomen. The hemoglobin was measured at 7.5 gm, and the red-cell count at 770,000 at birth.

Jaundice became marked in this baby, but he did "amazingly well" after transfusion. This has been considered as a case of kernicterus because the patient is stone deaf, but he seems to be alert and has no apparent motor handicap, which makes one seriously question the diagnosis of kernicterus. Infant R12348 was pallid, limp and edematous, with marked hepatosplenomegaly. The red-cell count was 1,550,000 at birth. These 2 cases can be truly classified as hydrops fetalis. Several other babies were very sick, with asphyxia or atelectasis. Considering the fact that about 50 per cent of our patients are referred because of previous trouble and that all were *selected* for exchange transfusion, this group of 42 infants probably represents a considerably more severe degree of erythroblastosis than would be found in a true cross-section of the population. Some, with high red-cell counts at birth, received exchange transfusion because of the finding of circulating antibodies in the baby's blood, and the same statement is true for a similar proportion of the group receiving blood from male donors. We no longer consider the presence of circulating antibodies a criterion for exchange transfusion, since we have found this qualitative determination to have relatively little value in prognosis. Some infants in each group had an exchange transfusion in spite of a relatively high red-cell count because of a titer of 1:64 or higher in the mother's serum, determined prior to delivery. This is a better criterion. Others received exchange transfusion because of the rapid development of jaundice, or the presence of unusual hepatosplenomegaly. A very few babies were treated with exchange transfusion solely on the basis of an unusually unfavorable past history of stillbirths or deaths from erythroblastosis.

In our previous studies the most striking sex difference was the marked relative infrequency of kernicterus in female babies. This was the observation that suggested the possible value of investigating the sex of the donor. Because Vaughan et al.⁴ had been able to demonstrate that kernicterus is an *acute* disease of the neonatal period and therefore theoretically preventable, it was hoped that the incidence of kernicterus might have been lower when blood from female donors was used for transfusion. Such a hope, however, was not borne out, according to the figures obtained from this analysis. Table 11 shows a 7.2 per cent incidence of kernicterus in the group of babies receiving blood from female donors, as compared with 8 per cent, an almost identical figure, in the group receiving blood from male donors. This is most disappointing, but is probably important evidence in the study of kernicterus. It is still more disappointing to note that all 3 babies with kernicterus who received blood from female donors survived. This does not constitute convincing statistical evidence that the survival of babies with kernicterus

is greater with the use of blood from female donors (the incidence of kernicterus is only about 7 per cent), but it is difficult to escape the conclusion that the use of such blood may save more of these badly damaged babies, whose prompt death has in the past so mercifully ended their problems in the great majority of cases.

EFFECT OF SMALL TRANSFUSIONS OF BLOOD FROM FEMALE DONORS

In an effort to ascertain the quantitative factors involved in the use of blood from female donors, an analysis was made of 200 infants with erythroblastosis fetalis who did not have an exchange transfusion but who did receive small transfusions of blood during the first day or first two or three days of life. In this preliminary survey, no beneficial effect of blood from female donors was seen for amounts up to 100 cc, so that one can say tentatively that a fair quantity of such blood must be given if its life-saving property is to be effective. This can be safely accomplished in the really sick infants only by exchange transfusion. 

DISCUSSION

It seems obvious that whatever the beneficial component of blood from female donors as far as erythroblastosis is concerned, it must be shared by virtually all young adult females, since otherwise one would not expect so striking an effect from more or less random bloods. It is true that all the donors were adult, and very few were over forty years of age (of the 42 donors, 1 was forty-two, 2 were fifty-three, and 1 was fifty-seven years of age). None were pregnant, none had recently delivered a baby, and none had ever had a baby with erythroblastosis. All were in good health so far as known.

Since it has been advised by some that the blood of the mother may be used with benefit for transfusion of the baby with erythroblastosis fetalis, particularly if one removes the antibody-containing plasma, it should be noted that in no case in our series was this performed. The time in the menstrual cycle at which the blood was taken has not been ascertained, but is a point of interest that deserves investigation, although no information of statistical value could be obtained from our material, simply because all the babies who received blood from female donors did well.

The beneficial effect of blood from female donors has been shown to result only from the use of relatively large quantities. This suggests the presence of a factor, in rather dilute form in most specimens of such blood, that might be concentrated and more active in one of the fractionation products now available for trial. Obviously, the screening of fractions that might be assumed to have no value, such as purified albumin, gamma globulin and fibrinogen, cannot be done on sick patients. The

nosis in erythroblastosis fetalis³ Table 8 shows a chance tendency (χ^2 of 3.58 not quite significant statistically) to use blood from female donors for immature babies. This partly balances the statistically unfortunate tendency to use blood from

others with siblings with erythroblastosis or with mothers given transfusions of Rh+ blood, 8 died, and of 60 with no history of erythroblastosis fetalis among siblings or transfusion of Rh+ blood in the mother, 12 died. There is thus no

Since it has been advised by some that the blood of the mother may be used with benefit for transfusion of the baby with erythroblastosis fetalis, particularly if one removes the antibody-containing plasma, it should be noted that in no case in our series was this performed. The time in the menstrual cycle at which the blood was taken has not been ascertained, but is a point of interest that deserves investigation, although no information of statistical value could be obtained from our material, simply because all the babies who received blood from female donors did well.

The beneficial effect of blood from female donors has been shown to result only from the use of relatively large quantities. This suggests the presence of a factor, in rather dilute form in most specimens of such blood, that might be concentrated and more active in one of the fractionation products now available for trial. Obviously, the screening of fractions that might be assumed to have no value, such as purified albumin, gamma globulin and fibrinogen, cannot be done on sick patients. The

more promising fractions are to be investigated as rapidly as possible. Meanwhile, it appears certain that exchange transfusion using blood from a female donor is the treatment of choice for babies with erythroblastosis fetalis. In the past two months we have deliberately given this type of blood by exchange transfusion to 13 babies with erythroblastosis fetalis. All have recovered.

Whereas all babies given blood from female donors only survived, it is equally true that all the deaths occurred in babies who received blood

potential value of a beneficial component of blood from female donors may not be limited to babies with erythroblastosis fetalis, and our preliminary study of other groups of babies requiring and receiving transfusion is promising.

SUMMARY

A study of 205 babies with erythroblastosis fetalis indicates beyond reasonable statistical doubt that exchange transfusion of blood from female donors results in a lower mortality than that from male donors. Of 137 babies receiving blood from male donors only, 27 died, a mortality of 19.7 per cent. Of 42 babies receiving blood from female donors only, none died.

The beneficial effect of a large amount of blood from female donors in babies with erythroblastosis fetalis is statistically very striking. In addition to the series of 179 cases in which no attention was paid at the time to the sex of the donor, 13 additional babies with erythroblastosis fetalis were deliberately treated with exchange transfusion using blood from female donors, with no deaths.

The quantitative aspect is briefly discussed. The beneficial component of such blood is not known, but isolated plasma fractions are being investigated. It appears that, for the present, exchange transfusion, using blood from a female donor, is the treatment of choice in babies with erythroblastosis fetalis.

We are indebted to Miss Jane Worcester, of the Department of Biostatistics, Harvard School of Public Health, for her helpful advice in the statistical analysis.

from male donors. The possibility that a harmful factor is present in some bloods from male donors should not be overlooked, but the evidence appears to favor the idea that the important factor is a protective substance in blood from female donors or the absence of such a substance in most bloods from male donors.

Finally, it appears impossible to save all live-born erythroblastotic babies by any method of treatment, since some are practically dead at delivery. It is possible that further statistical data will not substantiate the analysis here presented, though that seems highly unlikely from the evidence. At any rate, the beneficial effect of exchange transfusions using blood from female donors can be quickly ascertained from a brief study of current and past records in a number of clinics. It is hoped that such studies will be done. Obviously, the

FLEXOR TENDON GRAFTS IN THE HAND*

J EDWARD FLYNN, M D †

BOSTON

IN CIVILIAN life, acute suppurative tenosynovitis and trauma to the joint phalanges are the most common causes of loss of flexor function in the hand. Loss of flexor function means loss of the "hook and pinch" mechanism, inability to grasp and hold objects and weakness of grasp. Improper treatment of the complications of acute suppurative tenosynovitis and trauma to flexor tendons in the hands have too often resulted in amputation of the fingers. In selected cases the grafting of tendons may restore function to the involved parts if there is normal joint function, good circulation and normal sensation. The following report describes methods that have been found useful in preventing the severe disability that may result from acute suppurative tenosynovitis and traumas that involve the flexor function in the hand.

For this study 100 cases of acute suppurative tenosynovitis, treated at the Boston City Hospital,¹ were compared with 50 cases treated since the advent of antibiotics. This comparison showed that acute suppurative tenosynovitis occurred about 60 per cent as frequently since the use of antibiotics as it did previous to antibiotics. The complications of acute suppurative tenosynovitis have also decreased in incidence but are still numerous and severe. The relative incidence of some complications is presented in Table 1.

Fingers with these complications may be salvaged if there is normal joint function, good circulation and normal sensation.

Trauma is the most common cause for flexion contractures of the hand. The trauma may be operative or nonoperative. Some of the common traumatic causes for loss of flexor function of the hand are enumerated.

Infection following severance of a flexor tendon within a sheath causes proliferation and adherence of tendon ends to nearby structures. Infection in tendons outside sheaths causes a greater amount of cicatricial attachment.

When the ends of a sutured tendon are disproportionate, with one end of small diameter and another of large diameter, the free or unsutured end of the tendon will proliferate and become attached to surrounding structures. Sutured ends of the tendon may retract, and the gap becomes filled with scar tissue. Sublimis and profundus tendons, which are sutured in the same plane, will adhere to each other, cause flexion contracture

and limited motion. A sutured tendon may become adherent to overlying, underlying or surrounding scar, with resultant flexion deformity.

GENERAL PRINCIPLES FOR TENDON GRAFTING

All scar tissue must be excised. After excision of excessive scar a large defect is covered with a pedicle graft. The use of paratenon or a thin sheet of areolar tissue helps gliding of tendons.

A tendon transplanted with paratenon glides better than one grafted without this thin areolar tissue. Paratenon is abundant about the palmaris longus tendon. One should always test the presence of the palmaris longus tendon before operation. This tendon is absent in about 20 per cent of pa-

TABLE 1 Incidence of Complications of Acute Tenosynovitis

COMPLICATION	INCIDENCE BEFORE ANTIBIOTICS	INCIDENCE SINCE ANTIBIOTICS
	%	%

tients. The palmaris longus tendon is readily seen and felt with tension as in cupping the hand.

A tendon grafted proximally in the palm functions better than one grafted proximally in a finger, which is encased in a relatively tight cylinder that will not accommodate the edema at the sutured site of the tendon. There may be necrosis at the sutured site, and the suture line may become adherent to the surrounding structures if the grafted site is in the finger.

Before operation it must be determined that passive motion in all joints of the involved finger is normal and that circulation in the finger is adequate. Sensation in the involved part is of primary consideration. A patient has little tendency to use an insensitive finger that has received a tendon graft. He prefers to substitute a finger with normal sensation.

The two annular ligaments in a finger should be preserved to prevent flexion bowing. The grafted tendon is threaded beneath these pulleys. After acute suppurative tenosynovitis, the annular ligaments are often imbedded in scar tissue and may have to be excised. In such a case a pulley can be reconstructed after tendon grafting if necessary.

Secondary repair of tendons may be performed within two months of the accident. After two

*From the Department of Surgery, Tufts College Medical School.

Elizabeth's Hospital, attending surgeon, Veterans Administration Hos-
pital, West Roxbury.

months the severed tendon ends usually cannot be approximated, because the muscle has become contracted and fixed. When a tendon is lacerated, each end is usually traumatized for about 1 cm, so that some length of tendon must be sacrificed. Degeneration of disuse occurs in a tendon that has been nonfunctioning for several months and renders it unfit for repair. This reaction is found especially in the distal part of the tendon but not in the proximal part, which has become reattached and has been under intermittent tension.²

If there has been severance of the flexor profundus tendon distal to the proximal interphalangeal joint but with normal sublimis function, tendon grafting is probably not indicated. It is better to perform an arthrodesis of the distal joint in 30° flexion. However, in a patient whose occupation is highly specialized, a graft can be inserted within the finger itself.

An intact flexor sublimis of the ring finger can be cut from its distal attachment, withdrawn through a palmar incision and transferred to the little finger to replace a profundus tendon. The ring-finger sublimis can also be used to replace a flexor pollicis longus tendon in the thumb when tendon grafting is contraindicated or when the muscle of the flexor pollicis longus has been damaged.

Thatcher,³ Mayer⁴ and Ranshof⁵ have reconstructed tendon sheaths by using various material through the fingers to produce a gliding surface. However, paratenon and a moving tendon usually restore a good gliding mechanism.

The little finger is used very little in ordinary functions of the hand, and this finger is the most difficult in which to restore good function with a flexor tendon graft. Tendon grafting in the little finger should be attempted only in a patient whose occupation requires skilled use of this finger, such as a pianist or a typist.

OPERATIVE PRINCIPLES

After excision of scar tissue in the palm and finger, the flexor sublimis tendon is excised about 4 cm proximal to the excised proximal portion of the profundus tendon. The proximal stump of the sublimis may be sutured to the profundus tendon to give added power.

Tendons of small caliber are used for tendon grafting because they are readily vascularized without necrosis, are not constricted by the annular ligaments and will hypertrophy, if necessary. Free grafts swell at the sutured site during the early postoperative period, and pressure necrosis or adhesions of graft may occur if there is not ample space.² If the graft lies on exposed bone, paratenon should be interposed for gliding.

The palmaris longus is the most satisfactory tendon for grafting. This tendon may be obtained by two small transverse incisions in the forearm. However, it is more satisfactory to make a longitudinal incision in the forearm and excise the pal-

maris longus with a generous amount of paratenon to provide good mobilization.

The flexor sublimis tendon may be employed as a graft when both the sublimis and profundus tendons have been lacerated. The long extensor tendons of the second, third, fourth and fifth toes may be used, but they have a tendency to fray. The peroneus longus and plantaris tendons have occasionally been used.

Before a free graft is sutured to the flexor profundus tendon, the amplitude of excursion of the tendon should be determined by traction. It is futile to perform tendon grafting and expect a satisfactory range of flexion with a severely contracted flexor muscle.⁶

The tendon graft must be of proper length to ensure proper muscle balance and useful function. A graft is of proper length when it holds the finger in a neutral position, with flexor tension the same as in a normal finger.⁷

The tendon graft is sutured proximally to the profundus tendon, untreated No 3 silk with Bunnell technic being used. Usually, a portion of the paratenon that is adherent to the grafted palmaris longus tendon is carried over the sutured site. If the graft is sutured at the level of the lumbrical muscle in the palm, the sutured site may be covered with lumbrical muscle. The proximal suture site should never lie between the distal transverse palmar crease and the proximal interphalangeal crease.

The tendons in the affected finger are then exposed by a middle, lateral, longitudinal incision. The distal ends of the sublimis tendon are excised about 2 cm proximal to their insertions. When the sublimis tendon is excised too near its distal attachments, the proximal interphalangeal joint may hyperextend. This can be prevented by suturing of the distal stump of the sublimis tendon into the proximal phalanx, with this joint flexed at 10°.⁸

The profundus tendon is excised 1 cm proximal to its attachment in the distal phalanx. A small flap of bone is then raised with a chisel from the volar aspect and base of the distal phalanx. Two small drill holes are made in the bone defect. The drill holes emerge in the skin over the dorsum of the distal phalanx.

Catgut is never used for primary or secondary suture of tendons because of the danger of adhesions. However, adhesions are desirable when a tendon is grafted to the distal phalanx. For this reason, after the tendon graft has been threaded beneath the annular ligaments, a No 0 plain catgut is sutured to the end of the grafted tendon. The two strands of catgut then emerge from the core of the tendon. The strands of catgut are then threaded through the drill holes in the distal phalanx and tied over a button on the dorsum of the distal phalanx. The end of the grafted tendon now

fits snugly into the artificial groove in the bone. To reinforce the distal attachment of the grafted tendon, a mattress suture of No. 3 untreated silk is used to attach the distal end of the grafted tendon to the remnant of old profundus tendon. Using this procedure I have had no case in which the distal end of the grafted tendon has become detached.

POSTOPERATIVE TREATMENT

The postoperative treatment is the most important phase in tendon grafting. The hand and wrist are immobilized in a plaster cast for three weeks. The cast is then removed, and the button and remains of old catgut suture are simply wiped off the dorsum of the distal phalanx. When the cast

Motions of the metacarpophalangeal joint were normal. There was an operative scar over the lateral aspect of the finger. Sensation, circulation and passive flexion of all joints were normal.

At operation a longitudinal incision was made over the lateral aspect of the right middle finger. A transverse incision was made in the palm proximal to the distal transverse crease. Dense adhesions were found matting together all structures within the tendon sheath. The scarred tissue, which included sublimis and profundus tendons as far proximally as the distal third of the palm, both annular ligaments and most of the tendon sheath, was excised. The palmaris longus tendon was used for grafting in the manner described.

Ten weeks later, there was normal active flexion in all joints of the right middle finger (Fig. 1B) and normal extension in the two proximal joints, but a lack of the final 15° of extension in the distal interphalangeal joint (Fig. 1C). With flexion, some bowing of the grafted tendon was evident. However, with flexion there was good strength, and the tip of the middle finger touched the palm of the hand.

FIGURE 1 Flexion Deformity of the Right Middle Finger Due to Adhesions from a Previous Acute Suppurative Tenosynovitis (Case 1)

A shows deformity before operation, B normal flexion of right middle finger with tendon graft, and C slight bowing of grafted tendons caused by excision of the annular ligaments

is removed active motions are instituted, but care is taken not to hyperextend the fingers. After four weeks, moderately active, resistive exercises are begun, and in six weeks, flexion against resistance is encouraged. Each joint is considered individually in the forceful active flexion. Forceful but careful extension is performed after six weeks to prevent fixed flexion contractures. Occupational therapy is very helpful in restoring flexor function.

CASE REPORTS

CASE 1 A 24-year-old man had cut the volar aspect of the right middle finger with a piece of glass 1 year before entry. Acute suppurative tenosynovitis developed. Incision was performed, and the wound was drained for 3 weeks. For the past 9 months the patient had had a flexion deformity of the right middle finger.

Physical examination disclosed a flexion deformity of the right middle finger of 90° at the proximal interphalangeal joint and 15° at the distal interphalangeal joint (Fig. 1A).

In this case it may be that the reaction in the soft tissues caused by the previous infection, compensated in some degree for the loss of annular ligaments, since no pulley operation was performed.

CASE 2 A 26-year-old man had received a laceration of the palm of his left hand on broken glass 4 years previously. At the first operation the skin alone was sutured. One week later, when the patient was unable to flex his left index finger, the sublimis and profundus tendons were sutured in the palm. The left index finger was immobilized in extreme flexion for 3 weeks. Two weeks later a tendon-lengthening operation was unsuccessfully attempted in the wrist for correction of the flexion deformity, which persisted until the patient was admitted to the Veterans Administration Hospital in West Roxbury.

Physical examination revealed a scar extending from the volar aspect and proximal crease of the left index finger about 2.5 cm. proximally into the palm. This scar was adherent to the underlying flexor tendons. There was a flexion contracture of about 80° at each interphalangeal joint (Fig. 2A). Passive motions, circulation and sensation were normal.

At operation the scar was excised from the palm of the left hand. Adherent sublimis and profundus tendons and

the proximal annular ligament were excised in the palm. A pedicle graft was sutured to the defect in the palm of the left hand. Later, the sublimis tendon to the index finger was removed in the forearm and used for grafting because the palmaris longus tendon was absent.

After operation, flexion of the finger was greatly limited. Bowing of the grafted tendon was due to the loss of the an-

to the underlying flexor tendons of the middle and ring fingers. The left middle finger had the following ranges of motion: flexion of the metacarpophalangeal joint was possible 40° actively and 90° passively. Each interphalangeal joint could be flexed about 5° actively and 90° passively. In the left ring finger, flexion at the proximal joint was possible 40° actively and 90° passively. The middle and distal joints

FIGURE 2 Loss of Flexor Function Due to Adhesions between the Sutured Sites of the Sublimis and Profundus Tendons, with Adhesions in Overlying Soft Tissue but without Gross Infection (Case 2)

A shows contracture of left little finger after trauma, B bowing of grafted tendon, causing flexion of index finger, and C results of pulley operation, which aided flexion of index finger.

nular ligaments (Fig 2B). The bowing was corrected by construction of a proximal annular ligament with an extensor tendon from the lower extremity. On flexion, the tip of the index finger now reaches the palm of the hand (Fig 2C).

CASE 3 A 30-year-old dairyman fell on an icy sidewalk and cut the palm of his left hand on a broken milk bottle. The sublimis and profundus tendons to the left middle and

could be flexed 5° actively and 90° passively. Pressure from index and little fingers passively aided flexion of the middle and ring fingers (Fig 3).

The extensive scarring in the palm, including the profundus and sublimis tendons to the left middle and ring

FIGURE 3 Loss of Flexion of Middle and Ring Fingers Following Trauma and Sepsis before Operation (Case 3)

ring fingers were sutured within 2 hours of the accident. The palmar wound became septic and drained pus for 4 weeks.

On entry, 5 months after the accident, there were three scars on the palm of the left hand. The scars were adherent

to the underlying flexor tendons of the middle and ring fingers. A pedicle graft from the abdomen was used to cover the defect. Later, the sublimis tendon to the left middle finger was excised in the forearm and used as a graft for the flexor tendon to the middle finger. The palmaris longus tendon was grafted to the ring finger.

Ten weeks postoperatively, the patient had grasp and pinch mechanism in his left middle and ring fingers, and had resumed his regular work (Fig 4).

FIGURE 4 Postoperative Result in Case 3, Showing Range of Flexion in Middle and Ring Fingers after Tendon Grafting

CASE 4 A 21-year-old Negro received a laceration of the palm of his right hand when a jack handle broke. Three hours later the sublimis and profundus tendons to the right index finger were sutured in the palm. Eight weeks later,

the tendons and in the surrounding paratenon (Fig 6d) All scar tissue, including the matted sublimis and profundus tendons, was excised. A pedicle graft was cut from the abdomen. A split-thickness graft was cut from the thigh

FIGURE 5 Loss of Flexion of the Right Index Finger Due to Separation at the Sutured Sites of the Tendons and Retraction of the Tendons, without Gross Infection (Case 4)

physical examination showed a 6-cm. scar over the radial longitudinal crease of the palm (Fig 5). In the right index finger, motions of the proximal joint were normal. Flexion at each interphalangeal joint, however, was entirely absent

FIGURE 7 Normal Range of Flexion, Ten Weeks after Operation, in Case 4

and sutured to the donor site on the abdominal wall. The free edge of the pedicle graft was then sutured to the defect on the palm of the right hand. Three weeks later the pedicle graft was detached from the abdomen and sutured to the palm of the hand. The defect on the abdomen was closed by suture of the skin edge to the split-thickness graft. The pedicle

FIGURE 6 Operation in Case 4

A shows scoring between retracted tendons, B end of profundus and distal attachment of profundus tendon after excision (proximal annular ligament is preserved), and C suture of grafted tendon (scar in edge of graft may limit gliding of tendon)

actively but was possible 90° passively. Circulation and sensation of the right index finger were normal.

At operation the sublimis and profundus tendons were found separated at the previously sutured sites and retracted for about 1 cm. There was great scarring in the gap between

graft took well, and 3 weeks later an incision was made lateral to the pedicle graft. Through this the proximal end of the cut profundus tendon was exposed. A longitudinal incision was made over the middle of the lateral aspect of the right index finger from the base of the distal phalanx to the base

of the proximal phalanx. The sublimis and profundus tendons were excised from the index finger, 1 cm of profundus tendon being left at its attachment to the distal phalanx (Fig 6B). A longitudinal incision was then made in the forearm. The palmaris longus tendon was excised with a generous portion of paratenon on each side. The palmaris longus tendon was sutured to the proximal end of the profundus tendon with No 3 silk and Bunnell silk technic. The grafted tendon was then threaded beneath the carefully preserved proximal annular ligament into the finger. A small flap of bone was chiseled from the base of the distal phalanx. Two holes were drilled through the defect in the bone. A No 0 plain catgut suture was placed in the end of the tendon graft. The two strands of catgut were threaded through the two drill holes in the base of the distal phalanx. With traction on the sutures the distal end of the grafted tendon fitted snugly into the bone flap. The catgut sutures were then tied over a button on the dorsum of the distal phalanx. One silk mattress suture was placed, for reinforcement, in the remnant of the old profundus tendon and the end of the grafted tendon. It appeared that scar on one side of the pedicle graft might limit excursion of the grafted tendon (Fig 6C). Therefore, a block of paratenon was excised from the lower third of the lateral aspect of the thigh. A No 000 plain catgut suture was placed in each corner of the paratenon block. The paratenon was placed beneath the pedicle graft, the catgut sutures were carried through the palmar skin, and the lateral strands of the plain catgut sutures were tied in the palm. The wound was sutured with silk. The hand was immobilized in a plaster cast for 3 weeks. Silk sutures were removed in 1 week. After 3 weeks, the plain catgut sutures were wiped off the palm. Three weeks after operation the wounds were healed, and active motions were begun. Ten weeks postoperatively, there was essentially normal flexion in the index finger (Fig 7).

SUMMARY

Early recognition and early, proper treatment of acute suppurative tenosynovitis and trauma

will prevent the loss of function in the flexor tendons of the hand, but in more serious and improperly treated cases, the use of tendon grafts may restore useful function and obviate amputation.

Tendon grafting can restore function in a hand that has a loss of flexor action provided there is good circulation, normal joint function and normal sensation in the affected finger.

General considerations and operative principles for tendon grafting are presented.

Cases are reviewed in which tendon grafting restored pinch and grasp mechanism in hands with loss of flexor function after acute suppurative tenosynovitis and trauma.

A technic for tendon grafting for loss of flexor function in the hand is described.

I am indebted to Dr Thomas H Lanman for his criticisms and suggestions.

THE EFFECTS OF BIS-TRIMETHYLAMMONIUM DECANE DIODIDE AND DIBROMIDE ON NEUROMUSCULAR FUNCTION AND ON INDUCED CONVULSIONS IN MAN*

DAVID GROB, M.D.,† DUNCAN A. HOLADAY, M.D.,‡ AND A. McGEHEE HARVEY, M.D.§

BALTIMORE

BIS-TRIMETHYLAMMONIUM decane diiodide (C_{10} diiodide) has been found to be a potent agent that blocks neuromuscular transmission in animals^{1,2} and in man.^{3,4} As predicted by Paton and Zaimis,² C_{10} has proved to be a useful substitute for d-tubocurarine in the production of skeletal-muscle relaxation for certain clinical purposes. This communication describes the results of the administration of C_{10} to normal subjects and prior to electrically induced convulsions.

C_{10} is a white crystalline substance easily prepared in pure form. It is freely soluble in water and can be sterilized by heat without any deterioration. It is miscible with procaine and Pentothal and does not produce any irritation when injected into tissues.

Paton and Zaimis² observed that small doses of this material produced in a variety of animals a

profound neuromuscular block. In certain species this appeared to affect the skeletal muscles to a greater degree than the muscles concerned in respiration. The neuromuscular block was not antagonized by neostigmine, but was counteracted by bis-trimethylammonium pentane diiodide. MacIntosh⁵ found C_{10} much less potent than d-tubocurarine in causing the liberation of histamine or heparin in animals, and in producing block at autonomic ganglions. C_{10} is apparently excreted largely in the urine.

RESULTS

Effect of Graded Doses on the Pattern and Degree of Neuromuscular Block

C_{10} , as either the diiodide or the dibromide salt, was administered intravenously in graded doses on 92 separate occasions to 5 normal subjects and to 13 psychotic patients. The ages of the subjects varied from nineteen to fifty-five years (average, forty years), and the body weights from 47 to 77 kg (average, 62 kg).

§Professor of medicine, Johns Hopkins University School of Medicine, physician-in-chief, Johns Hopkins Hospital.

After the administration of 1 mg of C_{10} dibromide over a period of five seconds to two minutes there was moderate limitation of the extraocular movements, but little or no effect on the muscle strength in the extremities or trunk.

When the dose was raised to 1.5 mg and injected over a similar period almost complete limitation of extraocular movements resulted. The patients could elevate the head and move the arms and legs but could not maintain this activity against even moderate resistance. The grip strength as measured by a hand dynamometer was reduced by approximately 50 per cent. There was no subjective respiratory distress, but occasionally there was mild dysphagia.

The intravenous administration of 2.5 to 3 mg of C_{10} diiodide or of 2 to 2.75 mg of C_{10} dibromide, over a period of five seconds to two minutes, produced complete or nearly complete relaxation of the muscles of the neck, arms, legs, shoulder girdle and pelvic girdle. Within forty-five seconds of the termination of the injection there was limitation of the extraocular movements with diplopia, followed within one or two minutes by complete paralysis of the extrinsic muscles of the eyes. At this period there was slight to moderate ptosis. During the two to four minutes after the administration of the C_{10} , during which transient fasciculations were occasionally seen, there was a progressive decrease in the strength of the muscles of the extremities and trunk until the patient was unable to move the head, arms or legs. Usually, the fingers could still be flexed, but the grip strength as measured by the dynamometer was always below 2 kg. At this stage there was only slight weakness of the facial, masticatory, lingual and laryngeal muscles, and slight to moderate weakness of the pharyngeal muscles. The subjects were able to shut the eyelids tightly, wrinkle the forehead, smile and purse the lips. Mastication was unimpaired, and the tongue could be protruded with ease. The voice was usually diminished in intensity, but only slightly slurred or nasal in quality. Swallowing was almost always subjectively difficult, but could be performed with some effort. There was little accumulation of saliva in the pharynx, and no choking. In 10 of the 18 patients there was no subjective respiratory distress, and no alteration of the respiratory rate or of the thoracic excursion. Vital capacity, however, was usually reduced by as much as 25 per cent. Eight of the subjects experienced mild to moderate subjective respiratory distress, with acceleration of the respiratory rate, in 2, thoracic excursion was consistently diminished, and abdominal breathing shallow, cyanosis developed and rhythmic oxygen insufflation became necessary.

When the dose was raised to 2.8 to 4 mg thoracic respiration was uniformly diminished or even ceased. Diaphragmatic movements were lessened and ac-

celerated, and thoracic and diaphragmatic respiratory movements became dissociated. The patients complained of respiratory distress, cyanosis developed, and artificial respiration, by means of rhythmic oxygen insufflation from a breathing bag, became necessary for a period of three to five minutes. In addition to depressing respiration these doses augmented the weakness of the facial and pharyngeal muscles, provoking difficulty in swallowing saliva, and diminished the intensity of the voice, with slurring of speech.

These effects of C_{10} were reproducible in any given subject from day to day. The effective dose and the relative effects on the peripheral and respiratory muscles varied in different subjects, and these differences bore no close relation to body weight.

Duration of the Effects

The duration of the maximum degree of weakness varied with the dose of C_{10} . The weakness lasted one or two minutes after the administration of 1 to 1.5 mg, three to five minutes after 2.0 to 2.75 mg and approximately seven minutes after 2.8 to 4.0 mg. Subsequently, strength returned progressively and rapidly, becoming normal sixteen to twenty-five minutes after the largest doses. At this time repetition of the original dose produced the same pattern of weakness, with no signs of any cumulative action of the drug.

Rate of Administration

The optimal rate of intravenous administration of C_{10} was found to be 1 mg per minute. More rapid injection resulted in little if any increase in the degree of peripheral relaxation and sometimes led to an irregular distribution of the effects, as indicated by a difference in the degree of weakness in the opposite extremities and occasionally by an increase in the degree of subjective respiratory distress. With slower administration (over two or more minutes) there was a significant decrease in degree of the resultant muscle weakness.

Maintenance Dose

The degree of paralysis produced by the administration of 2.0 to 2.75 mg could be maintained at a uniform level by further injections of 0.5 mg every four or five minutes, or 1 mg every eight to ten minutes. Because of the individual variations in the response to the drug, not clearly related to differences in body weight, careful observation of the patient was necessary to prevent respiratory depression and to maintain the desired degree of muscular weakness.

Use with Convulsive Therapy

If electric-shock therapy was administered after C_{10} , at the height of the resulting paralysis, the severity of both the tonic and clonic phases of the

convulsion was lessened. The optimum time for the administration of the electric shock was three to five minutes after the injection of C_{10} . The convulsive movements were softened, and the arms and legs could be passively moved with ease at all stages. A dose of 1.5 to 1.75 mg of C_{10} dibromide injected intravenously over a period of one or two minutes usually produced a degree of muscular relaxation that reduced the severity of the convulsion by about 50 per cent. There was no evidence that the softening of the convulsions diminished their therapeutic effect in the psychotic patients observed.

Effects Other Than Those upon Neuromuscular Function

No prominent subjective or objective effects of C_{10} were observed except on neuromuscular function. Occasionally, there was transient giddiness immediately after the injection of the drug, possibly associated with paresis of the extraocular muscles. There was no alteration of the state of consciousness or awareness of the patient. No changes were recorded in pulse rate or blood pressure in either normotensive or hypertensive subjects, unless the respiratory exchange was depressed sufficiently to produce anoxia and retention of carbon dioxide. Electrocardiograms obtained in several patients before and after the administration of C_{10} showed no abnormalities. The serum concentration of sodium and potassium, measured in several patients at the height of the paralysis, were all within the normal range. As has been noted, transient muscular fasciculations, especially over the chest and abdomen, were often observed immediately after the administration of C_{10} and before any prominent degree of paralysis had developed. Cholinesterase determinations on blood samples drawn at this period showed no alteration in the activity of this enzyme in plasma or erythrocytes. The spontaneous movements were thought to be due to a direct stimulating effect of the C_{10} .

No signs suggesting the release of any histamine-like substance followed intravenous administration. As much as 3 mg of C_{10} diiodide was injected intrarterially, and, although there was complete paralysis of the local area for over an hour, no redness, swelling, wheal formation, rise of skin temperature or increase in the secretion of gastric acid was noted. This is in contrast to the effect of d-tubocurarine, which invariably provokes all the manifestations mentioned above after intra-arterial administration.⁶ The intracutaneous injection of 0.1 mg of C_{10} di-bromide produced a transient flare and slight wheal without pseudopod formation, in contrast to the marked flare, wheal and pseudopod formation resulting from the same amount of d-tubocurarine.

The absence of any alteration in skin temperature or in blood pressure in the supine or erect positions

after the administration of C_{10} suggests that this substance has no appreciable blocking action on autonomic ganglions.

COMPARISON BETWEEN C_{10} AND D-TUBOCURARINE

Each of the 13 patients who received C_{10} prior to electric-shock therapy and 1 of the normal subjects also received d-tubocurarine on one or more occasions. The dose was sufficient to produce a degree of weakness of the trunk and extremity muscles comparable to that produced by 2.0 to 2.7 mg of C_{10} dibromide. In most cases this required approximately 60 to 80 units of d-tubocurarine (9 to 12 mg of the pentahydrate) administered intravenously over a period of two minutes. All the patients had greater weakness of the facial muscles than that after the administration of C_{10} , 8 had more pronounced weakness of the muscles of mastication and a greater degree of ptosis, 10 had more difficulty in swallowing, resulting in accumulation of mucus in the pharynx, a similar number had greater reduction in the intensity of speech, which became more nasal and slurred, and 6 had more impairment of respiratory function and weakness of the tongue. Thus, compared on the basis of dosage producing similar degrees of relaxation of trunk and extremities, the effects of d-tubocurarine upon the muscles of the oropharynx in most patients and upon the muscles concerned in respiration in some patients were more pronounced than those of C_{10} . Complete or nearly complete peripheral relaxation could be obtained by means of d-tubocurarine without appreciable subjective respiratory distress or marked dysphagia in some cases, but the number was smaller than that with C_{10} . As with C_{10} , in many patients having no subjective respiratory distress, the vital capacity was, nevertheless, reduced by as much as 25 per cent.

The rapidity of development of the neuromuscular block following the administration of d-tubocurarine was similar to that after C_{10} , but the duration of the weakness following d-tubocurarine was considerably longer, the maximum paralysis lasting for approximately ten minutes, in contrast to only four minutes after C_{10} . The time required for complete return of strength was approximately forty minutes after d-tubocurarine, in contrast to about twenty minutes after C_{10} . The length of time following a full dose at which an equivalent amount could be given without the production of any cumulative effects was approximately ninety minutes after d-tubocurarine and only about twenty minutes after C_{10} .

This shorter action of C_{10} and its comparatively lesser effect on the pharyngeal and respiratory muscles make it a more satisfactory agent for the production of muscular relaxation prior to electric-shock therapy than d-tubocurarine. It also lessens the dangerous results of respiratory depression

inadvertently produced by either overdose of the drug or unusual sensitivity on the part of the patient. Finally, C₁₀ has the additional advantage that it is less active in causing the release of any histamine-like substance.

It should be emphasized that the effective dose of C₁₀ dibromide is about a fourth that of d-tubocurarine on the basis of weight and about a third on the basis of molarity. The effective dose of C₁₀ dibromide is slightly less than that of C₁₀ diiodide on the basis of weight but is the same on the molar basis, indicating that the bis-trimethylammonium decane ion is the active group.

TREATMENT OF C₁₀ OVERDOSAGE

Paton and Zaimis¹ have reported that bis-trimethylammonium pentane salts (C₅) antagonize the neuromuscular blocking action of C₁₀. The amount of C₅ that can safely be injected (10 to 35 mg intravenously) is limited because of its potent action in blocking autonomic ganglions. This results in pronounced postural hypotension, which may last for several hours, and occasionally, especially in hypertensive subjects, in a striking drop in blood pressure in the supine position.

In our experience the intravenous injection of 15 mg of C₅ diiodide at the height of the muscular weakness produced by 3 mg of C₁₀ diiodide did not result in a more rapid return of strength than occurred spontaneously. However, the production of a high local concentration of C₅ by the intra-arterial administration of 5 mg at such a time did result in a slightly more rapid return of strength in the injected extremity.

Neostigmine, which antagonizes the neuromuscular blocking action of d-tubocurarine,⁷ had no effect on the degree of muscular weakness produced by C₁₀ dibromide or on the rate of return of strength.

Before the administration of either C₁₀ or d-tubocurarine a rubber airway and an oxygen tank with mask and breathing bag with which rhythmic insufflation of oxygen can be carried out should be available in case respiratory depression should develop. When C₁₀ is administered additional precautions are not evidently necessary in view of the short action of the drug.

SUMMARY

bis-Trimethylammonium decane diiodide and dibromide (C₁₀), potent blocking agents of neuromuscular transmission, are useful in the production of muscular relaxation prior to electrically induced convulsions. The advantages of C₁₀ for this purpose are shorter duration of action and more rapid recovery of motor power, less pronounced effects on the pharyngeal, laryngeal, facial and in some cases respiratory muscles, and the absence of any histamine-like effects.

We are indebted to Drs John Whitehorn and Nicholas Balloch for permission to study cases undergoing electric shock therapy. We also wish to thank Dr W. D. M. Paton of the National Institute for Medical Research, London, for a supply of C₁₀ and C₅ diiodide, and Dr E. J. deBeer, of The Wellcome Research Laboratories, Tuckahoe, New York, for providing us with 'Sincunne' (C₁₀ dibromide) and C₅ dibromide for use in these studies.

THE USE OF BIS-TRIMETHYLAMMONIUM DECANE DIBROMIDE IN ANESTHESIA*

DUNCAN A. HOLADAY, M.D.,† A. McGEHEE HARVEY, M.D.,‡ AND DAVID GROB, M.D.§

BALTIMORE

SINCE 1942 partial curarization of patients during anesthesia has become an established procedure.^{1,2} This method, which provides satisfactory abdominal relaxation for surgical procedures and yet subjects the patient to a minimal degree of anesthesia, has obvious desirable features, but certain potential disadvantages. It has been convincingly demonstrated^{3,5} that the natural alkaloid, d-tubocurarine, may, upon parenteral injection, cause the release of a histamine-like substance, with consequent depression of blood pressure, bronchospasm and other undesirable reactions. Although these reactions are encountered infrequently during routine anesthetic procedures, they are always a possible source of difficulty in the susceptible patient.

In the event of temporary paralysis of the respiratory mechanism the trained anesthesiologist can maintain adequate ventilation by rhythmic manual compression of the rebreathing bag, but this does not precisely duplicate the results of the normal respiratory effort. d-Tubocurarine, if administered carefully, will produce profound abdominal relaxation with only moderate paralysis of the intercostal muscles and no appreciable impairment of diaphragmatic action. Transient apnea may be encountered, however, since the additional increment of drug affecting the diaphragm is a small fraction of that required for relaxation.

When Paton and Zaimis⁶ announced that bis-trimethylammonium decane diiodide (C_{10}) produced profound relaxation of extremity musculature, with little impairment of respiration, it was hoped that this favorable differential might also hold true for the abdominal muscles. With this possibility in mind, experimental and clinical studies were undertaken, and this communication is a preliminary report of the results.

The absence of any undesirable side effects of C_{10} ⁶ was first confirmed by one of us (D.A.H.) in laboratory experiments on animals anesthetized with the various general agents commonly used in our operating rooms. C_{10} was then used during the course of anesthesia in 172 patients undergoing major surgical procedures. In the large majority of cases the purpose was to obtain abdominal relaxation, but it was also employed to suppress coughing aggravated by an endotracheal tube

during light anesthesia, to relieve laryngospasm and to facilitate endotracheal intubation. An attempt was also made to quiet the respiratory effort for intrathoracic surgery by the use of C_{10} .

The surgical procedures included 158 abdominal and 3 thoracic operations, 4 craniotomies, 6 laminectomies and 1 radical dissection of the neck. It was planned to include in this series all patients to whom curare would have been administered. Exception to this rule was made in thoracic procedures for reasons discussed below. The patients ranged in age from sixteen to seventy-eight years, the average age being forty-five years, no attempt was made to select patients according to their evaluation as surgical risks.

RESULTS

The most satisfactory method for administration of C_{10} proved to be the following: 1 to 2 mg of the dibromide salt in a solution containing 1 mg per cubic centimeter were injected intravenously at a rate not exceeding 1 mg per minute, through the same tubing used for administering Pentothal or an intravenous infusion. Doses of 0.5 to 1 mg were then injected at intervals of five to ten minutes for as long as "curarization" was desired. When a period of twenty minutes or longer had elapsed since the previous dose, the initial dose could be repeated. Doses in excess of 1.5 to 2.0 mg were found likely to cause respiratory depression. The margin between the dose of C_{10} that produced adequate abdominal relaxation and that which produced some respiratory depression was usually small, and in a number of cases the amounts were identical. Injection rates more rapid than that recommended were prone to cause respiratory depression or transient apnea even when the amount injected did not exceed 1 mg.

The maximum total dose was 10 mg administered in six injections of 1 or 2 mg each over a seventy-minute period. Relaxation during this operation, a lumbar sympathectomy, was not deemed satisfactory, implying that insufficient dosage was employed. The largest single dose given was 2.5 mg (over a two-and-one-half-minute period), although 4 mg injected over a five-minute period was well tolerated.

Satisfactory abdominal relaxation followed the administration of C_{10} during 130 abdominal operations. The general anesthetic employed was Pentothal and nitrous oxide in 105 cases, ether (alone or in combination with other agents) in 18, and ethylene, cyclopropane or spinal anesthesia, supplemented by one or more of the agents men-

*From the departments of Pharmacology and Experimental Therapeutics and Medicine, Johns Hopkins University School of Medicine.

‡Professor of Medicine, Johns Hopkins University School of Medicine, physician-in-chief, Johns Hopkins Hospital.

§Instructor in Medicine, Johns Hopkins University School of Medicine.

tioned above, in the remainder. In all cases the depth of anesthesia was maintained in the upper planes of the third stage. During 18 other abdominal operations only fair relaxation was obtained with C_{10} , and in 10 others relaxation was unsatisfactory. It is believed that failure to obtain satisfactory relaxation was due to the administration of insufficient amounts of C_{10} , rather than to variations in the response of some patients to the drug. The duration of action of C_{10} is short, and unless frequent small doses are given "decurationization" occurs.

C_{10} fully controlled the cough reflex in 6 cases, it failed to do so in 1 patient in whom coughing was subsequently adequately controlled with d-tubocurarine. The drug satisfactorily facilitated endotracheal intubation under Pentothal anesthesia, and relieved laryngospasm encountered during a stormy ether induction. It did not appear to lessen the amount of Pentothal required to maintain an adequate plane of anesthesia.

Observable respiratory depression was encountered in 94 patients or 55 per cent of the series. This was usually manifested by a decrease in tidal volume and minute volume, with no change or an increase in the respiratory rate. These alterations were usually accomplished by activation of the anterior strap muscles of the neck. The type of respiratory depression produced by C_{10} seemed to differ somewhat from that produced by d-tubocurarine, which caused a quieter respiratory effort similar to that resulting from deep etherization. C_{10} , although weakening the respiratory effort, caused jerking, spasm-like contractions of the diaphragm that were annoying to the surgeon, especially during intrathoracic operations or those on the upper abdomen. Hiccups occurred during the operative period in 9 patients. The more severe depressions rarely persisted for more than six or seven minutes. Total apnea was not encountered.

The blood pressure and pulse rate did not fluctuate significantly in 148 cases after the administration of C_{10} . In 18 patients, in whom incompletely compensated respiratory depression was permitted to occur, broad alterations in cardiovascular activity did result, presumably secondary to partial asphyxia. One patient experienced a two-to-one heart block five minutes after receiving 25 mg of C_{10} . This persisted for approximately twenty minutes, during most of which there was appreciable respiratory depression. This arrhythmia reverted spontaneously and did not recur after subsequent injections of C_{10} .

Pentothal and nitrous oxide were the principal agents employed in 129 procedures, ether in 27 cases, ethylene, with or without ether, in 8, and cyclopropane, once alone and twice with Pentothal. In 5 cases spinal anesthesia was supplemented with Pentothal, nitrous oxide and C_{10} , or with ethylene and C_{10} . No obvious potentiation of the effect of C_{10} by any of these agents was observed. Dosage

and response to C_{10} were essentially similar regardless of the general anesthetic used.

No deaths occurred either in the operating room or during the immediate postoperative period. In general, the postoperative course of the patients seemed unusually benign, without adverse respiratory or cardiovascular manifestations. This is believed to be due, at least in part, to the lighter planes of anesthesia that were employed in the presence of adequate "curarization." Postoperative atelectasis or pneumonia was not observed. In 1 patient, a sixty-one-year-old woman who underwent a gastric resection for benign duodenal ulcer, moist basal rales were heard during the first twenty-four hours after operation and cleared spontaneously. Four patients died five or more days after operation. In no case was the cause of death in any way related to the anesthetic agents or technique.

DISCUSSION

The limited experience with C_{10} in anesthesia does not permit any final evaluation of its usefulness. The brief duration of its action necessitates more frequent injections than those required with d-tubocurarine. This imposes a burden on the anesthetist, as does the increased incidence of respiratory depression that results. On the other hand a standard dosage range may be used regardless of the anesthetic agent employed, since no potentiating effect is evident, as when d-tubocurarine is administered to patients under ether anesthesia. In the present studies there have been no effects of C_{10} that might be attributed to the release of any histamine-like substance.

SUMMARY

bis-Trimethylammonium decane dibromide (C_{10}) was employed as a "curarizing" agent during 172 general anesthetics. It was found to be capable of providing adequate abdominal relaxation, but was not without some interference with respiration. Its effect was of considerably briefer duration than that of d-tubocurarine. Its action was not potentiated by ether.

We are indebted to Dr. Alfred Blalock, Miss Olive Berger, R.N. and the Anesthesia Staff of the Johns Hopkins Hospital, whose co-operation made this study possible.

The bis-trimethylammonium decane dibromide (Syncurine) used in this investigation was generously provided by Dr. D. S. Searle, medical director, and Dr. E. J. deBeer, director of research, Burroughs Wellcome and Company, Tuckahoe, New York.

MEDICAL PROGRESS

MEDIASTINAL EMPHYSEMA*

MARK AISNER, M.D.,† AND JOHN E. FRANCO, M.D.‡

BOSTON, MASSACHUSETTS, AND HARTFORD, CONNECTICUT

MEDIASTINAL emphysema, its precursors and its sequelae have been known to clinicians for well over a century. Laënnec,¹ in his treatise on diseases of the chest, published in 1819, gave an amazingly accurate description of the condition under the heading of "interlobular emphysema." He was thoroughly familiar with certain phases of its pathogenesis, many of its symptoms and signs and its treatment. Similarly, Muller,² in 1888, advanced concepts concerning mediastinal emphysema, closely paralleling those of today. One of the characteristic physical signs — namely, the presence of bubbling crepitations occurring synchronously with the heart beats, and now usually referred to as Hamman's sign — was not unknown to Muller. Considerable case material was added to the literature after the influenza pandemic of 1918, and extremely detailed and accurate clinical descriptions of the development, course and sequelae of mediastinal emphysema are to be found in these writings.^{3, 4} In 1934 Hamman⁵ reported 3 cases of interstitial emphysema of the lungs, and a few years later he employed the term "spontaneous mediastinal emphysema."^{6, 7} In the many articles on this subject that followed, the use of the term "spontaneous" became widespread. Many of these subsequent reports presented cases in which factors of importance regarding the pathogenesis of mediastinal emphysema were obviously operative. Yet they were referred to as cases of spontaneous interstitial or mediastinal emphysema. The occurrence of this condition in the newborn, in asthma and during labor may be cited as examples. It is not unlikely that in all cases certain predisposing and precipitating factors exist, although in some cases these may be overlooked or may escape detection. In many patients the development of mediastinal emphysema proceeds slowly, so that the diagnosis is not made until several days have elapsed. Under such circumstances predisposing factors such as strenuous exercise and acts of straining are relegated to the background, and are not mentioned by the patient or inquired about by the physician. It appears, then, that the use of the word "spontaneous" serves no gainful purpose. On the other hand, it may deter the physician from critically

analyzing accompanying circumstances or from carefully evaluating some of the patient's activities during the few days preceding the onset of symptoms.

Laënnec, as early as 1819, was well aware of certain predisposing factors, and stated that "the most common of these is the prolonged forcible retention of the breath during powerful and long continued exertions, as in child-bed, in relieving the bowels when constipated, and particularly in raising heavy weights." He also commented that children were more subject to the disease than adults. "In them it occurs frequently during an attack of croup, or in severe catarrhs in which the bronchial obstruction is very great."¹ The accuracy of these statements is pointed out below.

The term "mediastinal emphysema" should be thought of as representing only one link in a chain of events. Its important precursor, pulmonary interstitial emphysema, and its many sequelae, such as subcutaneous emphysema, pneumothorax and pneumoperitoneum, should always be kept in mind.

Mediastinal emphysema has almost invariably been regarded as benign. However, one should not lose sight of the fact that it not infrequently endangers life. This has been stressed by the Macklins,⁸ who have employed the word "malignant" in describing these cases. The importance of the recognition of evidences of circulatory and respiratory embarrassment should be emphasized, since surgical intervention in some cases may be life saving. This is clearly brought out in Case 5 presented below and in a recent report by Karns and Daue.⁹ In each case a fatal outcome was averted by the performance of a mediastinotomy. Again, a similar procedure was not unknown to Laënnec, for he stated that "when the aerial infiltration extends to the external parts, a few pricks with the lancet at the lower part of the neck usually suffice to dissipate it."¹

SEQUENCE OF EVENTS IN THE DEVELOPMENT OF MEDIASTINAL EMPHYSEMA AND ITS SEQUELAE

A great contribution to the understanding of the pathogenesis of mediastinal emphysema has been the experimental work and clinical correlation of the Macklins.^{8, 10, 11} The primary event is rupture of the walls of the alveoli. Only alveoli whose bases rest against bronchi, bronchioles,

blood vessels, connective-tissue septums and pleura—the so-called “marginal” or “nonpartitional” alveoli—are concerned in the process “Partitional” alveoli whose bases lie against adjoining alveoli are not involved. As a result of rupture of the “marginal” alveoli air gains access to the underlying connective tissue. The transport of air thence occurs by way of the sheaths of the pulmonary blood vessels, the sheaths of the bronchi and bronchial blood vessels playing no role in this regard. By continued dissection along the pulmonary blood vessels, interstitial pulmonary emphysema supervenes, to be followed, with further dissection, by mediastinal emphysema. In some cases air may proceed subpleurally, resulting in the formation of subpleural blebs. The mediastinum may again be reached as the air progresses beneath the pleura. With the development of mediastinal pressures above that of atmosphere rupture may take place, resulting in pneumothorax. An alternative mechanism for the formation of pneumothorax is rupture of one of the subpleural blebs. The pneumothorax in most cases is on the left side. The trapped air may seek other escape channels: the subcutaneous tissues of the head, neck, chest, abdomen, back and extremities, the retroperitoneal tissues, and the peritoneal cavity. The progress of air along these channels is aided by the movements of respiration and by the building up of pressures within the tissues, which enhance routes of escape.

FACTORS INVOLVED IN RUPTURE OF THE “MARGINAL” ALVEOLI

A considerable amount of information about the mechanisms of alveolar rupture is attributable to the work of the Macklins, cited above, in which details are given. All have a single common factor—namely, a pressure gradient between alveoli and adjoining vessel sheath. Factor A of Macklin operates in cases in which the alveoli are over-expanded through overinflation of the lungs, without a concomitant widening of the lumen of the blood vessels upon which they border, thereby permitting the creation of a pressure gradient between the two, and allowing rupture. Factor B of Macklin exists when there is a reduction in the caliber of the pulmonary blood vessels without a corresponding diminution in the size of the alveoli, a similar pressure gradient being established. In certain cases a combination of these factors co-exists. However, leakage of air may fail to take place, in spite of overinflation of the lungs, if a simultaneous increase in the caliber of the blood vessels occurs. Thus, in massive collapse of the lung, the affected side receives less blood, whereas the hyperinflated uninvolved lung receives a correspondingly greater amount of blood. Alveolar rupture, as a result, does not occur. Similarly, after pneumonectomy the remaining lung that undergoes hyperinflation receives a greater volume

of blood, and the relation of alveoli to vessel sheaths remains intact.

A review of clinical cases of mediastinal emphysema demonstrates certain predisposing and precipitating factors of importance. The most significant of these is the production of local overinflation of the lung, which may result from a variety of causes. The following list is offered as a working clinical classification of the conditions under which mediastinal emphysema may be encountered.

Atelectasis with associated alveolar ectasia (compensatory hyperinflation of adjacent alveoli)

Infectious diseases (upper-respiratory-tract infections, pneumonia, tuberculosis, measles, influenza, pertussis, diphtheria, smallpox and so forth)

Inhalation of foreign bodies

Neoplasms of the lung

Atelectasis of the newborn (following the inhalation of meconium, mucus, secretions and so forth before or after birth)

Bronchial asthma

Increased intra-alveolar pressure resulting from forceful respiratory efforts against resistance

Closure of glottis (parturition, coughing, violent exercise, acts of straining)

Laryngospasm (pertussis)

Acute obstructive laryngitis (diphtheria, streptococcal infections)

Bronchial asthma

Playing of wind instruments, glass blowing and so forth

Tracheal insufflation

Intratracheal anesthesia

Resuscitation of the newborn, drownings, electrocutions and so forth by such methods as intratracheal insufflation and use of the pulmotor

Positive-pressure inhalation therapy

Combinations of these factors

It is obvious that patients are frequently seen in whom one or more factors predisposing to the development of mediastinal emphysema exist and yet rupture of alveoli does not occur. For example, one may observe cases of status asthmaticus complicated by atelectasis and patchy bronchopneumonia in which none of the symptoms or signs of mediastinal emphysema are found, although the physician has constantly been on the alert for them. Why one patient falls victim to this condition, whereas another, duplicating all existing circumstances, does not, remains unexplained, and this has raised the inevitable factor of constitutional predisposition.

SYMPTOMATOLOGY

The nature and severity of the symptoms depend in general on the degree of distention of the lung

MEDICAL PROGRESS

MEDIASTINAL EMPHYSEMA*

MARK AISNER, M.D.,† AND JOHN E. FRANCO, M.D.‡

BOSTON, MASSACHUSETTS, AND HARTFORD, CONNECTICUT

MEDIASTINAL emphysema, its precursors and its sequelae have been known to clinicians for well over a century. Laënnec,¹ in his treatise on diseases of the chest, published in 1819, gave an amazingly accurate description of the condition under the heading of "interlobular emphysema." He was thoroughly familiar with certain phases of its pathogenesis, many of its symptoms and signs and its treatment. Similarly, Muller,² in 1888, advanced concepts concerning mediastinal emphysema, closely paralleling those of today. One of the characteristic physical signs — namely, the presence of bubbling crepitations occurring synchronously with the heart beats, and now usually referred to as Hamman's sign — was not unknown to Muller. Considerable case material was added to the literature after the influenza pandemic of 1918, and extremely detailed and accurate clinical descriptions of the development, course and sequelae of mediastinal emphysema are to be found in these writings.³⁻⁵ In 1934 Hamman⁶ reported 3 cases of interstitial emphysema of the lungs, and a few years later he employed the term "spontaneous mediastinal emphysema."⁶⁻⁷ In the many articles on this subject that followed, the use of the term "spontaneous" became widespread. Many of these subsequent reports presented cases in which factors of importance regarding the pathogenesis of mediastinal emphysema were obviously operative. Yet they were referred to as cases of spontaneous interstitial or mediastinal emphysema. The occurrence of this condition in the newborn, in asthma and during labor may be cited as examples. It is not unlikely that in all cases certain predisposing and precipitating factors exist, although in some cases these may be overlooked or may escape detection. In many patients the development of mediastinal emphysema proceeds slowly, so that the diagnosis is not made until several days have elapsed. Under such circumstances predisposing factors such as strenuous exercise and acts of straining are relegated to the background, and are not mentioned by the patient or inquired about by the physician. It appears, then, that the use of the word "spontaneous" serves no gainful purpose. On the other hand, it may deter the physician from critically

analyzing accompanying circumstances or from carefully evaluating some of the patient's activities during the few days preceding the onset of symptoms.

Laënnec, as early as 1819, was well aware of certain predisposing factors, and stated that "the most common of these is the prolonged forcible retention of the breath during powerful and long continued exertions, as in child-bed, in relieving the bowels when constipated, and particularly in raising heavy weights." He also commented that children were more subject to the disease than adults. "In them it occurs frequently during an attack of croup, or in severe catarrhs in which the bronchial obstruction is very great."¹ The accuracy of these statements is pointed out below.

The term "mediastinal emphysema" should be thought of as representing only one link in a chain of events. Its important precursor, pulmonary interstitial emphysema, and its many sequelae, such as subcutaneous emphysema, pneumothorax and pneumoperitoneum, should always be kept in mind.

Mediastinal emphysema has almost invariably been regarded as benign. However, one should not lose sight of the fact that it not infrequently endangers life. This has been stressed by the Macklins,⁸ who have employed the word "malignant" in describing these cases. The importance of the recognition of evidences of circulatory and respiratory embarrassment should be emphasized, since surgical intervention in some cases may be life saving. This is clearly brought out in Case 5 presented below and in a recent report by Karns and Daue.⁹ In each case a fatal outcome was averted by the performance of a mediastinotomy. Again, a similar procedure was not unknown to Laënnec, for he stated that "when the aerial infiltration extends to the external parts, a few pricks with the lancet at the lower part of the neck usually suffice to dissipate it."

SEQUENCE OF EVENTS IN THE DEVELOPMENT OF MEDIASTINAL EMPHYSEMA AND ITS SEQUELAE

A great contribution to the understanding of the pathogenesis of mediastinal emphysema has been the experimental work and clinical correlation of the Macklins.^{8, 10, 11} The primary event is rupture of the walls of the alveoli. Only alveoli whose bases rest against bronchi, bronchioles,

†Assistant professor of medicine Tufts College Medical School junior visiting physician Boston City Hospital.

‡Formerly resident physician Boston City Hospital.

fully all cases of so-called spontaneous pneumothorax, particularly those on the left side, for evidences of mediastinal emphysema

Brief comment regarding the mode of production of tension pneumothorax is warranted, in view of the widespread impression that air becomes trapped in the pleural cavity by some valvular mechanism during the phase of inspiration. The only time that air can enter the pleural cavity against the high tension of the latter is when the pressure of the air in the affected lung is higher than that in the pleural space. This situation is encountered during such acts as coughing or straining, when the glottis is momentarily closed, as a result of which high pressures are built up within the lung. Air will thus be added to the pneumothorax only during acts of forceful expiration. This fact has frequently been confirmed by measurements of intrapulmonary and intrapleural pressures in human cases.¹⁹⁻²¹

The detection of subcutaneous emphysema needs little comment. It is a sign that is commonly overlooked. Its presence should make one suspicious immediately of the diagnosis of mediastinal emphysema. Its significance was appreciated by Laënnec, who commented that "should an external emphysema make its appearance at the same time, beginning in the neck, the diagnosis of course is rendered more certain." This finding most commonly involves the neck, the supraclavicular and infraclavicular fossae and the axillae. In some cases subcutaneous crepitation may be elicited over the back, abdomen, extremities and genitalia. An example of extensive generalized subcutaneous emphysema involving the head, neck, chest, abdomen, back, lower extremities and genitalia is presented in Case 6, described below.

In uncomplicated cases the temperature is usually normal. Occasionally, low-grade elevations are seen.

The blood pressure generally remains within normal limits, although not infrequently one observes an initial rise. In cases in which marked increases in mediastinal pressure are encountered, so that a tamponade effect exists identical to that seen in massive pericardial effusion, the blood pressure may fall. This has frequently been noted clinically, and has been reproduced experimentally. In such cases measures to overcome the increased mediastinal tension must be employed.

ELECTROCARDIOGRAPHIC CHANGES

In the majority of cases electrocardiographic changes are absent. Approximately 25 per cent of records show positive findings, but no characteristic pattern is presented. The significant abnormalities have been changes in the T waves, deviation of the ST segments from the isoelectric line, absent or greatly reduced initial deflection in the standard Lead I, decreased voltage and shifts in the electrical axis.^{7, 18, 22, 23} Pneumothorax per

se may produce similar changes.^{24, 25} Inversion of the T waves in all the conventional leads has been observed. In a recent report marked elevation of all the ST segments was noted.²⁶ In another case discussed by the same author the voltage of the QRS complex was trebled when the patient assumed the upright position. Significant alteration of voltage with change of position did not follow recovery. A third case presented a wandering auricular pacemaker, with resumption of normal sinus rhythm within five days. The electrocardiographic changes are generally transient, reversion to normal taking place in seven to fourteen days.

X-RAY FINDINGS

There seems to be little doubt that the diagnosis of mediastinal emphysema is often not suspected, and x-ray examination of the chest not made. On the other hand, the diagnosis, when suspected on clinical grounds, has not infrequently been ruled out on the basis of a single film taken in the postero-anterior projection. It should be emphasized that serial studies may be necessary, and that lateral views of the chest are essential, to demonstrate air trapped behind or in front of the heart. Air in the mediastinum is often visible as streaks of increased radiance running along the borders of the heart. The presence of air streaks along fascial planes and air pockets in subcutaneous tissue may be readily detected. Further aid, radiographically, may be furnished by the demonstration of pneumoretroperitoneum and pneumoperitoneum. As mentioned previously, x-ray examination is invaluable in disclosing a small pneumothorax not manifest clinically.

DIFFERENTIAL DIAGNOSIS

The chief difficulty in differential diagnosis arises from the similarity of the pain of mediastinal emphysema to that of primary cardiac disease, and from the presence in some cases of dyspnea, cyanosis, distention of veins and electrocardiographic changes.^{5, 22, 26, 27} The major illnesses that enter into consideration are angina pectoris, myocardial infarction, dissecting aneurysm of the aorta, pericarditis, mediastinitis and pulmonary embolism.

TREATMENT

Only symptomatic treatment is required in most cases. Because of the possibility of recurrences, bed rest should be insisted upon, even when symptoms are minimal. In the presence of markedly elevated mediastinal pressure, associated with increasing dyspnea, cyanosis and changes in blood pressure, incision above the suprasternal notch, to create a channel for the escape of air, may be life saving. In patients with tension pneumothorax decompression of the pleural space is indicated.

and mediastinum, the accessibility of escape channels and the anatomic location of the escape channels. The two important systems of the body involved are the respiratory and the circulatory. Respiration may be seriously interfered with by the splinting action of the air in the connective tissue of the lung. The lung, as a consequence of interstitial emphysema, may become extremely voluminous and rigid. The result is dyspnea, the degree of which will depend on the extent of the underlying process. Macklin refers to this as "airlock." Circulation may be hampered by means of the collapse of the pulmonary vessels, causing venous stasis and cyanosis—the "air-block" of Macklin. With increasing mediastinal pressure the function of the great veins entering the heart is impeded by compression, and the venous return not only from the lungs but also from the systemic circuit is thus impaired. Direct effect upon cardiac function is brought about by such factors as decreased venous return, tamponade identical to that seen in massive pericardial effusion and impairment of coronary blood flow.

The development of escape channels may have a markedly beneficial effect symptomatically. Subcutaneous emphysema, for example, acts to decompress the mediastinum, and dramatic amelioration of dyspnea and cyanosis may be observed under such circumstances. A reciprocal relation between mediastinal pressure and subcutaneous emphysema has been noted experimentally.¹⁴ The development of pneumothorax may similarly release increased mediastinal pressure. However, in patients in whom tension pneumothorax supervenes, augmentation of dyspnea and cyanosis occur.

The most frequently encountered symptom of mediastinal emphysema is chest pain, which, because of its various characteristics, has often been mistaken for angina pectoris or myocardial infarction. The onset of pain is sudden in most cases, although not invariably so. Its location is inconsistent, the commonest sites being precordial, substernal, the anterior portion of the chest, axillary, the posterior portion of the chest and midscapular. Radiation to the neck, left shoulder, left arm or back may occur. The intensity of the pain varies from case to case, being a mild form of discomfort in some and actually agonizing in others. It has been referred to as sharp, stabbing, knife-like or squeezing. It may be intensified in left lateral recumbency, and alleviated when the patient assumes the upright position. Just as in dyspnea and cyanosis, the establishment of escape channels may produce relief of pain. The duration of this symptom varies from momentary discomfort to pain lasting hours or days. Its disappearance is generally gradual.

In certain cases patients have been aware of the sensation of air within the chest, and some

have been able to hear it. Laënnec stated that "patients are sometimes sensible of a kind of crackling in the part affected."

Various other symptoms have been associated with mediastinal emphysema, among them anxiety, sweating, palpitation, epistaxis, dysphagia and pain on motion of the neck. When air has dissected retroperitoneally and into the subcutaneous tissues of the back, the patient may complain of back pain. Similarly, the presence of pneumoperitoneum may be associated with abdominal pain, and on occasions a surgical condition of the abdomen has been simulated.

PHYSICAL SIGNS

There are four signs of diagnostic importance in mediastinal emphysema. These are mediastinal crepitation, decrease or obliteration of cardiac dullness, subcutaneous emphysema and pneumothorax.

The presence of air in and about the mediastinal tissues produces sounds that have been variously described as crackling, clicking, bubbling, crunching, grinding, rasping, snapping, simulating the rattle of dried peas on a taut canvas, the crinkling of cellophane, the sounds of footsteps in packed snow on a dry, brisk day, the squeaking of a leather saddle, the cooing of doves and the rubbing together of distended balloons.¹⁵ Laënnec refers to this as "the dry crepitous rhonchus with large bubbles." Apart from these purely subjective characterizations, the sound produced by the bubbles of air has certain objective features. It is generally most easily detected in the left lateral recumbent position and during the expiratory phase of respiration. It is less readily audible when the patient is upright. The sound accompanies both systole and diastole, but may be louder during systole. Its relation to the cardiac cycle has been demonstrated phonocardiographically.^{15 16} The presence and the intensity of the sound are variable. When faint it may be mistaken for a pericardial friction rub. The duration of this finding varies from hours to several weeks, the average being about one week.

Diminished cardiac dullness, or hyperresonance over the sternum and precordium, is best elicited with the patient recumbent. In the upright position, and particularly when the patient leans forward, this sign may disappear. In many cases the maneuver of alternate percussion in the recumbent and forward positions may be of decided help diagnostically.

Of interest regarding the presence of pneumothorax is the fact that it is most often on the left side. Few instances of right-sided pneumothorax have been recorded.^{17 18} No adequate explanation for this has ever been offered. It should be borne in mind that in many cases the pneumothorax may be very small and may escape detection on physical examination. Conversely, one should study care-

fully all cases of so-called spontaneous pneumothorax, particularly those on the left side, for evidences of mediastinal emphysema

Brief comment regarding the mode of production of tension pneumothorax is warranted, in view of the widespread impression that air becomes trapped in the pleural cavity by some valvular mechanism during the phase of inspiration. The only time that air can enter the pleural cavity against the high tension of the latter is when the pressure of the air in the affected lung is higher than that in the pleural space. This situation is encountered during such acts as coughing or straining, when the glottis is momentarily closed, as a result of which high pressures are built up within the lung. Air will thus be added to the pneumothorax only during acts of forceful expiration. This fact has frequently been confirmed by measurements of intrapulmonary and intrapleural pressures in human cases.¹⁹⁻²¹

The detection of subcutaneous emphysema needs little comment. It is a sign that is commonly overlooked. Its presence should make one suspicious immediately of the diagnosis of mediastinal emphysema. Its significance was appreciated by Laënnec, who commented that "should an external emphysema make its appearance at the same time, beginning in the neck, the diagnosis of course is rendered more certain." This finding most commonly involves the neck, the supraclavicular and infraclavicular fossae and the axillas. In some cases subcutaneous crepitation may be elicited over the back, abdomen, extremities and genitalia. An example of extensive generalized subcutaneous emphysema involving the head, neck, chest, abdomen, back, lower extremities and genitalia is presented in Case 6, described below.

In uncomplicated cases the temperature is usually normal. Occasionally, low-grade elevations are seen.

The blood pressure generally remains within normal limits, although not infrequently one observes an initial rise. In cases in which marked increases in mediastinal pressure are encountered, so that a tamponade effect exists identical to that seen in massive pericardial effusion, the blood pressure may fall. This has frequently been noted clinically, and has been reproduced experimentally. In such cases measures to overcome the increased mediastinal tension must be employed.

ELECTROCARDIOGRAPHIC CHANGES

In the majority of cases electrocardiographic changes are absent. Approximately 25 per cent of records show positive findings, but no characteristic pattern is presented. The significant abnormalities have been changes in the T waves, deviation of the ST segments from the isoelectric line, absent or greatly reduced initial deflection in the standard Lead I, decreased voltage and shifts in the electrical axis.^{7, 15, 22, 23} Pneumothorax per

se may produce similar changes.^{24, 25} Inversion of the T waves in all the conventional leads has been observed. In a recent report marked elevation of all the ST segments was noted.²⁶ In another case discussed by the same author the voltage of the QRS complex was trebled when the patient assumed the upright position. Significant alteration of voltage with change of position did not follow recovery. A third case presented a wandering auricular pacemaker, with resumption of normal sinus rhythm within five days. The electrocardiographic changes are generally transient, reversion to normal taking place in seven to fourteen days.

X-RAY FINDINGS

There seems to be little doubt that the diagnosis of mediastinal emphysema is often not suspected, and x-ray examination of the chest not made. On the other hand, the diagnosis, when suspected on clinical grounds, has not infrequently been ruled out on the basis of a single film taken in the postero-anterior projection. It should be emphasized that serial studies may be necessary, and that lateral views of the chest are essential, to demonstrate air trapped behind or in front of the heart. Air in the mediastinum is often visible as streaks of increased radiance running along the borders of the heart. The presence of air streaks along fascial planes and air pockets in subcutaneous tissue may be readily detected. Further aid, radiographically, may be furnished by the demonstration of pneumoretroperitoneum and pneumoperitoneum. As mentioned previously, x-ray examination is invaluable in disclosing a small pneumothorax not manifest clinically.

DIFFERENTIAL DIAGNOSIS

The chief difficulty in differential diagnosis arises from the similarity of the pain of mediastinal emphysema to that of primary cardiac disease, and from the presence in some cases of dyspnea, cyanosis, distention of veins and electrocardiographic changes.^{5, 22, 26, 27} The major illnesses that enter into consideration are angina pectoris, myocardial infarction, dissecting aneurysm of the aorta, pericarditis, mediastinitis and pulmonary embolism.

TREATMENT

Only symptomatic treatment is required in most cases. Because of the possibility of recurrences, bed rest should be insisted upon, even when symptoms are minimal. In the presence of markedly elevated mediastinal pressure, associated with increasing dyspnea, cyanosis and changes in blood pressure, incision above the suprasternal notch, to create a channel for the escape of air, may be life saving. In patients with tension pneumothorax decompression of the pleural space is indicated.

Throughout this discussion consideration of mediastinal emphysema secondary to fractured ribs, blast injuries, other forms of trauma to the chest, caisson disease, rupture of the esophagus and so forth has deliberately been omitted. In such cases, factors other than those stressed here may be operative, some of which, on the basis of present knowledge, are not entirely clear.

CASE REPORTS

CASE 1 D C, an 18-year-old college student and athlete was admitted to the Boston City Hospital on July 11, 1940, complaining of pain in the chest of 1/2 hour's duration. He had been well until 1 week prior to admission, when a "cold" characterized by nasal congestion and cough productive of whitish sputum developed. Half an hour before entry to the hospital, while walking along the street, he suddenly experienced a sharp, stabbing, knife-like pain over the precordium, radiating to the left upper quadrant of the abdomen, the left shoulder and down the inner aspect of the left arm as far as the elbow. The pain became progressively more severe, was accentuated by respiration, was not relieved by rest and was associated with what the patient termed "a scraping noise in the chest."

Physical examination revealed diminished tactile and vocal fremitus over the upper half of the left side of the chest, posteriorly, and distant heart sounds.

The temperature was 99°F, the pulse 84, and the respirations 22. The blood pressure was 130/92.

On the following day a house officer reported the presence of a "variable friction rub" heard best just to the right of the xiphoid, accentuated on inspiration and absent in the sitting position. The white-cell count and sedimentation rate and an electrocardiogram were within normal limits. X-ray examination of the chest was reported as negative. On the 6th hospital day mediastinal crepitation was still audible at the lower end of the sternum. The patient was discharged on this day, against advice.

Two days after discharge from the hospital he was readmitted because of recurrence of chest pain similar to that experienced initially. Examination at this time revealed increased resonance over the left side of the chest, anteriorly and posteriorly, associated with decreased tactile fremitus and breath sounds. Mediastinal crepitation was readily audible to the left of the sternum, and extended to the fifth intercostal space. The blood pressure was 100/70. A repeat electrocardiogram and roentgenogram of the chest were normal. On the 5th hospital day mediastinal crepitation was no longer heard. The patient was discharged on the 10th day, asymptomatic, and showing no abnormalities physically.

CASE 2 A 15-year-old schoolboy was admitted to the Boston City Hospital on August 12, 1940, because of a paroxysm of bronchial asthma. He had been subject to asthmatic attacks since the age of five years, usually more severe during the summer months, when he also suffered from hay fever. The present paroxysm had begun on the evening prior to the day of admission.

Physical examination revealed moderate respiratory difficulty, congested nasal passages, diffuse rhonchi throughout both sides of the chest and slight cyanosis of the nail beds and lips.

The blood pressure was 125/100, the temperature 99.8°F, the pulse 99, and the respirations 24.

On the following day subcutaneous emphysema involving the anterior aspect of the neck and both supraclavicular fossae was detected physically, and a crackling sound synchronous with the heart beat was heard along the left border of the sternum. An x-ray film of the chest revealed air in the subcutaneous tissues, but no air was demonstrated in the mediastinum. Only the posteroanterior projection was taken. The above findings gradually disappeared, and the patient was discharged on the 10th hospital day.

CASE 3 N T, a 17-year-old schoolgirl, was admitted to the Boston City Hospital on September 21, 1942, because of severe frontal headache and pain over the anterior aspect

of the chest and neck of 24 hours' duration. She was known to have had asthma since early childhood. On the evening before admission she had been awakened from sleep by a paroxysm of difficulty in breathing, which had become progressively severe to the time of entry. Six hours later the dyspnea had become intense and was associated with cyanosis. It was noted that the patient's neck had become swollen, and she complained at this time of moderately severe substernal and precordial pain, radiating to the left shoulder.

On physical examination the patient was found to be dyspneic and slightly cyanosed. She complained of pain on motion of the neck. Subcutaneous crepitation was elicited on the right side of the neck and over the suprasternal notch. These areas were tender on pressure. Coarse rhonchi were audible throughout both lungs. Breath sounds, tactile fremitus and vocal fremitus were diminished anteriorly over the left upper lobe. A "crepitant sound synchronous with the heart beat" was heard in the region of the apex. This sound was reported as being of variable intensity and inconstant.

The temperature was 98.6°F, the pulse 90, and the respirations 24.

X-ray study of the chest showed moderate bilateral emphysema and a small pneumothorax involving the left upper lobe.

On symptomatic treatment the findings described above rapidly returned to normal, and the patient was discharged feeling well on the 8th hospital day.

CASE 4 C C, an 18-year-old girl who had had paroxysms of bronchial asthma since childhood, was admitted to the Boston City Hospital on November 13, 1946. Her present illness had begun at 4 a.m. on the day of admission, when she was suddenly awakened by a "tight feeling" beneath the sternum, associated with respiratory distress and wheezing. Shortly after the onset of these symptoms she experienced a "sharp, tearing pain," substernal in location, with radiation upward to the neck. This was accompanied by a sensation of choking. Self-administration of epinephrine and intravenous injection of aminophylline given later by her personal physician afforded no relief. Dyspnea became progressively worse, and she was hospitalized.

On entry the patient was in moderate respiratory distress. Subcutaneous crepitation was felt over the neck anteriorly, in both supraclavicular fossae and in the left infraclavicular fossa. The right side of the chest was more resonant than the left, approaching hyperresonance posteriorly. Expiratory wheezes were audible throughout both lung areas. There were impaired resonance and diminished breath sounds at the left base posteriorly. Mediastinal crepitation was not heard.

The temperature was 101°F, the pulse 104, and the respirations 24. The blood pressure was 110/70.

X-ray examination of the chest on the day after admission showed displacement of the heart and trachea to the left, elevation of the left leaf of the diaphragm, diffuse density involving the lower half of the left-lung field, extensive subcutaneous emphysema of the neck and shoulders and the presence of air along the left border of the heart.

The patient was treated with sedatives, ephedrine sulfate, intravenous injection of aminophylline and intramuscular administration of penicillin. Symptoms gradually subsided, and the temperature remained normal from the 6th day on. On the 10th hospital day x-ray examination of the chest was reported as within normal limits. The patient was discharged completely asymptomatic on the 14th day.

CASE 5 I B, a 19-year-old girl, was admitted to the Boston City Hospital on March 26, 1943, because of severe substernal pain, cough and dyspnea of 8 hours' duration. Three days before entry coryza characterized by nasal congestion and discharge developed. On the day prior to admission she engaged in sports, and that evening she danced for several hours. She retired at an early hour, and, except for a "head cold" and fatigue, felt fairly well. Fifteen minutes after being in bed she became nauseated, and vomited several times. This was soon followed by a paroxysm of coughing, during which she experienced severe, knife-like pain beneath the xiphoid, radiating through to the back. At the same time she became markedly dyspneic and orthopneic. The pain

*Previously reported by VanderLaan and Marsh.¹

grew progressively worse, and was intensified by inspiration and coughing.

Physical examination revealed marked respiratory distress. There was extensive subcutaneous emphysema involving the neck, face, occiput, supraclavicular and infraclavicular fossae, both breasts and the upper portion of the back. The precordium was hyperresonant to percussion, and the cardiac borders were not made out. Breath sounds were diminished bilaterally. The heart sounds were distant. Mediastinal crepitation was not elicited. The epigastrium was tender on pressure.

The temperature was 100.2°F, the pulse 108, and the respirations 30. The blood pressure was 130/95.

X-ray study of the chest at the time of admission showed only extensive subcutaneous emphysema. An electrocardiogram taken 2 days after entry was interpreted as within normal limits.

On the 2nd hospital day "muffled crackling sounds" synchronous with the heart beat were audible along the left sternal border, but these disappeared on the same day. With symptomatic therapy, including the use of oxygen, there was steady improvement in her condition.

On the 4th hospital day the patient suddenly took a turn for the worse. Severe dyspnea and cyanosis rapidly developed, and pain beneath the xiphoid was intense, 0.03 gm (1/2 gr) of codeine sulfate, 0.2 gm (3 gr) of phenobarbital, and 100 mg (1/6 gr) of morphine sulfate, given within a period of 1/2 hour, failed to relieve the pain. Oxygen administered by Boothby mask was without effect. The respirations rose to 40, and the pulse to 140. The blood pressure was 160/120. Subcutaneous emphysema recurred, was more extensive than previously and involved the face, head, neck and chest. The respirations continued to rise, and were shallow.

X-ray examination of the chest, done at the bedside, demonstrated the presence of air along the left border of the heart. An electrocardiogram at this time revealed diphasic T waves in Lead 2 and 3, with depression of the ST segments.

Because of the marked respiratory embarrassment, a thoracic surgeon was consulted, and the patient was transferred to the operating room, where a low-collar thyroid incision was performed under local anesthesia. This resulted in a dramatic and almost instantaneous relief of symptoms. When the patient was returned to the ward she was breathing normally, her color was markedly improved and her chest pain had gone. Her convalescence from then on was uneventful, and she was discharged well on the 13th hospital day.

CASE 6 W. S., a 78-year-old man, was admitted to the Boston City Hospital on May 22, 1947. For the past 30 years he had had repeated episodes of cough, expectoration and dyspnea, particularly during the winter months. He had worked as a laborer up until 20 years previously, when he had been forced to give up his job because of shortness of breath. During the 4 months prior to admission there had been a marked increase in the severity of dyspnea on exertion, and the cough had become more persistent. Because of the progression of these symptoms, he was referred to the hospital by his physician.

On entry the patient was dyspneic and the rate of respiration was 40 per minute. Expansion of the chest was limited but equal. There was hyperresonance to percussion bilaterally. The breath sounds were diminished, and rhonchi were audible throughout both lungs. Moist rales were heard at the right base. No cardiac enlargement was made out. The heart sounds were distant and regular. The blood pressure was 140/80. The fingers were clubbed.

X-ray examination of the chest on the day after admission showed a partial pneumothorax at the left base, with an estimated 30 per cent collapse of the left lower lobe. Five days later the lung fields were reported as being emphysematous; no evidence of the previous pneumothorax having been demonstrated.

During this interval treatment had consisted of supportive measures, intramuscular administration of penicillin and oxygen. The patient had shown definite improvement in the dyspnea and cough.

On the 10th hospital day he suddenly became markedly dyspneic, and physical examination disclosed evidence of a tension pneumothorax on the left. Thoracentesis was immediately performed and 1000 cc of air was removed from the left pleural cavity. The needle was fixed to the chest

wall, and connected to a rubber tube the other end of which was immersed in water. On the following day, because of mechanical difficulties with the apparatus, the needle was replaced by an intercostal catheter inserted into the seventh interspace. During these 2 days progressive and extensive subcutaneous emphysema was observed, involving the neck, face, chest, abdominal wall, thighs, legs and genitalia. Considerable air was removed by means of mechanical suction through a 16-gauge needle placed in the subcutaneous tissue of the left anterior side of the chest. In spite of these attempts at decompression, the patient died on the 13th hospital day, 4 days after the onset of the tension pneumothorax.

At autopsy, performed 7 hours after death, there was extensive subcutaneous emphysema of the entire body. The serotum was distended by air, which could be forced into the lower abdominal wall by compression. Numerous blebs of varying size were present in the retroperitoneal tissues, especially about the descending colon. The left pleural cavity contained air and 200 cc of pink fluid. The mediastinum showed numerous large and small air-filled blebs. The right auricle and ventricle were dilated. The right lung was edematous and its surface presented many subpleural blebs containing air. The left lung was collapsed, and several large subpleural blebs covered the surface of the upper lobe. The pathological diagnoses were hydropneumothorax, left, bronchiectasis, atelectasis and pneumonia, left lower lobe, emphysematous blebs, right and left lungs, pulmonary edema, mediastinal and subcutaneous emphysema, marked, and acute cor pulmonale.

CASE 7 D., a baby boy, was delivered by cesarean section at the Boston City Hospital at 10 15 a.m. on July 27, 1941. At birth the baby appeared normal, and exhibited no respiratory difficulty. During the evening of this day it was observed that his respirations were labored, and that he was cyanosed. Several attempts were made to aspirate mucus from the upper respiratory passages and trachea. Oxygen and carbon dioxide were administered by mask. Despite these measures, the infant died at 9 45 o'clock on the following morning.

At autopsy, performed 24 hours after death, upon removal of the sternal plate a large air-filled sac was encountered in the anterosuperior mediastinum, not communicating with the pericardium, and lying posterior to the thymus. This air sac measured 5 by 7 cm. Many smaller bullae averaging 1.5 by 2.0 cm. were found inferior to the sac and between the sternum and the pericardial cavity. Both lungs were atelectatic. Along the anteromedial aspect of the left lung were three small subpleural blebs. Air was found beneath the reflection of the pleura and the hilus of the left lung, communicating with the large air sac described above. Section through the hilar region of the left lung revealed "evidence of separation of the parenchyma from the vessels and bronchi by spaces which appeared to have contained air." The pathological diagnoses were atelectasis of the right and left lungs, interstitial emphysema of the lungs, and mediastinal emphysema.

CASE 8 A. B., a 26-year-old housewife, was admitted to the Boston City Hospital on November 20, 1947, because of pain in the chest and back of 4 days' duration. The pain had occurred suddenly, after the patient had bent over to pick up something and was described as severe, sharp and substernal, with radiation through to the back. It had persisted to the time of entry. No intensification was noted with respiration, but the pain was definitely worse in the left lateral recumbent position. Dyspnea had been present since the onset of the illness and was also aggravated when the patient lay on her left side.

During the three months prior to admission, the patient had lost 24 pounds in weight. For 1 month she had been bothered by a productive cough having raised about 4 tablespoonfuls of green never bloody sputum daily. Associated with her present illness were severe night sweats, never previously experienced.

On physical examination the patient appeared acutely ill, flushed and in marked respiratory distress. There was definite evidence of recent weight loss. Subcutaneous crepitation was elicited about the base of the neck and in the supraclavicular fossae. The trachea was deviated to the right. The left side of the chest was hyperresonant to percussion and the breath sounds were diminished to absent. Broncho-

vesicular breathing and fine moist rales were heard over the right upper lobe.

The temperature was 103.8°F, the pulse 140, and the respirations 38. The blood pressure was 118/80.

X-ray study of the chest after admission revealed an extensive pneumothorax on the left and soft, mottled, tuberculous infiltration involving the right upper lobe. Air was demonstrated beneath the left leaf of the diaphragm.

The sputum was positive for tubercle bacilli.

The patient was seen on the day of entry by the thoracic surgeon, who treated the tension pneumothorax at first by repeated aspiration and then by the insertion of an indwelling needle connected to a water seal. The dyspnea was markedly improved, and the chest pain gradually subsided. Throughout the hospital stay, the temperature remained elevated, varying from 99 to 102°F. A left pleural effusion developed, which on tapping yielded 800 cc of straw-colored fluid. On December 16 the patient was transferred to the Boston Sanatorium for treatment of the pulmonary tuberculosis.

CASE 9 H. D., an 18-year-old schoolgirl, was admitted to the Boston City Hospital on July 2, 1935. Five days prior to entry she had suddenly been seized by severe, sharp pain in the left side of the chest while at the dinner table. The pain was intensified by respiration, and was accompanied by dyspnea. She was under the care of her family physician, who finally referred her to the hospital, because of progression of her symptoms and difficulty in obtaining her pulse and blood pressure.

On entry she appeared critically ill, was in great respiratory distress and presented signs typical of tension pneumothorax on the left side, 1500 cc of air was removed immediately by aspiration, resulting in definite relief of her symptoms. On the following day there was evidence of left pleural effusion, but no tap was performed because of the marked improvement in the patient's condition. On July 21, however, 300 cc of straw-colored fluid was removed from the left side of the chest, and on July 31, 300 cc of bloody fluid was aspirated. A low-grade fever (maximum temperature of 100°F) persisted for several weeks, but gradually subsided with the resorption of the chest fluid.

The temperature was 97.8°F, the pulse 122, and the respirations 44. The blood pressure was 70/46.

X-ray studies confirmed the findings of pneumothorax and hydropneumothorax.

Guinea-pig inoculations performed on two occasions with the pleural fluid were negative for tuberculosis.

The patient was discharged on October 4, asymptomatic, and showing only the evidences of thickened pleura by x-ray study. The diagnosis was spontaneous pneumothorax with complicating hydrothorax and hemopneumothorax.

On February 26, 1938, approximately 2 1/2 years later, she was readmitted to the Boston City Hospital. She had been perfectly well in the interim, until the day prior to entry, when she noted the sudden onset of pain in the region of the left shoulder, radiating downward over the left posterior portion of the chest and axilla. The pain had occurred while she was walking down the street. Deep breathing and coughing aggravated the pain.

On physical examination the patient did not appear acutely ill or distressed. The lungs were essentially normal. The area over the sternum was hyperresonant to percussion, and cardiac dullness was obliterated. With the patient leaning forward the hyperresonance over the sternum was lost. Just to the left of the lower end of the sternum definite mediastinal crepitation was audible. This finding was confirmed by several observers. No subcutaneous emphysema was demonstrable.

X-ray examination of the chest on the following day revealed clear lung fields.

The course in the hospital was perfectly benign, and the patient was discharged on March 4, with a diagnosis of mediastinal emphysema.

A note received by the hospital from this patient in April, 1947, disclosed that she was in excellent physical condition, and that she had had no further recurrences of her former difficulties.

SUMMARY

A review of the pathogenesis and predisposing factors in the development of mediastinal emphy-

sema is presented, along with the signs and symptoms characteristic of the condition.

In view of the many factors, often overlooked, that lead to the development of mediastinal emphysema, it seems advisable to drop the term "spontaneous" in such cases.

Although the majority of cases pursue a benign course, one should always be watchful for signs of severe mediastinal compression, which may require mediastinotomy as a life-saving measure.

The common complication of tension pneumothorax requires measures to decompress the pleural cavity.

The possibility that many cases of so-called "spontaneous" pneumothorax, especially when left-sided, actually represent a phase of mediastinal emphysema, is pointed out.

Nine cases illustrative of various aspects of mediastinal emphysema are presented.

NEW HAMPSHIRE MEDICAL SOCIETY

PROCEEDINGS OF THE ONE HUNDRED AND FIFTY-EIGHTH ANNIVERSARY (Continued)

House of Delegates, June 13, 14 and 15, 1949

Dr Sycamore moved that each county medical society be requested to take action similar to the action taken by the Cheshire County Medical Society, to appoint a committee of the staff to review the Blue Cross and Blue Shield admissions, and, secondly, that each hospital staff be urged to co-operate fully with Blue Shield, by appointing an active review committee, and that each county committee of the educational campaign be instructed to communicate with each hospital in the county to secure co-operation in this program

The motion was duly seconded

The Speaker then asked for a vote on the motion, which was carried

The Speaker asked for a vote on the second part of the motion — that each hospital staff be asked to co-operate fully with Blue Cross by appointing an active review committee. The motion was carried. The next part of the motion, that each county committee of the educational campaign be instructed to communicate with each hospital in the county for their co-operation in the program, was then put to vote and carried

Speaker Dube observed that the Committee on Medical Economics should bring up the question of electing or re-electing the officers for the Blue Shield

Dr Sycamore stated that it was the duty of the House of Delegates to approve the Board of Directors for the Blue Shield. He moved that the following officers of Blue Shield be approved: Leslie K. Sycamore, of Hanover, president, Hiram E. Upton, of Burlington, Vermont, vice-president, Charles R. Eastman, of Kensington, vice-president, Ray W. Pert, of Concord, treasurer, and Frank J. Sulloway, of Concord, clerk. The directors included the following: F. Ray Adams, of Springfield, Vermont, Right Reverend Monsignor J. S. Buckley, of Concord, O. E. Cain, of Keene, Laurence C. Campbell, of Barre, Vermont, Albert M. Cram, of Bridgewater, Vermont, Right Reverend Bishop John T. Dallas, of Lee, Harold Daoust, of Nashua, Francis J. C. Dube, of Center Ossipee, Fred Fernald, of Nottingham, Theodore H. Har-

wood, of Burlington, Vermont, John A. Hunter, of Dover, Elbridge E. Johnston, of St. Johnsbury, Vermont, Douglas Kitchel, of St. Johnsbury, Vermont, James M. Langley, of Concord, John Lawson, of Barre, Vermont, Roland McSweeney, of Brattleboro, Vermont, Frank A. Mahoney, of Bennington, Vermont, Carleton R. Metcalf, of Concord, S. Aldis Miller, of St. Albans, Vermont, J. J. Morin, of Rochester, Clinton R. Mullins, of Concord, George M. Putnam, of Contoocook, Allan D. Sutherland, of Brattleboro, Vermont, Roy D. Watkins, of Rutland, Vermont, and Isadore Zimmerman, of Manchester. R. S. Spaulding was named executive director.

This motion was seconded and was carried

The report of the Committee on Medical Education and Hospitals was then presented, as follows:

The chief activities of this committee during the past year have been in connection with the work of the advisory councils appointed by the State to consult with the Department of Health, which functions as the administrative agency in the operation of the Hill-Burton Hospital Act within the State, and an Advisory Board, which was made up of the same membership, to act with the Department of Health on new legislation in the field of hospital licensure.

The formulation of a State plan of hospitalization has been completed and is about to be published. The specific hospital projects within this plan have been delayed principally because of the problems of local finance and the uncertainty of costs. Although in the general field of construction it has been presumed that costs have stabilized themselves, there has been no large amount of substantiation of this supposition by the few instances where plans have been submitted for actual bid. It is believed that the progress in the field of the State hospital plan has been satisfactory and has been generally well accepted.

During the past year the Department of Health has conducted hospital inspections in conformity with the new laws regarding licensure. This legislation was designed to put more control in the Department of Health, particularly in relation to nonpublic institutions, which have been poorly controlled in the past, and fire hazards, medical supervision and so forth. The adoption of any regulations, which must be standard in their application, has brought perhaps minor irritations to some of the older and well established institutions, but it is to be remembered that reasonable uniformity in requirements are necessary to the carrying out of the whole program.

This committee believes that the Society should make an official effort to increase the enrollment of its membership at the New England Postgraduate Assembly. The

Assembly was held last year at the Copley Plaza Hotel, Boston, on November 3, 4 and 5, with a total registration of 804, of which New Hampshire contributed an enrollment of 49. This assembly, which is largely an effort of the Massachusetts Medical Society, has been of increasing value. Its sponsorship may ultimately come under the various New England state medical societies, a topic that has already been discussed before the Council of the New England State Medical Societies, if adopted, this plan would make the assembly a distinctly proportionate responsibility of the New Hampshire Medical Society. Meanwhile, efforts could be made among the county societies to inform the members of the value and the proximity of this program.

JOHN P. BOWLER, *Chairman*
JAMES W. JAMESON
HOWARD P. SAWYER

Dr Leonard, for the Committee on Officers' Reports, submitted a minor correction to the report backed by a list received from the chairman of registration of the 1948 New England Postgraduate Assembly. Inasmuch as this improves the position of New Hampshire in the roll call, a census of 55 instead of 49 New Hampshire doctors registered at the Assembly was reported. By New Hampshire counties, they were as follows: Hillsborough, 13, Rockingham, 11, Grafton, 7, Merrimack, 7, Strafford, 5, Belknap, 4, Cheshire, 4, Carroll, 2, Coos, 1, and Sullivan, 1. There were 24 doctors who went from the counties bordering on Massachusetts, 31 went from the other counties. Only 33 New Hampshire doctors attended the Assembly in 1947 so that the 1948 registration represented nearly double the former attendance.

Dr Leonard moved that the report of the Committee on Medical Education and Hospitals be accepted.

This motion was duly seconded and was carried.

The report of the Committee on Mental Hygiene was presented, as follows:

Two bills pertaining to commitment to the state hospital and nomenclature of forms to be used were passed. One, a voluntary act on the part of the patient, now requires agreement to a two-month period of treatment and a two-week period, after their request for release, prior to discharge. This permits a longer period of treatment, which in nearly every case is necessary to obtain the maximum benefit, because although the advanced type of treatment of shock therapy shortens the duration, the length of stay permits psychotherapy together with "total push" used with groups. Time is also obtained to complete a more intensive study of the personality traits in each case.

The second, on the regular form of commitment by two physicians, has finally permitted the doing away with the now obsolete term "insane" and allows the committing physicians to interpret emotional functional conditions of a severe or moderately severe nature, permitting a regular commitment. It also allows for the removal of the stigma of the terminology "insane," which the patients, as well as their relatives, disliked so much.

The State has been very fortunate in the fact that Dr. John L. Smalldon has become superintendent of the state hospital. He has brought to his duties years of experience in psychiatry and administrative ability so essential to this type of hospital. Under his leadership, those who work with him have already been definitely stimulated to intensified effort, not only on effecting cures in those already mentally ill but also to assist in promoting steps of preventing mental illness.

More and greater efforts must be made toward the prevention of this form of illness, for as the span of life

physically has been prolonged, we are perceiving an increase of anxiety or depressed states in the aging person due to various environmental factors. If reached early, a psychosis of severe nature may be avoided, and the necessity of hospitalization prevented. At the present time 44 per cent of admissions to the state hospital occur in persons over sixty-five years of age. Either steps to prevent must be found or else such an overcrowding will occur that some form of community hospital will have to be arranged for in each county.

From the hospital has emanated the development of outpatient clinics in Rochester, Portsmouth, Nashua, Manchester, Keene and Claremont. Soon we hope that clinics will be arranged for in Laconia and Berlin. Primarily, these are for follow-up work with patients sufficiently recovered to have returned to their homes, but they may be made available for cases referred by physicians when patients are in need of psychiatric advice and are financially unable to go to some psychiatrist in private practice. In addition, the Mental Hygiene Child Guidance Clinics under the director, Dr. Anna Philbrook, have been continued with admirable success, which might be further enhanced by increased personnel.

More adequate extension of the services of the mental-hygiene clinics in the State has been hampered by lack of adequately trained personnel. This in turn has resulted from the inability of the classification board that determines the salaries paid to various state employees to raise the minimum salaries for qualified applicants to equal that granted in other New England states. Unless a special effort is made to obtain an adequate staff for the clinics and the study home contemplated in former Governor Winant's residence, the entire mental-hygiene program will remain bogged down and become a program on paper only. The director of the Mental Hygiene Clinic will not be able under the circumstances to carry on alone as far as the psychiatric end is concerned, for the administrative duties will no doubt absorb much of her time, leaving little time for clinical work with patients. In view of the fact that part of the funds for the Mental Hygiene Clinics is of federal origin, this niggardliness in such an important program appears ill advised, especially when one of the aims of the Mental Hygiene Clinics is to prevent the need for hospitalization for future patients in the state hospital.

The Committee desires also to bring to your attention that during this past year the Department of Mental Hygiene and Child Guidance Clinics took another step forward toward its goal of establishing a study and receiving home. The home of the late Ambassador John Winant was purchased by the State for this purpose. The state program is now titled "Winant House, New Hampshire Mental Hygiene Clinics." The proposed use of the Winant house is for the diagnosis and treatment of emotionally disturbed children needing more careful diagnosis than can be provided in any existing outpatient clinic, thus helping to prevent delinquency and later mental illness. This service is provided for children needing a more extended period of psychiatric treatment, including those with diagnoses of psychosis, epilepsy, feeble-mindedness or needing long-term care. The Clinics moved from the Thayer Building at the state hospital on November 15, 1948. Since that time a full schedule of clinics has continued, in addition to planning with trustees and architects for remodeling. We have had interviews with applicants for positions such as matrons, caretakers, girls and boys as supervisors, nurses and teachers. The staff are very interested and enthusiastic about this project and have given much time and thought toward making sound plans for a program that will benefit many children and parents.

There are two buildings — the main house with twenty-five rooms and seven baths, and the kennel building, which has two four-room apartments upstairs as well as a large room with the same space downstairs. The main house will be used as a residence for twenty-five children and at first will be a combined unit for both receiving and study home. The building will require a minimum of remodeling and will give the children an environment that is homelike and not crowded. The children will be living in rooms that are large, sunny and pleasant, therefore sleeping arrangements will not be crowded. There will

be single and double rooms. The maximum will be four in a room. This will afford privacy, which is much needed for children who are emotionally disturbed. The kennel building will be the administrative building and will house the clinic staff and medical unit.

The thirty-two acres of wooded land will be ideal for children's picnics, hikes and nature study. There will be two playground areas, one for younger group and one for older children, as well as a swimming pool.

It is believed that this program can get under way well within the capital funds appropriated for this purpose.

From November, 1948 to March, 1949, 71 clinics have been held, 465 individual patients have been seen, and there were 525 total visits to the clinics.

The need for a state-wide program for dealing with alcoholism is an accepted fact. Many alcoholic patients would benefit from a judiciously executed program of physical and mental rehabilitation. At present much of the load is being carried by members of the state-hospital staff, for the admission rate for alcoholism has increased from 2 to 14 per cent of all admissions in the past year. There are plans proposed by the Board of Inebriates for the opening of a special hospital for the treatment of alcoholism in the State. This, besides entailing a high initial financial outlay, will also require a large annual budget for maintenance and with the mental-hygiene system in the State bogged down for lack of funds for qualified personnel, the advisability of proceeding with an expensive plan for the treatment of alcoholism should be given closer scrutiny before another white elephant is foisted on the taxpayer. It is suggested that an independent study be made of existing facilities for the treatment of alcoholism, and at least one psychiatrist and one other physician included in this board. The problem of alcoholism in New Hampshire differs considerably from that in other New England states or New York State. The incidence of alcoholism is less, and in view of the fact that in most instances the problem is psychiatric or psychosomatic, the advantage of having the treatment of alcoholism come under both the Department of Health and Mental Hygiene Clinics should be considered.

The last suggestion is that a law to be presented to the Legislature be sponsored and supported by the Society. This law would permit children under five years of age, who required treatment or care for mental deficiency, to be entered at the Laconia State School. At this time no facilities that are really suitable are actually available for such children, and many social agencies are at a loss as to how they can adequately care for these children, for the homes are very frequently entirely unsuited to care for them for obvious reasons.

The carrying out of such a law would also require the voting of sufficient funds to provide, at the Laconia State School, for increase of personnel and quarters for such children.

Finally every effort, from all sources, including social agencies, churches, mental hygiene clinics, psychiatrists in private practice and physicians generally should be directed toward the prevention of mental illness or at least its early recognition and institution of proper treatment to prevent a more serious condition from developing.

A. B. HOWARD, M.D.
SIMON STONE, M.D.
EDWARD S. MORRIS, M.D.

Dr Leonard, for the Committee on Officers' Reports, moved that the report of the Committee on Mental Hygiene, with its recommendations, be accepted.

This motion was duly seconded and was carried.

The report of the Committee on National Emergency Medical Service was then presented.

In the report submitted by this committee last year it was stated that plans and enabling legislation for civilian defense must be necessarily on a national level and that organizations on a local level must wait directives or orders from the Office of the Director of National Defense. In the interim time that report much thought and study

has been given to the problem by the Office of Civil Defense Planning. Chairman Russell J. Hopley of the Civil Defense Planning Board submitted a report to the Secretary of Defense in November, 1948. This report was 300 pages of text, was supplemented by 17 organizational charts and proposed model legislation on federal, county and local levels and is purchasable for \$100 from the Superintendent of Documents, United States Printing Office, Washington 25, D. C. In this report it was recommended that the Director of the Office of Civil Defense Planning should report to the Secretary of Defense or directly to the President. The former was thought to be preferable. Four deputy directors are provided for plans and operations, medical and health service and special-weapons, technical services and training. Under the general supervision of the medical and health services and special-weapons defense deputy director would be four broad divisions: medical and health services, radiologic defense, chemical defense and "other special-weapons defense," the last named concerning itself with a subject that is still alluded to only inferentially — biologic warfare. It was recommended by Mr. Hopley's committee that bureaus organized similarly would be set up by the several states, cities and metropolitan areas. It is recommended by your committee that no action on the recommendations of this report by Mr. Hopley be taken until the report has been studied by the Council on Medical Emergency Service of the American Medical Association and suitable directives from the latter promulgated. Because of growing interest in civilian defense and disaster planning and because the enormous impact of nuclear physics and chemistry with its attendant hazards has already shaped the size of things to come, it is believed that the attention of the members of the Society should be directed to two communications on this subject. One, entitled "Problems of Medical Care in the Atomic Age" by Harold Lueuth, M.D., appeared in the *Illinois Medical Journal*, for August, 1948, and another, entitled "Medical Care of the Nation in the Event of Another War," by James C. Sargent, M.D., appeared in the *Journal of the American Medical Association* of January 15, 1949.

A matter of grave concern to the nation during the past nine months is the critical shortage of doctors in the armed forces. In February the Armed Forces Medical Advisory Committee advised Secretary of Defense James Forrestal to start a drive to recruit four thousand doctors and dentists for the armed forces by December, 1949. That committee asserted that medical students who completed their studies while others were in uniform were under "moral obligation to serve now." The committee set up to advise Mr. Forrestal on medical needs of the armed forces termed the shortage of doctors and dentists critical. They asked the Secretary to begin a recruiting drive immediately directed toward 15,000 young men who were deferred in World War II in order to complete their professional training. The Armed Forces Medical Advisory Committee estimated that the armed forces would be short 1500 physicians and 1600 dentists by July 30, 1949, and 2200 physicians and 1400 dentists by December, 1949. This advisory committee is composed of members of the American Medical Association, representatives of the Surgeons General of the Army and Navy, and the Air Force Surgeon. Thus, there is civilian medical representation at this high-policy level of the Government whose aim will be to safeguard the interests of the public, the armed forces and the medical profession. This committee wishes to point out to prospective volunteers for the armed forces that the Medical Administrative Corps has been expanded so as to leave doctors more time for medical duties and to relieve them of paper work. An additional stipend of \$100.00 per month is being paid to medical officers who volunteer for active duty prior to being called for induction. Training opportunities and career-guidance plans have been developed. Intensified research programs have been activated. Numerous other changes effected make service in the armed forces a more valuable professional experience than has heretofore been the case. It can safely be predicted that the doctors needed by the armed services will be obtained one way or another and if it is not done on a voluntary basis it will be done compulsorily. This committee reiterates this year its belief that young physicians who derived all or a part of their medical education

from the Army ASTP program or the Navy V-12 program and who have not already served on active duty should be the first group of physicians to volunteer for active duty with the armed forces. On December 12, 1948, President Sensenich of the American Medical Association addressed a letter to these young doctors urging them to volunteer for service in the armed forces. Of the physicians under the age of twenty-six years who were written to, only 500 requested application blanks for a commission. This, of course, was very short of the anticipated number of requests for commissions. There were a total of about 8000 such doctors whose education was provided for by the Government under ASTP and V-12 programs. In March Secretary Forrestal sent a letter to each of these men urging them to volunteer immediately for active duty in such numbers as to allow replacement of medical officers now on active duty who have had two years of active duty following ASTP or V-12 training.

Your committee strongly supports the program of the Government to recruit doctors for the armed forces and urges doctors who have served little or no time on active duty to volunteer now.

DANIEL J. SULLIVAN, M.D.
CLARENCE E. DUNBAR, M.D.
JOHN C. ECKELS, M.D.
JOSEPH M. MCCARTHY, M.D.
BERNARD J. MANNING, M.D.

Dr. Leonard, for the Committee on Officers' Reports, moved that the House of Delegates place on record the following statement and instruct the Secretary to transmit it to each member of the Society and to the press: "The House of Delegates, as the representative governing body of the New Hampshire Medical Society, believes that the increasing needs of the armed forces place a moral obligation upon the young physicians in the Society who derived all or part of their medical education at the expense of the Government and who have not yet served on active duty." He also moved that the Report of the Committee on National Emergency Medical Service be accepted.

After some discussion the first motion was carried.

Dr. Leonard then moved that the Report of the Committee on National Emergency Medical Service be accepted.

This motion was duly seconded and was carried.

The report of the Committee on Public Health was then presented, as follows:

The Committee has been active in the various hearings of public-health bills introduced into the current session of the General Court.

Senate Bill No. 7, an act relative to the practice of physiotherapy, received careful attention, and considerable time was spent on its investigation and on presentation of arguments against the original wording of the Bill. It was believed that such freedom as the Bill provided the physiotherapist would materially jeopardize the accepted standards of medicine in New Hampshire.

Other bills affecting the public health were also given attention in form of consultations, appearance at hearings and personal conversations.

Owing to the extensive attention given to medicine by the 81st Congress it was thought wise not to promulgate any considerable changes in the present public-health organization within the State. Letters have been written to the New Hampshire delegation in Congress, and personal interviews were held with two of the members. Assurances were given that everything in their power would be done to thwart any measures conducive to the lowering of medical practice or the altering of the physician-patient system.

DONALD G. BARTON, Chairman

Dr. Leonard, for the Committee on Officers' Reports, moved that the report of the Committee on Public Health be accepted.

This motion was duly seconded and was carried.

Dr. Leonard then moved that the sum of \$100.00 be contributed to the Council of the New England State Medical Societies.

This motion was duly seconded and was carried.

The report of the Committee on Tuberculosis was presented.

The participation of our country in World War I was but a few years ahead when the Society authorized the formation of this committee. In that year, 1914, tuberculosis was close to the top of the list among the leading causes of death throughout the nation and in the State. The death toll from tuberculosis in New Hampshire was over 500 annually, and the death rate 114 per 100,000 population.

The intervening years have witnessed increasing development and acceleration of knowledge, equipment and facilities to control the disease throughout the nation and in the State. Tremendous progress has been made, and the gains that have been achieved in reducing the mortality and morbidity of tuberculosis cause many tuberculosis workers to speak hopefully of the possibility of actual eradication of the disease in fifteen to twenty-five years. The more conservative among us estimate a period of approximately fifty years for complete eradication of tuberculosis in the United States, assuming continued intensive efforts for control and eradication, and barring the occurrence of unfavorable factors such as serious depression, widespread unemployment and resultant inadequate nutrition for great proportions of the people.

The progress in the control and toward the eradication of tuberculosis in New Hampshire is particularly gratifying. The 1914 toll has been reduced to 85 deaths in 1947 and a rate of 15.5 per 100,000 population and in 1948 to 68 deaths and a rate of 13.1. New Hampshire has the lowest mortality rate of any state east of the Mississippi River, and stands fourth in the nation. Since 1915 the decline in the tuberculosis death rate in New Hampshire has been the greatest in the nation, being approximately 87 per cent. This encouraging record is particularly gratifying in view of the fact that the State is the second most highly industrialized among the states of the nation in proportion to population.

We believe it is a most laudable ambition, and within our possibilities, for New Hampshire to increase the effectiveness of its campaign to the end that the State may be the first among the states of the nation to win the goal of complete eradication.

The phenomenal gains that have been won and the promising outlook for the ultimate eradication of tuberculosis are due in large part to the whole-hearted co-operation of physicians, nurses, other professional workers, tuberculosis patients and the people in both governmental and voluntary capacities in the efforts for control and eradication.

Throughout the years the Committee on Tuberculosis has endeavored to stimulate the interest and enlist the active support of members of the Society in the campaign for control and eradication. It has also endeavored to give all possible assistance to members of the Society in providing services for the early discovery of tuberculosis among their patients and in the families of their patients. The entire facilities of the chest clinics throughout the State, with resources of chest x-ray examinations, tuberculin tests and tuberculosis nurses' services, have been placed at their disposal. These facilities have been utilized by the physicians to an increasing extent, more particularly during the past five years, not only for checkup on known and suspected cases but also for the examination of contacts.

Probably in no other state in the nation is so large a proportion of the physicians participating actively in the program for discovery and prompt supervision and treatment of tuberculosis. There is good reason to believe that

this is the deciding factor in the phenomenal reduction in tuberculosis mortality and morbidity.

Our sanatoriums have contributed greatly to the reduction in the death rate from tuberculosis. Yet it is found that a large number of active cases are under supervision and treatment in homes. The increasing use of chest surgery, particularly thoracoplasty, has contributed materially to the number of cured cases in many parts of the State.

Within the past year the Department of Health has obtained a traveling chest x-ray unit for mass x-ray examinations. This unit is designed to provide chest x-ray studies for large numbers of people upon an industry-wide or even community-wide basis. It is emphasized that if everyone received such an examination all cases of tuberculosis would be discovered. However, there is much more to such a program than mere x-ray examination. If such a program is to be a success, much preliminary work must be done in the industry or the community before the films are taken so that most, if not all, of the people respond. Equally important, after the taking of the x-ray films adequate follow-up work has to be done to determine which cases are clinically active. Many films show shadows suggestive of tuberculosis, when no clinical disease is present. Experience reveals that in a state with a low mortality and morbidity from tuberculosis, such as New Hampshire, a considerable percentage of the films showing shadows suggestive of tuberculosis are found to be those of well nourished persons who are free from symptoms. These are usually cases of spontaneously healed tuberculosis. Yet the discovery of hitherto unknown active cases can hasten the goal of eradication. It must be remembered that it is also possible for chest x-ray films to appear normal in some persons in whom active clinical tuberculosis is present, since approximately 25 per cent of the lungs is hidden by the bony framework of the chest and the chest organs. There are also certain dangers that must be recognized if the full value of the x-ray survey is to be obtained. One of these is the average layman's belief that if his x-ray film is normal he does not have tuberculosis. Another is that one negative chest x-ray examination means that the person will not have tuberculosis in the future. Both conclusions are sadly erroneous. It cannot be too strongly emphasized that although chest x-ray examination is a distinct aid in the diagnosis of tuberculosis a definite diagnosis should not be made from the x-ray film alone, nor is it always possible to rule out tuberculosis on that basis alone. All the resources for diagnosis such as history, physical examination, sputum examinations, gastric lavage and sedimentation rate, may be needed to establish or rule out a case of clinically active pulmonary tuberculosis.

The traveling unit of the Department of Health provides a 70-mm film. This is the screening process. When the suspicious cases are found the 70-mm film must be followed up by a standard 14-by-17-inch film. However, as has been said before a film of any size must be considered as a diagnostic aid to be used in collaboration with all other resources to establish a definite diagnosis.

The success of a mass chest x-ray survey depends upon adequate follow-up study of all suspicious cases. This is a real responsibility. Failure to meet it can ruin the entire program. The responsibility rests largely with the general practitioner. Here in New Hampshire as elsewhere, the Department of Health refers patients with suspicious shadows upon the films to their own physicians. In many cases responsibility has been accepted and serious effort made to establish a definite diagnosis, and to facilitate prompt and adequate treatment. In some cases duty has been shirked, and occasionally x-ray reading has been given to the patient with indifferent advice about follow-up study.

Our experience with the tuberculin test convinces us that it will play an important part in the final eradication of tuberculosis. This test is most valuable when the death rate is low and there are comparatively few reactors. It is more significant after the death rate has been reduced and there are comparatively few cases to be found. The mass x-ray surveys are most useful when the death rate is high and the incidence of positive tuberculin-test reactors is high. The percentage of positive reactors to the tuberculin test among the young people of high school

age in New Hampshire has been reduced from approximately 60 twenty-five years ago to about 10 at the present time. It is not a large undertaking to test all children of school age. A child who presents a positive reaction should be considered a potential case of clinical tuberculosis and kept under supervision.

Of equal importance, search should be made for the source of infection in the families of positive reactors in children. The younger the child, the more likely it is that the source of the infection is in the immediate household. In 2 recent cases of positive-reactor children, the mother in one, and the father in the other were found to have active pulmonary tuberculosis, with tubercle bacilli in the sputum. The co-operation of the parents in both cases was brought about through the interest and active part taken by the family physicians.

It should always be remembered that tuberculosis is present as much in the older age group as in young persons. The older people deserve more attention and need more checkups for tuberculosis than they are receiving now and are often the source of infection of younger family members or associates. The coughing grandmother taking care of the baby is frequently the cause of tuberculous meningitis.

Many advances have recently been made in the treatment of tuberculosis. Surgery has played an important part, and has taken a high place in treatment. Several years of use of streptomycin and other antibiotics have served to demonstrate their advantages, disadvantages and limitations in the treatment of tuberculosis. It is possible that in the future some antibiotic may prove to be the long-sought cure.

In this report the Committee has sought to present a brief outline of our present position in the fight against human tuberculosis in New Hampshire, our objectives, and an appeal for the continued whole-hearted participation of our membership. For the success of the program for control and eradication a large measure of credit and appreciation is due to the physicians of New Hampshire. If the future program for eradication is to function at its best, it must be recognized and accepted by the general practitioner that no plan can be a success without his assistance and co-operation.

The Committee urges the continued and increased use of the chest x-ray examination by physicians in their general practice and in the hospitals. We also urge the wholehearted co-operation of the members in the mass chest x-ray surveys of the Department of Health. Particularly do we urge prompt follow-up study by the physician of all persons whose chest x-ray films show definite or suspicious shadows. Every resource should be utilized by the members to establish the presence or absence of clinically active pulmonary tuberculosis in these cases.

We hope for the continued wholehearted co-operation of the members in the tuberculin testing of the school population of the State to the end that all potential cases may be found, as well as the patients with possibly active "open" cases who may be the spreaders of the infection among them.

ROBERT B. KERR, M.D.
FRANK G. SELDON, M.D.
JOSEPH D. SPRING, M.D.

Dr. Leonard, for the Committee on Officers' Reports, moved that the report of the Committee on Tuberculosis be accepted.

This motion was duly seconded and was carried.

Mr. Angus B. Woodbury, for the Committee on Public Relations, then described the campaign in New Hampshire against compulsory health insurance.

The Committee on Public Relations met on March 13, 1949, and determined to put in force some plan to counteract growing interest in President Truman's compulsory health insurance legislation.

The Angus B. Woodbury advertising and public-relations agency was consulted and subsequently engaged to carry out the Society's educational and informational campaign.

Action was immediate. The agency prepared releases for newspapers and radio stations announcing plans for the campaign. At the same time a representative of the Woodbury firm was assigned to the task of organizing "co-ordinating committees" throughout the State.

The immediate objective—to organize and to publicize—was carried out with dispatch, and within ten days the people of the State were aware that the doctors intended to broaden medical services and urge greater patient-physician participation in voluntary health care plans as the best assurance against compulsory health insurance or socialized medicine.

An organizational plan written by the agency was put into actual operation in every county. By the end of the first month these various committees were quite well organized.

Spearheading the New Hampshire campaign was an extensive publicity effort, which at the end of three months had resulted in the publishing of some 1500 column inches of copy. Had this been purchased at ordinary newspaper advertising rates, the total cost to the Society would have been approximately \$13,000. Owing to the news value of the releases prepared by the agency and submitted to the newspapers, editors found reader interest in them, and this extensive publicity was obtained without cost.

Co-ordinated with the publicity part of the public-relations program was a speaking schedule. The agency was able to enroll support of several prominent citizens, who, along with the campaign staff, have filled more than 50 speaking engagements throughout the State. It is conservatively estimated that between 4500 and 5000 people have heard some of our speakers outline the danger points of socialized medicine.

We have speakers scheduled through July 11.

Upwards of 20,000 pieces of literature have been distributed, most of it personally to members of county "co-ordinating committees" by the campaign staff.

Extremely close contact has been maintained between the Society's public-relations counsel and the various voluntary health care programs, particularly Blue Cross and Blue Shield.

Owing to the liaison established and developed, there has resulted an obviously increased and improved relation between the Society and the county societies, the pharmacists, nurses and hospital units. We cite the Cheshire County Medical Society proposal as the best example.

On at least three occasions the New Hampshire Medical Society has been publicly complimented for having one of the best organized and most effective campaigns against socialized medicine in the country.

A worthwhile and efficient organization has been built up in New Hampshire. It has now begun to function well, but each organization or "co-ordinating committee" is aware that much still remains to be done if the defeat of socialized medicine is to be accomplished.

This civilian and professional organizational effort ought to be continued, developed and enlarged as the occasion demands.

The effort put forth in this state has resulted in more than 4500 individual letters to the congressional delegation in Washington and to the President, in opposition to socialized medicine, as a result of such overwhelming public opinion, the delegation has committed itself to oppose compulsory health insurance legislation as currently proposed.

Maintaining status quo will not be enough.

Actually only a small percentage of the people of the State have yet expressed themselves on this all-important national issue. Much educational work remains to be done.

It is known that there are at least half a dozen "health bills" before Congress, any one of which might be pressed for adoption as an Administration measure. True, Senate Bill No. 5, and its House counterpart, No. 783, are accepted as being the "Truman plans." However, should public opinion change nationally, congressional sentiment, which now seems to be in favor of voluntary rather than compulsory insurance might change—perhaps overnight. The best assurance against subterfuge is a strong, continued and active campaign.

Through this educational campaign effort, the physicians have stepped up their public relations to a point of favor

in the eyes of the press as well as the general public. Good relations through public relations ought to be maintained as a safeguard, not only in opposing socialized medicine but also in furthering voluntary health care.

To date, the Society's three-month campaign has been effective and therefore successful. It has made it possible for more New Hampshire people to understand better the dangers of compulsory health insurance than was anticipated last March.

The campaign has been an affirmative one in that out of it has come something constructive—the Cheshire County Medical Society plan being a case in point.

The total estimated cost is \$2899.93.

Hearings have already started in the House and Senate on the hodgepodge of national "health bills." These hearings are being closely watched by the American Medical Association. Somewhere in this maze of social-reform measures will be found legislation with a preponderance of compulsion attached to it. Just what form and character legislation will take once it clears either House or Senate subcommittees is as mystifying as the reason why the President still insists on compulsory health insurance without a public demand for it.

But, politics being a continuing guessing game, neither the American Medical Association nor individual state medical societies can afford to lower their guard to a point of being ill prepared to meet social schemers in their whims about medicine. The only real answer, obviously, is to keep organizations active.

Subcommittee hearings, such as are now going on, can be lengthy affairs. They can be adjourned without prior notice. They can be postponed if it appears politically expedient to do so. They can be stepped up or abandoned.

Health measures, including compulsory health insurance, could be tossed into the full committee—either in the House or Senate—tomorrow. This probably will not happen, however,—and for several reasons.

President Truman, it must be remembered, has told the American people that he thinks they need, want and must have Government-controlled medicine. For some reason yet to be explained, he believes that there is a people's mandate for compulsory health insurance. There is no such mandate.

Mr. Truman and his leaders, failing to find it expedient to force compulsory health insurance now or before Congress decides to go home for the summer around August 1, can well wait until the second session of the 81st Congress is called back into session next January—or sooner.

Before compulsory health insurance, as now proposed, is either brought out for debate in Congress or relegated to the ash pile where it rightfully belongs, there will probably be some real old-fashioned horse trading.

It is reasonable to assume that either Mr. Truman or Congress may "give" a little to get this national health issue off the hook. When this "giving" starts, that is the time to watch out.

If Congress goes home by August 1, or shortly thereafter, without taking action on "socialized medicine," the Administration will undoubtedly go to work this fall to "educate" the people as to why compulsory health insurance should be a must on the agenda for the second congressional session.

Such a campaign—the Government has sponsored similar ones before—would have no holds barred. If the Society should weaken to a point of feeling "self-satisfied" by that time, it would be a major mistake.

It should be remembered that the Administration will continue its campaign for social reforms this fall, whether Congress is in session or not. Then, when the nation's lawmakers come back next January, Washington will have cleared some of the legislative decks to place "socialized medicine" before the people.

Thus, 1950 is certain to be a year of promise.

Either the President and the Administration will keep their promise to get through compulsory health insurance legislation, or the medical profession will keep its promise—and see that compulsory health insurance dies a just death.

Already, as Congressman Hugh Scott pointed out in his talk at Concord a few weeks ago, overtures are being made to make this whole issue of the "nation's health" a political football in the elections in 1950.

The American people must be kept alert to the dangers of socialization, especially this attempt to take away the freedom and individual initiative known so well to prevail in the medical profession. Such alertness will come about only through continued education and information effort, a responsibility already assumed by America's physicians.

Too much effort, downright energy and serious thought have gone into this campaign of the New Hampshire Medical Society's to be cast aside now that the first taste of a rather negative victory has been so pleasing.

If the old adage is true, and "nothing succeeds like success," looking ahead to more than partial victory regarding this national issue of compulsory health insurance may well be expected.

The doctors know what red tape, Government forms and political control would mean to the medical profession. The people are beginning to know too. A continuing campaign should practically assure defeat of compulsory health insurance in 1950.

But, as the president of the Society, Dr. Clarence E. Dunbar, has so well stated, a continuing public-relations program will do more than help defeat compulsory health insurance. It will help in furthering the doctors' efforts to broaden voluntary health care programs that in themselves offer the best assurance against socialized medicine.

A broad state-wide organization, composed of physicians and lay people, has been developed with a view toward carrying on an extensive educational and informational campaign.

This organization should now be subdivided into small community groups—in cities by wards and in counties by towns.

An effort should be made to make this a "public" campaign for the remainder of 1949 and in 1950. From the co-operation already received from civic and professional groups, such an objective is not impossible of attainment.

Organizational units and subunits can be created and developed immediately, adopting as their project broader medical services, as well as greater understanding and participation in voluntary health care through education. And this whole endeavor can be under the sponsorship of the New Hampshire Medical Society.

Large quantities of literature are available and can be used as "hand-out" material in every ward and town in the State. This has not yet been done, obviously owing to the high gear in which the previous campaign was turning. But it should be done and is recommended as a part of an extended campaign.

In connection with this effort will be the development of an inter-town and inter-city speaking schedule. Every community has within its borders certain people who enjoy taking the public platform on some subject of national importance. Already, our files contain the names of several people who would be willing to take part in such a program.

As much as possible, future organization should be composed of lay people, all working under the technical guidance and assistance of state and county medical society officers. This will make for less close supervision on the part of busy physicians and more responsibility and general program maintenance by the New Hampshire Medical Society's campaign headquarters staff.

There should be a wider distribution of the now well known picture "The Doctor." Quantities of this print are available, and it is recommended that the Society consider as a part of the extended campaign the possibility of using state-wide window displays. These displays would be made up by the campaign staff. In this manner, thousands of people would have a first-hand opportunity to "see" what the educational campaign is all about. Such an effort would also add to the effectiveness of the individual "community" organized campaign.

During the summer and fall months of 1949 considerable emphasis should also be placed on stimulating the educational and informational effort to include appeals to approximately 1,000,000 summer visitors.

Building organizations to enable the combining of local and summer visitor interest will go a long way toward getting a double value through a single effort. This plan ought to be carried out in the seacoast resort areas and the lake and mountain sections, where county organizations already in existence could easily be expanded.

The continuation of a state-wide speaking schedule will be an important part of an extended campaign. This effort has proved so effective during the past three months that broader development of public speakers will be of invaluable assistance. This phase of the campaign, of course, would be carried on by the campaign headquarters or public-relations counsel.

Obtaining qualified speakers, making arrangements, scheduling dates and such related functions are to be considered as a part of the broad program.

It must be apparent to all members of the Society that publicity has played an important part in the success of the state-wide effort thus far. In an extended program, the emphasis would obviously shift from organizational publicity to the developing of more educational material and announcements of new ideas for broader medical service and participation in voluntary programs. Then, too, it will be a part of any new program to extend an educational effort to include as much free radio time as it will be possible to obtain. As in the past, publicity for all weekly and daily newspapers will be carried out.

In the broadening of organizational work there will of necessity be a need for greater liaison between the Society and the general public, schools, colleges, industrial plants, theaters, stores, allied professional groups and professional workers. This would be a part of the extended campaign.

In the developing of new ideas for greater medical services and more extensive participation in voluntary health care programs, it will be necessary for the Society's public-relations counsel to work closely with the Society officers and many of the units mentioned above.

Distribution of literature to all the people of the State will be a part of the extended campaign. This will include an effort to get literature to all organizations, industrial plants, men's clubs, women's groups, veterans' organizations and professional groups. Owing to the time limit involved distribution to date has obviously been only spotty. There ought to be a concentrated effort literally to cover the State between now and early 1950.

Depending somewhat on the outcome of current compulsory health insurance legislation, it may be necessary for the Society's public-relations counsel to aid in working closely with national and state legislative leaders during the legislative session of 1950, or in New Hampshire, the proposed fall session of the Legislature.

It is proposed that during the extended campaign, the Society's public-relations counsel develop a working arrangement with the many New Hampshire service organizations such as the Lions, Kiwanis and Rotary. This would be for the purpose of filling speaking engagements and distributing literature, and for obtaining resolutions against socialized medicine for the next legislative period.

During the past three months the campaign headquarters had several requests for information from school units. This leads us to believe that in the extended campaign an effort ought to be made to provide schools and colleges with educational material and to assist them in carrying on talks involving the health program.

Consideration should be given to the possibility of developing a motor-corps unit in the Woman's Auxiliary. Such a unit would be most effective when compulsory health insurance legislation is reported out of the full House and Senate committees. A motor corps traveling around the State would stimulate and arouse people to the point of writing to congressmen in opposition to compulsory insurance. This could be made a very effective part of the campaign if it becomes necessary to use it.

Dr. Leonard, for the Committee on Officers' Reports, moved that the report of the Committee on Public Relations, as presented by Mr. Woodbury, be accepted, and also that the Committee on Public Relations contract for the continuation of the educational campaign in New Hampshire.

This motion was duly seconded.

President Dunbar stated that the whole question was bound up with the matter of raising the dues—whether an executive assistant to the Secretary.

die right away, but hangs on for two or three years. She has two or three nurses at home, as well as hospital bills, so that the bills amount to around \$20,000 to \$25,000, which wipes out his entire savings. Now, that doesn't happen very often. It is not always cancer, sometimes it is some other devastating disease, requiring constant care.

I have talked to the Blue Shield men, and they think if they were given adequate safeguards against abuse, they could underwrite catastrophic illness policies at a very low premium. Mr. Spaulding thought, for a wild guess, that something in the neighborhood of \$5.00 a year would take care of it, provided they were safeguarded against abuses.

That is one of the big arguments of the public, and, although it doesn't happen very often, it becomes very widely known.

And, by the way, we got these points from the public, they did not come from the medical profession. Mr. Shea, head of the AFL Electricians of New Hampshire, brought these salient features before us, and we are very much indebted to him.

We find that many people are complaining that although they pay for Blue Cross and Blue Shield coverage, when they go into the hospital, they find they still owe \$100.00 or more, depending upon the fees charged. The Blue Cross has been paying around 90 per cent of the bill. The surgeons send them a bill for \$150.00, the anesthetist costs \$25.00, and the assistant a little more. So that after he is paid by Blue Cross he still owes \$100.00.

We propose for wage groups (and we should settle that point this morning) that earn \$2500 that the medical profession go on record so that the insurance company can sell to the public, saying, "We will cover you entirely," and accept the indemnifying fee as the final fee for those in that wage group.

Now, with the people who earn more money than that, the surgeon and other physicians connected with the case are perfectly free to accept whatever extra charges they think the traffic will bear.

But we should like to be able to guarantee the general, average man with a family that after he pays the fee for Blue Shield and Blue Cross, his worries, financially, are over.

I don't think that we need to go into the other point, of solving this problem of over-hospitalization and the taking up of grievances with the public. I think that that was well covered last night.

Dr. Sycamore stated that when the plan had originally been set up, it was debated whether it should be made a service contract, with a definite income limit, which has some complications that are a little difficult to administer that could perhaps be avoided by agreement among the members that, in effect, a service contract could be made if fees were equal to the scheduled benefit. No exact income limit was ever set. He believed that such a limit should be set and the agreement made a little more specific. In the plans that have a service contract with income limit, there is quite a wide variation in that limit. The average on most of the plans in comparable areas is around \$3500 for a family.

He suggested that the principle of a service contract up to a definite income limit be approved, by acceptance of the benefit schedule as a fee schedule, and that it be left to the Committee on Medical Economics and the Board of Trustees of the New Hampshire-Vermont Physicians' Service to set that income limit, after appropriate study.

Secretary Metcalf asked if there were any difficulty in determining a man's income.

Dr. Sycamore replied that that was one of the problems, and was the reason why the benefit schedule had not previously been approved. There was an increasing tendency to charge over the schedule, even in low-income cases, and it might be necessary to put the new schedule into effect, to protect the subscribers.

Dr. Walck asked who was to determine the income bracket into which the subscriber belonged. In Strafford, the doctors voted on the principle of the Cheshire County Plan, but they would have nothing to do with determining the group in which the subscriber belonged.

Dr. Jessup stated that many patients were operated upon, basically on the recommendation of the internist, and yet the surgeon was the only one qualified to receive payment. He believed that the internist, who actually did most of the work, was entitled to something. He did not think it fair that the patient should pay it.

Speaker Dube stated that the question raised could be answered by the fact that some patients had only surgical and not medical coverage. Blue Cross was the hospital plan, and the doctors had nothing to do with that. Blue Shield, of course, had both surgical and medical coverage, but, if the patient had surgical coverage only, he did not get the medical reimbursement.

Dr. Brown observed that there was a similar situation in regard to obstetrics and the prenatal and postnatal care that is rendered.

Dr. Sycamore moved that the principle of a service contract in the lower income group be approved, that the level of the income covered and the mechanism be worked out by the Committee on Medical Economics and the Board of Trustees of the New Hampshire-Vermont Physicians' Service, and that the conclusions be studied by the groups concerned and reported back to the next meeting of the House of Delegates.

The motion was then duly seconded and was carried.

A supplementary report of the Committee on Medical Economics, which had been turned in on the previous day but had been held out for consideration, was then presented, as follows:

As the Blue Shield movement has assumed an increasingly important place in the field of medical economics, it has become increasingly obvious that a national agency was necessary to make possible the handling of contracts for national employers and widely scattered groups such as large labor unions. A year ago, a co-ordinated program was developed for Blue Shield and Blue Cross to establish a national enrollment and insurance agency. This proposal was submitted to the House of Delegates of the American Medical Association at its interim session last November, but was not approved.

Associated Medical Care Plans, the national organization of Blue Shield Plans, then proceeded with plans for a national Blue Shield agency independent of Blue Cross. This proposal, also, was submitted to the House of Delegates of the American Medical Association, through the Council on Medical Service, at its session last week in Atlantic City. The Council, believing that the Associated

Medical Care Plans had grown to the point of being able to stand on its own feet, recommended that there should be complete separation between the American Medical Association and the Associated Medical Care Plans, and that Associated Medical Care Plans should be free to proceed according to its own best judgment in dealing with its own problems. These recommendations were duly approved by the House of Delegates.

As a result of this action by the Council on Medical Service and the House of Delegates of the American Medical Association, Associated Medical Care Plans has requested each member plan to approve or disapprove the proposals for a national enrollment and insurance organization, and to submit the proposals also to its sponsoring medical society. The directors of the New Hampshire-Vermont Physicians' Service have approved these proposals. The House of Delegates of the New Hampshire Medical Society, meeting in special session last October, approved the plan for a national Blue Cross-Blue Shield Agency. It is therefore the recommendation of the Committee that the House of Delegates approve the principle of a Blue Shield National Service Agency.

LESLIE K. SYCAMORE, M.D., *Chairman*
J. C. DUBE, M.D.

Dr. Leonard, for the Committee on Officers' Reports, moved that this report be accepted, but did not feel like making any recommendation, in the hope that the motion would be made from the floor.

Mr. Spaulding stated that the new scheme of separation seemed to have stirred up some doubt that the national medical group had. He believed there was no question that it would help in holding or getting back some of the people lost, so as to provide the same benefits everywhere.

Dr. Leonard moved that the report be accepted.

Dr. Johnston asked if everybody present was aware that several organizations are very much opposed to this move, especially the organizations in the Pacific Northwest.

Dr. Sycamore briefly indicated the way that this national program would function, as follows:

There would be, in the first place, no interference at all with the local program of any plan. In case of enrollment of a national group, each plan would supply what its particular policy offered, and then if there was further coverage desired by the national group, the national plan would supply that additional coverage on an indemnity basis.

The whole purpose, of course, is to make it feasible to enroll large groups as a unit, which is what the employer wants, if he has plants in various states, he wants to make one agreement, and have one uniform contract, and not have to deal with different contracts in different areas.

The objections that have been raised have come mostly from the Pacific Northwest, as Dr. Johnston has said. And certainly, they do not represent the opinion of the majority of either the plans or the medical societies that voted the approval, which was something like 175 to 12. It is believed that this is an essential part of the voluntary prepayment program. The actual mechanism of setting it up is something that we do not need to go into here. The House of Delegates of the American Medical Association did not attempt to go into the details of the program, they merely accepted the principle of it.

If we have a national program, it would be easier for the Government to take it over, but that is not the way the Government works. When they have set up any program, they have their own administration, and any compulsory government insurance here would be under the Social Security Office, and it would not be a question of taking over.

We had a recent example in British Columbia, when the Provincial Government adopted the program, and the Blue Cross Plan just went out of business.

So that I don't think that is a valid objection.

I think the main objection is that we might as well have a Government bureaucracy running us as a medical bureaucracy.

Well, I think there is quite a difference between being run by our own elected representatives, who know our own problems, and being run by Government officials.

Dr. Dye asked if there would be disagreement between certain segments of working men who belong to a given group in New Hampshire and another group in Michigan, who are under the same company-coverage plan, with different benefits in different states.

Dr. Sycamore replied that that was the reason for the national program: additional coverage would be given when necessary.

Dr. Leonard stated that the motion implied that the supplementary report of the Committee on Medical Economics be accepted and not that it carried with it the approval of the House of Delegates to the questions raised in the report.

There was a chorus of "ayes," and the motion was carried.

Dr. Sycamore then moved that this House of Delegates approve in principle the establishment by Associated Medical Care Plans of a national service agency.

Dr. Leonard asked whether that included the previous Blue Cross and Blue Shield and the combined health services.

Dr. Sycamore answered that this was a Blue Shield proposal, disassociated from Blue Cross.

Dr. D. G. Smith stated that he had asked a number of times why the proposed national enrollment insurance agency was not approved last December. Strafford County had been quite upset to think that the American Medical Association did not approve of the plan. Some of the reasons given at that time were that any attempt to set up uniform premium rates, uniform benefits and uniform policies would meet with failure, because hospital rates and surgical fees are not uniform throughout the United States, and cannot easily be made uniform, the demands for services are not uniform, nor are the social customs and the wage scales.

What labor was trying to do through its demands on Blue Cross and Blue Shield to establish uniformity was actually to prove that the voluntary plans are a vehicle for forcing the Government social reforms on the population.

Another reason given was that a complete service policy for everyone in the population, without regard to income level, could not be provided. A central fund of \$500,000 was not enough to equalize the differences between the policies in the various states.

There was also the idea that federal subsidies would be utilized for the poor risks, the chronic and

the medically indigent. The fear was that if the Government subsidies came in, it would be only a short time before the federal Government took over the plans. Some of these ideas were in opposition to the national insurance agency, but Dr Smith thought they could be straightened out and overcome. But the opinion was that it would be quite a problem to get such a company on a sound footing, and further, that the American Medical Association did not want to go into it and form an insurance company.

Dr Sycamore asked why the principle had been approved at the last session.

Dr Smith replied that a definite need for such an organization was felt so that there might be checks on the medical profession and so that the plan could be made to work. The fear that the federal Government would take over still existed.

Dr Sycamore pointed out that at the last session of the House of Delegates, the American Medical Association did adopt a resolution, first separating the A M C P from the A M A and then approving a national program by A M C P, on the Blue Shield level, and not on the combined Blue Cross and Blue Shield plan. When the Blue Shield was put out, it was put out with the principle that the low-income group would be helped to meet the economic tragedies of illness, if this program was for the purpose of enabling labor unions and employers of labor to provide at cost, protection against illness, injury and so forth, a co-operative in medicine for the use of industry seemed to be provided. Why should not that be done, as at the present time, by the regular insurance companies, who insure manufacturers against injuries and so forth to their employees.

Mr Spaulding stated that National Medical Care Plans was in no way intended to replace or to be workmen's compensation insurance. Employees were enrolled through their employers. The only thing that this national organization would be was an insurance company, set up under the laws of Illinois, where an employer and a union could equalize their benefits, all over the country. In some areas, the fee schedule was much lower than the present rate in New Hampshire. It was one of the principles of these national unions to provide benefits for all their members. The large employer groups were a result. The national organization, which could provide equalized benefits, would help to get subscribers back. The local operations would not be changed in any way. If the national level was set at \$100 for an appendectomy, and some plan only paid \$50 the local plan would still pay the \$50 and the national organization would pay the other \$50. It could never be a service contract, it would always have to be a contract of service only when the doctors agreed.

Dr Sycamore restated his motion that the House of Delegates approve the principle of a national service agency by associated medical plans.

This motion was duly seconded and was carried.

Dr Johnston moved that the House of Delegates formally ask the Blue Shield representatives in New Hampshire to look into the feasibility of setting up catastrophic illness insurance, and after they had looked at the actuarial tables and so forth, to report at a subsequent meeting.

This motion was duly seconded and was carried.

CASE 35471

PRESENTATION OF CASE

A fifty-three-year-old carpenter was admitted to the hospital because of intermittent jaundice.

The patient was perfectly well until approximately two and a half years before admission, at which time he had an illness characterized by marked weakness, malaise and jaundice, with no pain or fever. Recovery was complete in a four-week period. A second identical episode of jaundice occurred approximately two years before admission. He was studied at another hospital and a Graham test revealed a nonfunctioning gall bladder on repeated examination. He had a red-cell count of 3,000,000 and an icteric index of 60 units. The temperature chart was irregular, with occasional spikes to 102°F. The patient recovered in about three weeks. Several other attacks of painless jaundice with chills and fever occurred. Eight months before admission an elective cholecystectomy was performed at another hospital. The common duct was found to be much enlarged, it was opened and scooped out, but no stones were found. Large dilators were passed into the duodenum. The stomach and duodenum appeared normal. Cholecystectomy was performed, and the pathological report on the gall bladder was chronic cholecystitis. The patient did well postoperatively until six weeks before admission, when he had another episode of jaundice, ushered in by epigastric gaseous distress, marked anorexia and a 10-pound weight loss. The jaundice increased in severity, and the temperature spiked intermittently to 103°F. Because of the recurrence of jaundice, the patient was referred to this hospital.

On physical examination he was slightly emaciated and moderately jaundiced. The lungs were clear, and a Grade I apical systolic murmur was audible. The liver edge was felt 4 or 5 fingerbreadths below the costal margin and was nontender. The tip of the spleen was palpable. There was no ascites.

The temperature was 105.4°F, the pulse 100, and the respirations 24. The blood pressure was 140 systolic, 70 diastolic.

The urine was positive for bile, and the sediment contained several white cells and a rare granular cast. Blood studies disclosed a red-cell count of 2,100,000, with 8.5 gm of hemoglobin, and a white cell count of 45,800, with 91 per cent neutrophils. The total protein was 6.16 gm per 100 cc, with 2.72 gm of albumin and 3.44 gm of globulin. The nonprotein nitrogen was 30 mg per 100 cc, and the van den Bergh reaction was 3.4 mg per 100 cc direct and 4.6 mg indirect. The prothrombin time was 24 seconds (control, 17 seconds). The cephalin-flocculation test was ++ in twelve hours and ++++ in twenty-four hours. The alkaline phosphatase was 50.4 mg per 100 cc. The urine urobilinogen was 4.5 Ehrlich units. The stools were brown, and 1 out of 3 specimens examined gave a ++ guaiac reaction.

The patient had an almost daily elevation of temperature to between 102 and 104°F. Sulfadiazine had little effect. Several transfusions were given. On the twelfth hospital day, the patient went into shock and passed several bloody stools. Fluid and blood were given with some improvement. The jaundice became more marked. He died with a picture of pulmonary edema on the thirteenth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. LELAND S. MCKITTRICK*: I have not even the comfort today that goes with seeing the x-ray films, from which one constantly anticipates but rarely gets a great deal of help. There are certain things that seem to be perfectly clear cut. Here is a man, who for over two and a half years had recurrent attacks of epigastric pain, with dark urine, jaundice, sometimes clay-colored stools, chills and fever. I would not know how to make any diagnosis on a basis of the history except that this man had a cholangitis.

Now the real difficulties begin. We know that he was operated on eight months before entry, and that he had no stones, at least no stones were found, that he had a dilated common duct (the record does not say whether the duct was thickened, and it does not give any information about what was in the duct or information of the character of the bile or other important items that would be helpful), and that he had a large, dilated ampulla. That information is a little bit difficult to put together with complete satisfaction, because almost all the cases of cholangitis that I see have as a basis for the cholangitis a mechanical obstruction to the duct. In contrast here one finds a widely open ampulla with nothing in the duct. Nevertheless, I am forced, for want of any other explanation in the history, to say that this patient had had re-

*Visiting surgeon, Massachusetts General Hospital.

current attacks of cholangitis. Our major problem then is to try to determine what the background of that cholangitis was.

I suspect we have every right to believe that early in his career he had little or no liver damage. I do not know how much a negative biopsy of the liver means, but it must mean a good deal. After he came in here the condition was somewhat different. He had a large prostate for two and a half years. He then had a reversal of the albumin-globulin ratio and a prolonged prothrombin time. We do not know whether these were due to liver damage or something else because we do not know how long after entry he developed them. He apparently improved promptly after the use of vitamin K. Nevertheless, at the time of admission, there was reversal of the albumin-globulin ratio, a positive cephalin-flocculation test and possibly a prolonged prothrombin time. I think there is no question that he had liver disease, biliary in type and secondary to this process, that had been going on for two and a half years. The large spleen I would think to be quite in keeping with the longstanding recurrent episodes of infection.

I assume that this patient, who went into shock, passed several bloody stools and then died regardless of treatment, might well be considered to have died primarily of hemorrhage. Were it not for the underlying disease, blood loss alone would perhaps not have killed him, but it seems to me that the condition that finally caused his death was probably a fairly massive hemorrhage of some type. If he had an increase in his prothrombin time, it is perfectly possible for him to have had a massive hemorrhage from a diffuse process along the gastrointestinal tract. There, again, I do not know how one can possibly do more than guess where this hemorrhage came from—from an erosion or localized area or from a diffuse process. If we knew the subsequent prothrombin time, and if it had responded satisfactorily to vitamin K, which I am sure he was given, we would be less apt to expect a diffuse source of the bleeding as a cause for the hemorrhage, because the prothrombin time was not too prolonged. I am simply going to go on the assumption that in all probability this hemorrhage, which played a part in his death, came from a localized area rather than a diffuse area along the gastrointestinal tract such as we see in the late stages of jaundice and other conditions that interfere with the clotting mechanism.

That brings us down, if our reasoning is logical, to the problem of explaining two things: his final hemorrhage on the basis of a localized lesion and his recurrent bouts of cholangitis. These bouts lasted six weeks—that is a long time for a bout of cholangitis to last—and then spontaneously cleared up, and he was perfectly all right for a period of several months. I am going to go on the assumption that this man did have intermittent

blockage of the common duct. I just do not know how to explain it on any other basis. Intermittent blockage comes most commonly from a stone, but it could come from some type of growth. We know that carcinoma of the ampulla, or carcinoma of the head of the pancreas, may cause intermittent jaundice, but the thing that bothers me here about making either of those diagnoses is that this does not seem to have been a progressive lesion so far as the obstruction to the common duct is concerned. It was progressive so far as the evidence of cholangitis is concerned, and he died in my judgment ultimately of that combination. I cannot quite visualize the usual carcinoma of the ampulla or duodenum in that area as giving this kind of clinical picture. I would expect it ultimately to have become a more or less progressive, obstructive process, so I have to satisfy myself by laying aside the diagnosis of carcinoma of the ampulla of Vater or carcinoma of the duodenum or pancreas for something that is more intermittent. I know that I am not a good enough surgeon to find a stone in the common duct always, and we know the fact that a stone was not found does not mean that it was not there. A stone that has eroded into a vessel and causes ulceration, hemorrhage and death is a perfectly conceivable explanation for this condition. On the other hand he had clay-colored stools only occasionally. Some of these attacks lasted for six weeks, and it is difficult for me to believe that throughout this period he had a stone there, and particularly if it produced a block, that it did so for two to six weeks.

The other possibility is some kind of tumor, either benign or relatively benign, or so situated that it would intermittently block the common duct, causing essentially the same thing that a stone would cause. It would have been much more difficult to discover at operation. It may have become necrotic, with ulceration and bleeding as a final episode. It is conceivable that the patient had a polypoid tumor in the distal portion of the common duct that caused this type of picture. Because I want to be a little different, and not just bet on the horse that usually wins, it seems to me that some mechanism such as that would come nearer to satisfying my concept of this picture than that of stone. I simply am going to hazard a guess, and it is a guess, that he had some such obstruction as a polypoid tumor in the distal common duct that caused intermittent blockage, with superimposed cholangitis. I suspect that he had multiple abscesses of the liver at the time of death, and I believe that the precipitating factor in his death was probably hemorrhage from a localized area of necrosis and ulceration. I think also that he had a biliary type of cirrhosis.

DR SEDGWICK MEAD: Would you consider the possibility of liver abscess as precipitating the terminal event?

DR McKITTRICK Multiple, not single I would not know how to fit a single abscess into this picture

DR CHESTER JONES One of the things lacking in his picture was a spiking temperature I think we all considered the lack of a daily swinging temperature and chills very strong evidence against multiple liver abscesses

DR McKITTRICK Yes, I would agree

DR JONES It is always very pleasant to see someone else go through the same amount of sweating that one has gone through when confronted with a case like this Dr Myles Baker and I saw this patient over a period of three weeks before we and the house staff arrived at a final conclusion We thought that the cholangitis, jaundice, fever and laboratory data were in favor of obstruction and that there was a diffuse liver process resulting from years of intermittent partial obstruction In spite of that the liver biopsy was reported as normal I entertained the diagnosis of cirrhosis, doubting the correctness of the biopsy report, and asked to see the slide, it was sent to us from the other hospital I went over it subsequently with Dr Mallory It did not seem to fulfill the usual criteria that I would expect to find with biliary cirrhosis The section I saw, as I recall it, had among other things definitely dilated sinusoids They were very wide, and I wondered at the time and made a note that this might be Chiari's syndrome with blockage of hepatic veins Then the question came up concerning what might produce that condition Chiari's syndrome, especially one of hepatic-vein blockage, can be due to various abnormalities, the commonest of which is cancer It may be due to an inflammatory process It may be found in straight cirrhosis, not of the biliary type The terminal event, the massive hemorrhage, would make me wonder whether there was an active ulcerative lesion that was connected with the original cause of the disease I would think it would probably be placed in or near the ampulla of Vater, probably in the duodenum We were trying to get him ready for surgery of course

CLINICAL DIAGNOSES

Gastrointestinal hemorrhage
Cholangitis
Obstructive biliary cirrhosis

DR McKITTRICK'S DIAGNOSES

Polypoid tumor of common duct with ulceration and hemorrhage
Cholangitis
Biliary cirrhosis
Multiple abscesses of liver?

ANATOMICAL DIAGNOSES

Adenocarcinoma of ampulla of Vater
Hemorrhage, massive, into biliary and intestinal tracts

Cholangitis, acute and chronic, slight
Pancreatitis, chronic
Operative wound, old cholecystectomy

PATHOLOGICAL DISCUSSION

DR TRACY B MALLORY At post-mortem examination the intestinal tract and the common bile duct were filled with fresh, red blood On clearing that away we found the common duct to be widely dilated, as were the ampulla and the opening into the duodenum Around the area where the ampulla should have been was a large ulcer with a border of obviously carcinomatous tissue The primary lesion in this case was undoubtedly a tumor of the ampulla, and as Dr McKittick

FIGURE 1

stated, polypoid in the early stage but later becoming frank, ulcerative carcinoma It was a well differentiated and slowly growing adenocarcinoma (Fig 1) and could well have been present for two and a half years The liver was much enlarged, weighing 3000 gm The microscopical sections were characteristic of biliary cirrhosis I was surprised in view of the history that there was relatively little

evidence of cholangitis. The other findings were coincidental. There were no esophageal varices. The spleen was considerably enlarged, it looked like an infectious spleen rather than that of a portal hypertension. Nothing else of significance was found.

DR JONES: I assume that the original biopsy was taken close to the gall-bladder bed. How much difference is there between a biopsy from that location and a biopsy of the liver taken from a site farther away from the gall-bladder bed, in a patient with biliary cirrhosis?

DR MALLORY: In cases of frank cholecystitis there may be localized inflammation in the adjacent portions of the liver. It is not a fair picture of the liver as a whole. I do not think there would be any danger of missing a generalized process such as biliary cirrhosis from the taking of a biopsy. The danger is the reverse. One might discover a local lesion and interpret it as a general one.

DR MCKITTRICK: What do you suppose caused the episodes of obstruction? Edema with ulceration?

It is intriguing that the surgeon who operated found dilatation of the ampulla as you found at autopsy, and yet the patient still had these definite bouts of obstructive jaundice. There must have been obstruction to cause such a dilatation.

DR JONES: That original finding was eight months before.

DR MALLORY: Dr Kernohan, you have probably seen many cases of this type at the Mayo Clinic. Do you want to tell us about them?

DR JAMES W. KERNOHAN: I have seen this phenomenon several times: ulceration around the ampulla of Vater with intermittent jaundice, and at autopsy a papilla or common duct widely open, with terminal hemorrhage.

CASE 35472

PRESENTATION OF CASE

First admission. A sixty-two-year-old Italian housewife, para V, gravida VIII, was admitted to the hospital complaining of vaginal bleeding.

She had been well until the age of fifty, twelve years before admission, when her menstrual bleeding became very profuse. She was given "radium to the uterus" at another hospital, following which her periods ceased. Three weeks before admission a slight, constant, bloody, vaginal discharge began.

Physical examination showed an obese well developed woman in no discomfort whose only significant abnormality was an orange-shaped mass in the left lower quadrant. Urine and blood examinations were not remarkable. Vaginal smears were consistent with adenocarcinoma. Intravenous pyelogram, a barium enema and a metastatic series were negative. At operation a nodular tumor was found in the left cornu of the uterus and a radical

total hysterectomy with bilateral salpingo-oophorectomy was performed. Pathological examination showed an adenocarcinoma of the fundus, Grade III. Following an uneventful recovery the patient was discharged to the tumor clinic, where she received 3950 r from the million-volt machine with good response.

Second admission (fifteen months later). For the year following discharge she was seen at regular intervals. No sign of recurrence was noted, and the patient felt well and gained 15 pounds. Two months before her second admission she had a two-day episode of dull pain in the right lower quadrant unassociated with other symptoms and relieved by a hot water bottle. She was then well until six days before admission, when similar right-sided pain recurred, unaccompanied by gastrointestinal or urinary symptoms. No light stools or dark urine was noted. She consulted her physician, who, after finding one degree of elevation of temperature, advised hospitalization although the pain abated spontaneously.

Physical examination revealed a patient in no apparent distress. The temperature was 99.5°F. There was no abdominal spasm or costovertebral-angle tenderness. However an 8-cm, movable, slightly tender right-lower-quadrant mass was felt. The urine was normal. The hemoglobin was 12.0 gm per 100 cc, and the white-cell count was 8400. Intravenous and retrograde pyelograms showed displacement of the lower pole of the right kidney anteriorly. A barium enema disclosed incomplete filling of the cecum and confirmed the presence of an abdominal mass.

The patient was started on Crysticillin therapy in spite of which the temperature fluctuated between 99 and 102°F, although the white-cell count remained normal. On the ninth hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR GORDON A. DONALDSON*: One would gather that this patient was the cause of considerable thought and study on the surgical service, where she remained nine days preoperatively. Inasmuch as the x-ray films were of such value, I think we ought to see them early to direct our discussion. I think it is of interest and of value that x-ray films taken fifteen months previously were reported as normal.

DR JOSEPH HANELIN: I have only the films of the present admission. The first examination done was a plain film of the abdomen, which was followed by an intravenous pyelogram, and later a retrograde pyelogram. On the intravenous pyelogram it is possible to see the large mass opposite the right iliac crest, extending almost an equal distance above and below the crest.

DR DONALDSON: Is that the cecum?

*Assistant surgeon, Massachusetts General Hospital.

DR HANELIN I am not certain. In a number of the films, although they are not described in the protocol, are two small calcifications in the region of this density. One is triangular in shape, and one is circular. The left kidney appears quite normal. The right kidney is unusually placed. The lower pole is swung medially and somewhat in an anterior direction. The ureter may be displaced slightly in a medial direction. The apparent displacement of the upper calyces probably results from the distortion caused by rotation of the kidney rather than an intrinsic renal lesion. Films of the chest and skull were normal. A barium enema done between the intravenous pyelogram and the retrograde study shows deformity of the cecum. The cecum is elevated, and in a spot film it is seen to terminate abruptly. The appearance of the cecal deformity is suggestive more of an extrinsic mass with a nodular outline than of a tumor arising from the cecum itself. In the spot films the two small calcium densities are again noted. They seem to be in relation to the edge of the deformed cecum and make one wonder about the possibility that they are fecaliths in the appendix.

DR DONALDSON I gather that the cecum does lie high. Also, this mass is larger than the protocol led me to believe, certainly larger than 8 cm. If this is a mass it is 20 by 20 cm, perhaps.

Two events took place in the interval between the time when the x-ray studies were read as normal and the present x-ray films. One is the finding of a definite adenocarcinoma of the uterus, which was removed. Moreover, this adenocarcinoma was a palpable one preoperatively. Because of the fact that it was palpable and she was given x-ray treatment after removal of it I would conclude that her cancer was an extensive one. I think the opinion in the gynecologic service is that x-ray treatment rarely need be given after radical total hysterectomy for fundal cancer unless gross disease such as peritoneal implants is left behind. There is one other point in favor of recurrent disease, and that is the site of the mass seen by x-ray study. It is possible to have recurrence in this location from carcinoma of the uterus because of the distribution of the ovarian lymphatics. They run up in this direction, and tumor or cells, after reaching the lymph nodes, could displace the lower pole of the kidney anteriorly. However, in spite of these points in favor of recurrent cancer, I should turn

to the other events that took place in the interim—that is, the onset of definite attacks of right-lower quadrant pain eight weeks before, lasting a couple of days, the other having occurred one week before and lasting approximately six days. These episodes were definite and caused the patient to go to a doctor.

This brings us to the latter part of the history and leaves us with a story of pain, the finding of this mass on physical examination and the x-ray report. I think it boils down to analyzing these points to bring us to a diagnosis.

In one last attempt to tie the present mass up with the previous operation, I wonder if this might have been a residual hematoma, or a foreign body resulting from previous operation. About a year ago at these conferences a case was presented* in which a hysterectomy had been done, with the subsequent development of a mass requiring reoperation approximately six or eight months later. At that time a large cyst was found—a persistent, slowly organizing hematoma around the left ovarian pedicle. In today's case, however, a mass had never been felt on numerous occasions in the Out Patient Department follow-up study, and I doubt if such a cyst was present. Another possibility is that this was secondary to the heavy x-ray therapy. Could it be that this was ileitis with abscess formation in a woman who was otherwise well and had gained 15 pounds in weight? I believe both are unlikely. I think Dr. Hanelin would agree that this tumor causes extrinsic pressure on the cecum and not within the cecum itself. We have to look outside the cecum. A huge lipoma at the pole of the cecum could give such a picture. The cecum and hepatic flexure are favorite sites for large-bowel lipomas. The mass is quite large, however.

Of course the obvious organ in this region is the appendix. Could this have been a carcinoid of the appendix? Finally, could it have been an inflammatory process in the appendix itself? The temperature did not respond to Crysticillin therapy. We do not know how much Crysticillin she received, but it is a fact that organized pus produced by the flora in the colon does not respond to antibiotics, and one usually has to resort to surgical drainage of such collections of pus. I think that is a point that directs us toward an abscess produced by the

*Case Records of the Massachusetts General Hospital (Case 35032)
Am. J. Med. 240:111-113, 1949

colon bacillus and other cocci. The most likely cause for such an abscess is the appendix. The white-cell count was not elevated. Very often in retrocecal appendicitis, in elderly people particularly, the white-cell count is not elevated. There are other points in favor of a retrocecal location. The x-ray picture showed displacement of the cecum anteriorly. The pain, moreover, began in the right lower quadrant and gave quite bizarre subjective symptoms. This is the story very often found in retrocecal appendicitis. I think it is very unlikely that the kidney was behind all this trouble. I am left with a diagnosis of inflammation, probably arising in the appendix, and in all probability well walled off by the cecum and omentum.

DR JACOB LERMAN: Did the retrocecal mass extend high enough to distort the kidney?

DR HANELIN: I would think not.

DR DONALDSON: Appendicitis going on for two months might be associated with large lymph nodes in that region, which possibly might distort the kidney.

CLINICAL DIAGNOSIS

Appendiceal abscess

DR DONALDSON'S DIAGNOSIS

Appendiceal abscess

ANATOMICAL DIAGNOSIS

Metastatic adenocarcinoma of appendix with appendiceal abscess

PATHOLOGICAL DISCUSSION

DR BENJAMIN CASTLEMAN: The surgical service's preoperative diagnosis was also appendiceal

abscess. At operation the surgeon disclosed a large, firm retrocecal mass that looked like an old appendiceal abscess. It was very adherent to the ileum and cecum but was freed from them without entering either organ. In the process what was believed to be the stump of the appendix was removed. When we received the material it was in several pieces. One piece, obviously the tip of the appendix, about 5 cm in length, was surrounded with brawny inflammation. The proximal piece was apparently opened and it was also part of the appendix. On microscopical examination the tip and distal parts of the appendix looked just like an appendiceal abscess. There were acute and chronic inflammation and fibrosis around and invading the wall of the appendix, which was very edematous, but the part adherent to the cecum, the proximal part that had broken off, contained in the serosa an area of adenocarcinoma, very similar to the carcinoma of the uterus previously removed. The appendiceal abscess about which there was no doubt, had therefore been produced by carcinomatous obstruction of the proximal portion of the appendix. There were some foci of calcification in one of the sections.

DR HANELIN: Was there any explanation for the apparent renal displacement?

DR CASTLEMAN: The surgeon did not mention it. I am sorry he is not here. In going over the old sections of the cancer of the fundus, it was apparent that the tumor was highly malignant, it had invaded the myometrium at the time of the first operation, and the ovaries and tubes were adherent to it.

REJECTED SUITOR

OSCAR R. EWING, federal security administrator, appears to have misjudged the quality of his listeners in a speech made before the National Association of Retail Druggists on September 20. Mr. Ewing, apparently unmindful of the professional quality of the pharmacists' services, based his appeal for their support of compulsory health insurance almost entirely on the profit motive.

"Certainly," he reminded them at one point in his address, "any major progress we make in this age-old struggle against sickness and disease is sooner or later reflected in larger receipts for your own cash register." Again, in referring to the check-ups given last year to nearly two million children by public-health doctors or private physicians, he added, "And I don't doubt that most of the mothers wound up in the local drugstore with a doctor's prescription of one sort or another to be filled." And again, "Let me point out that the drug

trade flourishes in the shadow of the hospital," and "If we can double the number of hospital beds available — as we intend to do over the next ten years — the effect upon your business will be literally enormous." Nor are these the only examples of the theme song of this particular oration.

Since the days when the apothecary was often the doctor and the doctor usually compounded his own prescriptions, up to the present, when the large-scale pharmaceutical manufacturer is a close ally in the progress of modern medicine, the reputable druggist has been an unselfish partner of the reputable physician in the care of the sick. Working long hours, frequently holding himself available day and night for emergency service, the responsible druggist rightly considers himself as something much more than a tradesman.

Subsequent to Mr. Ewing's speech a resolution was passed by the Association repudiating the federal political health scheme.

Mr. Ewing, in his administration of the Federal Security Agency, has demonstrated his capacity for becoming a valuable and highly regarded public servant. There is little doubt that he is one of the able men of the present administration. The question can be raised, however, whether he is serving his country to his fullest capacity while he is almost obsessively preoccupied with the promotion of a plan to which the country is apparently not receptive.

PRIVATE SUPPORT OF SCIENTIFIC RESEARCH

IN THESE days of ever-expanding federal aid to, and participation in, scientific endeavor it is encouraging to consider the record of projects in scientific research that function entirely through contributions from private sources. Private philanthropy, in recent years, has received less than its due share of recognition, mainly owing to the fact that Government aid has been extended on such a scale and with such publicity that more modest contributions, by contrast, appear to be of small moment.

The achievements of investigators supported by grants from such sources as the Rockefeller and Carnegie foundations speak for themselves — even

when compared with work performed under the sponsorship of the federal Government. An example of the organizations that offer substantial, if little-publicized, aid to scientific research on a world-wide scale is provided by the Ella Sachs Plotz Foundation for the Advancement of Science. Of particular interest are the grants, made during the twenty-fifth year of the Foundation's existence, to men working on various experiments in the United States: to Dr. Charles P. Laman, of Harvard Medical School, for the purchase of apparatus essential to the continuation of metabolic studies in hibernation, to Dr. Bernard J. Miller, of Jefferson Medical College of Philadelphia to defray the cost of equipment for the direct determination of blood volume by measurement of the dye T-1824 in the circulation of the ear, to Dr. Carl Neuberg, of New York University, for research on inorganic and organic phosphates, to Dr. C. I. Reed, of the University of Illinois, for the purchase of x-ray apparatus for the study of metabolism of bone as influenced by various sex hormones, and to Dr. Ernst A. Scharrer, of the University of Colorado, for the purchase of amphibia for continuation of work on neurosecretion.

All due publicity should be given the aid offered by the Ella Sachs Plotz Foundation as well as the larger grants made in the names of the Markles, the Carnegies and the Rockefellers. This is not to deny that, at present and probably for years to come, federal support of scientific investigation will still be essential. But these sources of private aid should be kept in mind when the record of Government sponsorship is held up as evidence that extended federal participation and other steps along the road to state control of scientific research should be provided for. So long as the philanthropic organizations, great and small, continue their contribution no state dole in the sciences appears necessary.

IS SYPHILIS VANISHING?

UNDER the title of "The Vanishing Lesion," Dr. C. Morton Smith,¹ twenty-nine years ago, wrote the following sentences:

The disappearing of cutaneous syphilis lesions confronts us with a new problem. The teacher of clinical syphilis

must regard this changing condition with real apprehension. One no longer sees in the clinic the array of active lesions that were formerly available for teaching purposes.

Today, the evidence points not only to the further vanishing of cutaneous lesions but also to an actual decrease in the incidence of syphilis itself. This decrease is shown most strikingly in a table, published in a recent number of the *Journal of Venereal Disease Information*,² that indicates the sharp decline in latent and early cases of acquired syphilis reported by states and territories since the year 1941 when reporting by stage was first initiated by the various states.

Over a similar period the statistics of the Army and the Navy have shown decreases in the discovery rate of syphilis. Of course the discovery rate may not be the incidence rate, but the United States Public Health Service believes that an analysis of the accumulated figures gives support to the fact that syphilis is decreasing. Theoretically, more cases should have been detected if they existed because during the last few years contact investigation has improved, the medium of public appeal has been emphasized and one may assume that the effectiveness of case finding has improved rather than diminished.

It is possible that the widespread use of penicillin in the treatment of gonorrhea and other diseases accounts to some extent for the decreased incidence of syphilis. It had been thought that the amount of penicillin used for gonorrhea would be insufficient to control syphilis as well, but the follow-up study of men discharged from the armed forces after treatment of gonorrhea by penicillin has not, thus far, revealed any significant amount of syphilis that was masked by the drug. Such cases, however, should still be followed for the possibility of syphilis.

It is also possible, with the shorter schedule of therapy in use today, that the treatment of syphilis has been shifting from public clinics to the offices of private physicians. Whether the private physician reports cases of syphilis as faithfully as the clinics do is a matter of doubt, but available evidence indicates that the decrease reported in private practice is comparable to that in the clinics.

There are still many areas in the country in which well organized case-finding programs and reporting

systems have not yet been developed. Every effort should be made to extend the use of adequate case finding and reporting to the whole nation, and to detect all possible cases of syphilis that arise so that adequate treatment can be given and the late effects of the disease prevented.

Although the day of the "one-shot cure" for syphilis has not yet arrived and it is still too early to be sure that a latent period is not produced by penicillin therapy, it is encouraging that the incidence of syphilis has shown this definite decrease in the last few years.

THE CHRISTMAS SEAL

THE annual sale of Christmas Seals, between November 21 and December 25, not only serves as a reminder that the money contributed in this campaign provides the entire financial support of the National Tuberculosis Association and its 3000 affiliated organizations but also re-emphasizes the challenge offered by a disease that ranks seventh among the leading causes of death. Each year the Association asks for contributions so that its effort toward control and eventual suppression of tuberculosis may continue.

The facts about this disease are sobering, in spite of the progress that has been made. Tuberculosis kills nearly 1000 Americans a week — at a rate of 1 person every eleven minutes — and remains the leading cause of death among persons from fifteen to thirty-four years of age. It causes more deaths than any other infectious disease or any disease due to a germ, being responsible for 1 out of every 30 deaths among white people and 1 out of every 12 among Negroes. The economic losses are also serious: the care of tuberculous patients in hospitals in a single state (New York) cost \$23,000,000 last year, and expenditures from public and private sources in the country as a whole are estimated at

more than \$350,000,000 a year, to this figure must be added the cost of hospital construction, lost wages, lowered production and broken homes. The toll is even more disheartening when it is realized that, although the disease is both preventable and curable, at least 500,000 Americans have active tuberculosis, and only half these cases are known to health authorities.

It is this quarter of a million people on whom the program of control must be concentrated. Thus far, the most important step in this direction has been the chest x-ray examination, by means of which the disease can be discovered in its early, symptomless stage, when it is easiest to cure. Part of the activity of the tuberculosis organizations consists in group and, in co-operation with public health agencies, community-wide x-ray surveys. The year-round campaign of the National Tuberculosis Association and its subsidiary groups emphasizes education and dissemination of correct information, case finding, rehabilitation and medical research — a sound program of preventive medicine.

Tuberculosis, in the forty-five years of the Association's existence, has dropped from first to seventh place among the leading causes of death, the death rate being cut 85 per cent. This encouraging trend must be continued. But until control has reached the point where the disease no longer kills and no longer causes economic loss on a vast scale, the effort toward eradication must be supported. All physicians are urged to contribute generously through the purchase of Christmas Seals, the symbols of an excellent program of preventive medicine made possible by a voluntary and united response to the appeal of the sick and unfortunate.

Boston Eye and Ear Infirmary — *The new edifice in Charles Street, is nearly ready for the reception of patients. It is to us a complete architectural abortion. There is neither elegance nor convenience discoverable to our eyes, in its exterior. A beautiful site for a public building has, we think, actually been spoiled.*

MASSACHUSETTS MEDICAL SOCIETY

DIRECTORY OF OFFICERS AND FELLOWS

The 1949 edition of the *Directory of Officers and Fellows of the Massachusetts Medical Society* is now available. Fellows may receive a copy of the directory by writing to the Secretary at the Society Headquarters at 8 Fenway, Boston

H QUIMBY GALLUPE, *Secretary*

PHYSICIANS MUST TAKE OATH

To the Fellows of the Massachusetts Medical Society

The following memorandum from the Division of Vocational Rehabilitation of the Massachusetts Department of Education dated October 28, 1949, is of interest to any physician who may be employed by the Commonwealth

H QUIMBY GALLUPE, *Secretary*

To Rehabilitation Division Personnel
From Mr Edward D Callahan

Subject Chapter 619, Acts of 1949, "An Act barring certain people from the public service"

The above-mentioned act becomes effective on October 28, 1949. A copy is attached to this memorandum. The Attorney General has advised the Secretary of State that "It is my opinion that every person upon entering the employment of the Commonwealth or of any political subdivision thereof, including counties, cities, towns and districts, is required under the express terms of the statute, before entering upon the discharge of his or her duties, to take the prescribed oath, or affirmation, in the form set out in the statute and subscribe his or her name to it on a blank form prepared for the purpose, under the penalties of perjury. Under the terms of St. 1949, Chapter 619, it will not be necessary for anyone to take the oath or affirmation before a justice of the peace, or other officers qualified to administer oaths."

Under present interpretation of the new law it will be necessary for the Division to secure the signature to the oath card of any individual whose services are to be used by the Division. This signature is to be secured before any authorization for service is to be sent to an individual and before any proposal for service is sent to Administrative Office. Physicians whose services are to be used for a general or specialist examination, tutors, or any other individual whose services are to be used should be advised of the requirements of the new law and signature secured. The signed card should be attached to the proposal sent from the District Office to the Administrative Office. No proposal for service by an individual will be approved unless a signed card is attached with the exception that if a person has signed a card which has been sent to the Administrative Office subsequent proposals will be accepted without an additional signed card. It will not be necessary to secure signed cards from agencies such as schools, hospitals, or companies authorized to furnish employment training. The act applies to the services secured from an individual. When signed cards are received at Administrative Office they will be sent later to the Secretary of State for filing. If an individual whom you plan to use for service to the Division does not wish to sign a

card the Division cannot authorize the service. District Supervisors should advise me of any such refusals.

A supply of oath cards is transmitted herewith. It is not necessary to keep a copy of signed card in District Office but I suggest a list be kept of individuals signing cards in order to know that a second card does not need to be secured.

When a proposal is sent to Administrative Office a statement can be typed on proposal "Oath card attached." This statement should carry a check mark to the right. If no card is needed because a signed card has earlier been sent a statement "Oath card previously submitted" should be typed and a check mark made to the right of the statement.

Chapter 619

AN ACT BARRING CERTAIN PEOPLE FROM THE PUBLIC SERVICE

Chapter 264 of the General Laws is hereby amended by adding at the end the three following sections — *Section 13* No person who is a member of the communist party, or is a member of or supports any organization which advocates the overthrow by force, violence or other illegal or unconstitutional methods, the government of the United States or of this commonwealth shall be employed in any capacity by the commonwealth or any political subdivision thereof.

Section 14 Every person entering the employ of the commonwealth or any political subdivision thereof, before entering upon the discharge of his duties, shall take and subscribe to, under the pains and penalty of perjury, the following oath or affirmation —

"I do solemnly swear (or affirm) that I will uphold and defend the Constitution of the United States of America and the Constitution of the Commonwealth of Massachusetts and that I will oppose the overthrow of the government of the United States of America or of this Commonwealth by force, violence or by any illegal or unconstitutional method."

Such oath or affirmation shall be filed by the subscriber, if he shall be employed by the state, with the secretary of the commonwealth, if an employee of a county, with the county commissioners, and if an employee of a city or town, with the city clerk or the town clerk, as the case may be.

Section 15 Violation of section thirteen or fourteen shall be punished by a fine of not more than ten thousand dollars or by imprisonment for not more than one year, or both.

Approved July 30, 1949

NOTE — The above is applicable to "every person entering the employ of the Commonwealth or any political subdivision" hereafter. In the case of new employees (entering) see to it that they file such oaths before the city clerk or town clerk who will, no doubt, furnish the blank forms.

DEATHS

AKIN — Moses Akin, M.D., of Ellenville, New York, died on July 11. He was in his sixty-second year.

Dr Akin received his degree from Tufts College Medical School in 1925. He was a nonresident member of the Massachusetts Medical Society.

His widow and a sister survive.

GRANDISON — Wilfred G. Grandison, M.D., of Charlestown, died on November 6. He was in his seventy-fourth year.

Dr Grandison received his degree from Tufts College Medical School in 1901. He was a former president of the Charlestown Medical Society and a fellow of the American Medical Association.

His widow, a son, two daughters, three sisters and two brothers survive.

HEPBURN — James J. Hepburn, M.D., of Norwood, died on October 26. He was in his sixty-seventh year.

Dr. Hepburn received his degree from Harvard Medical School in 1909. He was formerly surgeon-in-chief of Boston City Hospital and was professor of surgery, emeritus, at Tufts College Medical School. He was a member of the New England Surgical Society and a fellow of the American College of Surgeons and the American Medical Association.

His widow, three sons and two sisters survive.

RUEL — Joseph A. Ruel, M.D., of Haverhill, died on July 28. He was in his seventy-first year.

Dr. Ruel received his degree from Tufts College Medical School in 1911. He was a member of the staff of Hale Hospital.

His widow, a daughter and a granddaughter survive.

RUSHFORD — Edward A. Rushford, M.D., of Salem, died on October 25. He was in his sixty-seventh year.

Dr. Rushford received his degree from Tufts College Medical School in 1905. He was a fellow of the American Medical Association.

His widow, a son and two daughters survive.

NEW HAMPSHIRE MEDICAL SOCIETY

DEATH

KING — Francis B. King, M.D., of Derry, died on July 10. He was in his forty-sixth year.

Dr. King received his degree from Tufts College Medical School in 1934. He was formerly medical referee for Rockingham County and was a member of the staff of Alexander-Eastman Hospital in East Derry.

His widow, a daughter, a son, his mother and a brother survive.

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

CONSULTATION CLINICS FOR CRIPPLED CHILDREN IN MASSACHUSETTS

The December schedule for Consultation Clinics for Crippled Children in Massachusetts under the provisions of the Social Security Act follows:

ORTHOPEDIC CLINICS	DATE	CLINIC CONSULTANT
Lowell	December 2	Albert H. Brewster
Salem	December 5	Paul W. Hugenberger
Haverhill	December 7	William T. Green
Brockton	December 8	George W. Van Gorder
Greenfield	December 12	Charles L. Sturdevant
Gardner	December 13	Carter R. Rowe
Worcester	December 16	John W. O'Meara
Fall River	December 19	David S. Grice
Springfield	December 20	Garry deN. Hough, Jr.
Pittsfield	December 21	Frank A. Slowick
Hyannis	December 22	Paul L. Norton

RHEUMATIC FEVER CLINICS

	DATES
North Reading	December 6, 13, 20, 27
Fitchburg	December 7, 14, 21, 28

Physicians referring new patients to clinics should get in touch with the district health officer to make appointments. Patients are seen by appointment only.

MISCELLANY

INSTITUTE FOR SPEECH CORRECTION

Under the will of a Springfield physician, the Institute for Speech Correction is now receiving the perpetual income from a substantial legacy. All income from this fund is awarded in the form of tuition scholarships to pay that portion of a

student's tuition which he himself is unable to finance. Full scholarships are awarded to many worthy students. Thus far there have been ample scholarships to provide for all who need them.

Scholarships are now available for stutterers, lispers, deaf persons and persons of any age who are handicapped with other speech and voice disorders, upon recommendation of their family physicians.

The Institute is a nonprofit, educational corporation. Several eminent physicians and educators serve without remuneration on its board of trustees.

CORRESPONDENCE

AMERICAN CANCER SOCIETY

To the Editor The editorial entitled "First Things First," which appeared in the October 13 issue of the *Journal*, makes a plea for a united fund-raising drive for all national health organizations to take the place of the separate campaigns of the March of Dimes, American Red Cross, American Cancer Society and so forth. The editorial states, "No more than two drives should be tolerated by the people in any one community." (This refers to one joint drive for local charities and another joint drive for the national organizations.) The American Cancer Society is convinced that any such joint drive would be harmful to the people of the country and, this summer, has made the following statement explaining why it believes as it does:

The American Cancer Society is much more than a charity. The most fundamental reason why anybody should give money to the American Cancer Society, or work for it as a volunteer, is not to help somebody else — but to contribute to the future security of his family and himself.

The most important and extensive work of the American Cancer Society concerns research and education. These activities benefit rich and poor without distinction.

The greatest single reason why the American Cancer Society cannot agree to attempt raising the funds it needs through the federated plan is that to do so is unfair to the giver, and would probably increase the number of cancer deaths forthwith. Here is why: the Society's fund-raising effort takes place during the month of April, which has been designated by Congress as Cancer Control Month. Volunteer workers for the Society use the occasion of calling on people to secure contributions also to instruct and educate the givers on what to do about cancer, how to detect it in its early stages. The April cancer drive is a huge educational effort as well as a big job of fund-raising. The education of people to "see your doctor in time," to "watch for cancer's danger signals" — with detailed descriptions of what these signals are — is undoubtedly the most effective single weapon available to the American Cancer Society for saving lives now. This is how people are saved from the ravages of cancer today.

Experience has shown it is vitally important to carry out the fund-raising and the educational efforts together. When a person gives his money to fight against cancer, he feels he has a stake in the whole thing. He becomes more vigilant about his family and himself. It would be a needlessly dangerous experiment to try to separate the educational and fund-raising efforts in the war against cancer. Of course, educational work is carried on by the Society at all times during the year but the great push is during the fund-raising drive — when the Society's more than one million volunteers take to the field.

To suspend this nationwide life saving crusade, and instead to be pipe-lined funds effortlessly and by remote control — through federated drives — is totally unthinkable to anyone who knows anything about the cancer problem.

CHARLES C. LUND, M.D., President

American Cancer Society
(Massachusetts Division), Inc.

CONTROL OF LIPOATROPHY

To the Editor I read with great interest the paper "Lipoatrophy Following the Injection of Insulin" by W. S. Collins and associates in the October 20 issue of the *Journal*. These authors suggested a method of control of insulin fat atrophy by a simple procedure of repeated insulin injections into the depressed areas. In the interest of diabetic patients I believe that this suggestion should be accompanied with a warning that very often these areas of atrophy become unresponsive to injection because of fibrosis, with concomitant lack of expansibility. This causes the necessity of increasing the pressure on the plunger of the syringe to force the insulin into the resistant tissues. Mishaps, such as spillage when the needle slips off the syringe, and even breakage of the syringe frequently occur. Moreover, the absorption time of the insulin from the atrophied area is uncertain. These factors occasionally increase the difficulties of good control in the able diabetic patient.

JAMES C. BRUDNO, M.D.

Quincy, Massachusetts

BOOK REVIEW

Das large Becken. Geburtshilfliche Studie über das Assimilationsbecken. By Prof. Dr. Heinz Kirchhoff, physician-in-chief of the Municipal Women's Clinic, Lübeck. 8°, cloth, 144 pp., with 111 illustrations. Stuttgart: Georg Thieme, 1949. Imported by Grune and Stratton, Incorporated, New York. \$6.00.

The studies on which this monograph is based were begun at Kiel and Leipzig before the war and were completed in 1947 at the Women's Clinic in Lübeck. The author describes as an anatomic and clinical entity a developmental disturbance, the assimilation pelvis, first noted nearly half a century ago by Breus and Kolisko, but not hitherto recognized as of obstetric importance.

The assimilation pelvis, of which Kirchhoff describes three principal types, arises from variations in the transitional vertebrae between the lumbar and sacral regions, and is characterized by the presence of six lumbar vertebrae, by sacralization of the last lumbar vertebra and usually by the existence of five pairs of anterior and posterior sacral foramina. The result produces what has been called the canal pelvis, which Kirchhoff terms the long pelvis, because the length of the birth canal is actually greater than the internal conjugate diameter—it is longer than it is deep, or broad anteroposteriorly. It is not the same as the flat rachitic pelvis, with which it may be combined.

The assimilation pelvis Kirchhoff has found by x-ray examination to be much commoner than is ordinarily supposed. He believes it to be a frequent cause of dystocia and prolonged labor because it interferes with the normal mechanics of labor by preventing the engagement and descent of the head. It therefore becomes an obstetric problem of profound importance, and its recognition before labor is essential and imperative.

The book has 111 illustrations by Ingrid Schaumburg, and a bibliography of forty titles.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Campbell's Operative Orthopedics. Editor, J. S. Speed, M.D., associate editor, Hugh Smith, M.D. In two volumes. 4°, cloth. Vol. I, 879 pp., with 573 illustrations. Vol. II, 849 pp., with 566 illustrations. St. Louis: C. V. Mosby Company, 1949. \$30.00.

This new edition of a standard treatise is the joint work of eleven specialists. The first edition was published in 1939 and reprinted in 1942. Dr. W. C. Campbell died in 1941. The text has been revised, and chapters on preoperative and postoperative care, peripheral-nerve injuries and amputations

have been added and new sections have been written on mold arthroplasty, ruptured intervertebral disks and on difficult and unusual nonunions. The illustrations also have been revised by the elimination of a third of the original drawings, which have been replaced by twice their number. The whole field of modern orthopedics has been covered, and the material is well arranged. Lists of selected references are appended to the various chapters, and there are author and subject indexes for each volume. The publishing is excellent. The set is recommended for all medical libraries and orthopedists and surgeons interested in surgery of the bones, joints, muscles and tendons.

The Pharmacologic Principles of Medical Practice. A textbook on pharmacology and therapeutics for medical students, physicians, and the members of the professions allied to medicine. By John C. Krantz, Jr., professor of pharmacology, School of Medicine, University of Maryland, and secretary of the general committee of revision of the *United States Pharmacopoeia*, and C. Jelleff Carr, associate professor of pharmacology, School of Medicine, University of Maryland, and auxiliary members of the revision committee of the *United States Pharmacopoeia*. 8°, cloth, 980 pp., with 94 illustrations. Baltimore: Williams and Wilkins Company, 1949. \$10.00.

This new textbook is intended for the medical student and the practicing physician. The main portion of the text is arranged according to the systems of the body. The first part is devoted to history, principles and an introduction to drugs. The second discusses the antiseptic drugs, including the antibiotics. An appendix concerns the discovery and evaluation of new drugs. Lists of selected references are appended to the various chapters. A comprehensive index concludes the volume. The text on twenty-three subjects was referred to competent authorities for review and criticism before the final manuscript was prepared. The book, therefore, in a way is a composite effort of a number of specialists. The material is well arranged, and the publishing is excellent in every way. It is recommended for all medical libraries and to all persons interested in clinical pharmacology, and should merit a wide distribution.

Atlas of Neuropathology. By Wm. Blackwood, M.B., F.R.C.S.E., assistant pathologist, the National Hospital, Queen Square, London, T. C. Dodds, F.I.M.L.T., F.I.B.P., F.R.P.S., laboratory supervisor, Department of Pathology, University of Edinburgh, and lecturer to the Society of Radiographers (Fellowship Course) Scottish Branch, and J. C. Sommerville, A.I.M.L.T., senior technician, Department of Neuropathology, University of Edinburgh and Scottish Mental Hospitals' Laboratory. With a foreword by Professor A. Murray Drennan, M.D., F.R.C.P.E., F.R.S.E., professor of pathology, University of Edinburgh. 8°, cloth, 199 pp., with 262 illustrations. Baltimore: Williams and Wilkins Company, 1949. \$9.00.

This atlas presents in one small volume a large number of illustrations in monochrome and color of the pathologic conditions most often met with in neuropathology. The illustrations have been made from slides and specimens, and the volume is intended for clinicians and pathologists beginning the study of the subject. The work is based on the demonstrations given in the laboratory of the Scottish mental hospitals and in the University of Edinburgh over a period of years. The material is divided into ten parts, the first of which illustrates the various cells and the reaction of the neurone to disease. The succeeding parts portray vascular disease, organismal infection, demyelinating disease of unknown etiology, intoxications and deficiencies, degenerations, mechanical trauma, hydrocephalus and displacements, tumors and errors in development. The text is confined to descriptions of the conditions illustrated. There is a good index. The plates are excellent, and the printing, which was done in Great Britain, is very good. The atlas should be in the reference collections of the large medical libraries and available to neurologists and pathologists.

The Epidemiology of Hemolytic Streptococcus during World War II in the United States Navy. By Alvin F. Coburn, M.D., The Rheumatic Fever Research Institute, Northwestern University Medical School, and Donald C. Young, M.D., medical director, Communicable Disease Service, Herman

Kiefer Hospital 8°, cloth, 229 pp., with illustrations and tables. Baltimore: Williams and Wilkins Company, 1949 \$4.00

This monograph constitutes a study of streptococcal diseases as they occurred in the four years of World War II, among more than 3,000,000 young Americans. It is a comprehensive study and supplies quantitative data on contamination by hemolytic streptococcus. There is a bibliography of seventy-three titles and a good index. The volume is well published. It is the type of book that should be in all medical libraries.

Early Recognition of Disease. Edited by Sir Heneage Ogilvie, K.B.E., D.M., M.Ch., F.R.C.S., and William A.R. Thomas, M.D. 8°, cloth, 134 pp. London: Eyre and Spottiswoode Publishers, Ltd., 1949. 10s. 6d. net. (*The Practitioner Handbooks*).

This monograph forms one of the English *Practitioner Handbooks*. It is a composite work by a group of fourteen specialists and covers the field of internal medicine, the eye, orthopedics, arthritis, cancer, mental disorders, neurologic diseases, complications of pregnancy and pediatrics. It is intended as a ready guide for the general practitioner. There is a good index and the small volume is well published.

Some Common Psychosomatic Manifestations. By J. Barrie Murray, M.A., M.D. (Cantab.), M.R.C.P., diagnostic physician, Tavistock Clinic, honorary physician, Bolingbroke Hospital, and honorary physician, The Margaret Street Hospital for Diseases of the Chest, London. 12°, paper, 101 pp. London: Oxford University Press, 1949. \$2.50.

In this small book the author discusses the effort syndrome and its symptoms, physical signs and differential diagnosis. There are also short chapters on the "low-back syndrome" and on treatment of psychosomatic disorders. There is a short bibliography and an index. The book is well published.

Manual of the International Statistical Classification of Diseases, Injuries, and Causes of Death. Sixth revision of the International Lists of Diseases and Causes of Death. Adopted 1948. Volume I. 8°, paper, 376 pp. Geneva, Switzerland: World Health Organization, 1948.

This sixth edition of a standard classification succeeds the *International Lists of Causes of Death*, the title of the fifth edition. It differs appreciably in its scope and arrangements from previous editions. It provides a single list applicable to both morbidity and mortality statistics, it defines the content of the individual categories of the classification with as much international uniformity as possible, considering the differences in languages and terminology, it represents for the first time international agreement on a uniform method of selecting the main cause to be tabulated, if more than one cause is stated on the death certificate, and the manual includes international rules to assist the compiler of morbidity and mortality statistics in the application of the classification. In the introduction the history of attempts to classify diseases from the time of Sauvages (1706-1777) to the present is given. The manual is well published and should be in all medical libraries.

NOTICES

ANNOUNCEMENTS

Dr. John J. Byrne announces the opening of an office at 520 Commonwealth Avenue, Boston, for the practice of surgery.

Dr. John A. Conroy announces the removal of his office to 684 Commonwealth Avenue, Newton Centre.

Dr. Ward I. Gregg announces the removal of his office to 1269 Beacon Street, Brookline.

WOMAN'S AUXILIARY TO SUFFOLK DISTRICT MEDICAL SOCIETY

A meeting of the Woman's Auxiliary to Suffolk District Medical Society will be held in Sprague Hall, Boston Medical Library, 8 Fenway, Boston, on Thursday, December 1, at 2:30 p.m. The speaker will be Mrs. Charles E. Ayers, of Worcester, president of the Woman's Auxiliary to the Massachusetts Medical Society.

LECTURES ON MORALS AND MEDICAL CARE

The last two of a series of four lectures on morals and medical care, sponsored by the Workers of the Common Life, will be delivered by Joseph F. Fletcher at St. John's Church, Roxbury Crossing, at 8 p.m., on the following dates:

Tuesday, November 29: The Right to Control Parenthood.
Tuesday, December 6: The Right to Die.

Admission is free.

NEW ENGLAND CARDIOVASCULAR SOCIETY

A meeting of the New England Cardiovascular Society will be held at the Peter Bent Brigham Hospital, Boston, on Monday, December 5, at 8:15 p.m., Dr. Samuel A. Levine presiding.

PROGRAM

Some Electrocardiographic Observations in Potassium Intoxication. Drs. Harold D. Levine, John P. Merrill, Walter Somerville and Stephen Smith, III.
Heart-Muscle Metabolism in Cardiac Failure Studied by Coronary Venous Catheterization in Man. Drs. Walter T. Goodale, Robert E. Olson, Donald B. Hackel and Lewis Dexter and Miss Florence W. Haynes.
Circulatory Dynamics in Constrictive Pericarditis. Dr. C. Glenn Sawyer, Richard Gorlin, James W. Dow, Eugene C. Eppinger and C. Sidney Burwell.
Salt Excretion during Water Diuresis. Dr. William B. Schwartz.
Further Observations on the Surgical Treatment of Coarctation of the Aorta. Dr. Robert E. Gross.
Paroxysmal Ventricular Tachycardia. A study of 107 cases. Drs. Samuel A. Levine and Charles A. Armbrust, Jr.

NEW ENGLAND PEDIATRIC SOCIETY

A meeting of the New England Pediatric Society will be held on Wednesday, December 7.

11:00 a.m. - 12:00 p.m. Clinical Session by Dr. Charles A. Janeway and staff. Amphitheater, Peter Bent Brigham Hospital.
12:00 p.m. - 1:00 p.m. Clinicopathological Conference. Amphitheater, Peter Bent Brigham Hospital.
2:30 - 4:30 p.m. Scientific papers dealing with ACTH. Amphitheater of Building C, Harvard Medical School.
4:45 p.m. Open discussion by members of the Massachusetts Chapter of the American Academy of Pediatrics concerning the findings of the recently published Academy study. (Members of the society are cordially invited).
5:30 p.m. Refreshments at Longwood Towers.
6:30 p.m. Dinner at Longwood Towers (price, \$3.25).
7:30 p.m. Psychiatric Aspects of Rheumatic Disease. Dr. Alfred O. Ludwig.

THROMBOANGIITIS OBLITERANS*

An Evaluation of Therapy, with Special Reference to Lumbar Sympathectomy

EDWARD HAMLIN, JR., M D † RICHARD WARREN, M D, ‡ AND HARRISON E. KENNARD, M D §

BOSTON

THROMBOANGIITIS obliterans is an uncommon disease. The diagnosis was made at the Massachusetts General Hospital in only 180 cases during the twenty-year period 1926-1945. It makes up for its infrequency, however, by its chronicity, the 180 patients having had a total of 780 different admissions, or an average of over 4 admissions per patient, each one of which averaged thirty-two days or a grand total of 24,960 patient days or sixty-eight-and-one-third patient years. Thus, the problem of therapy is of considerable importance both to the patient and on general economic grounds.

The diagnosis of thromboangitis obliterans at the Massachusetts General Hospital is made for the most part on clinical evaluation. Surgical specimens have shown to a large extent the non-specific histology of the inactive phase of the disease. At the Massachusetts General Hospital a young male with evidence of obliteration of the major arteries in the lower extremities without x-ray evidence of calcification and almost always with a relatively long history of intermittent claudication fulfills the necessary criteria for diagnosis. A history of migrating phlebitis, ulceration of toes, increased susceptibility to cold and excessive use of tobacco serve as confirmatory evidence.

The sufferer from thromboangitis obliterans is relatively young, well under the age when arteriosclerosis may produce much the same clinical picture. Eighty-seven per cent of our patients were in the third to fifth decades, and 41 per cent were between thirty and forty years of age (Table 1).

It should be noted that 22 patients are listed in Table 1 as having thromboangitis obliterans although their first admission to this hospital occurred at fifty years of age or older. We believe that

by the time the age of fifty is reached thromboangitis obliterans will seldom initiate symptoms and also that in an old case symptoms at the age of fifty may be attributed to superimposed arteriosclerosis and yet in this group, the evidence on review of the records favors the diagnosis of thromboangitis obliterans, although, as emphasized above, it is by no means conclusive.

Incidentally, one of these more elderly patients was one of the 2 women in our series, aged sixty-

TABLE 1 *Ages, by Decades, of Patients at Time of First Admission*

AGE	NO OF PATIENTS	PERCENTAGE
10-19	1	less than 1
20-29	26	14
30-39	75	41
40-49	58	32
50-59	18	10
60-69	4	2
Total	180	

one, and the diagnosis was established by histologic examination.

It has been mentioned above that the symptoms of intermittent claudication in thromboangitis obliterans are usually of long duration. In this series the average interval between onset of symptoms and admission to the hospital was fifty months.

From a geographic standpoint 57 per cent of our patients were born in this country, 34 per cent in Russia or Poland, 6 per cent in Canada and 4 per cent each in Italy and Portugal. It is of interest that only 21 per cent were of Jewish extraction.

No particular occupation was engaged in by the group, there being an even spread among nine listed types of work. This is in agreement with the findings of others.¹

Since smoking is considered a contributory cause of the failure of therapy and by some, of the disease

*From the Department of Surgery, Massachusetts General Hospital.

†Associate in surgery, Harvard Medical School; assistant surgeon, Massachusetts General Hospital.

itself, we have endeavored to determine its incidence. Of 155 of the 180 patients from whom we could obtain definite information, 108 smoked more than 20 cigarettes a day, 44 smoked less than a package, and only 3 claimed that they never smoked.

TREATMENT

Almost all the forms of therapy that have been advocated for thromboangitis obliterans have been employed by the Vascular Service of the Massachusetts General Hospital at some time. These include nonspecific foreign protein, intravenous administration of hypertonic saline solution and of ether, histamine, ascorbic acid and sodium citrate solution. Some of these therapies were employed on only a very few patients, but none have impressed the Vascular Service sufficiently to ensure their continued use at the Massachusetts General Hospital.

Supportive

At the present time, the treatment of legs without open lesions consists of "foot hygiene," postural exercises² as modified by Allen,³ sympathectomy⁴ and an attempt at education of the patient including interdiction of tobacco.

Each patient is given a printed sheet, which contains information concerning the care of the feet and toenails and also diagrams and instructions including specific timing for postural exercises. The timing is determined by observation of the period necessary to produce blanching of the feet on elevation and full engorgement on dependency. It is believed that these times should be redetermined at intervals of a month or so.

Properly performed exercises are regarded as advantageous to the patient in two ways: there is good reason to believe, on the basis of repeated observations, that the development of collateral circulation is aided, and there is a benefit to morale, because the patient realizes that he is actively engaged in the therapy of his own disease.

It has been found that the patient's interpretation of the exercises must be checked at every opportunity, otherwise, gross errors and probably no benefits result.

Many of the forms of therapy described above could be included under "general education," but a specific effort is made to inform the patient of the nature of his disease, what the prognosis is, how it may be bettered, what sort of occupation he may engage in, how pain and discomfort may be handled and, most important of all, the need for avoidance of tobacco.

Obviously, the individual patient should be viewed with a proper perspective. It is better to enjoy life without legs than to spend every waking hour doing exercises to save legs that can never be of further use. Possibly, it is better in rare cases for a patient to smoke and thereby endanger his

legs than to suffer severe withdrawal symptoms, but if the patient disregards his instructions it should be because he has calculated the risk rather than through ignorance.

Sympathectomy

Lumbar sympathectomy has been considered to be the most effective form of therapy that we have employed. Since 1936 virtually all patients with thromboangitis obliterans have had bilateral lumbar sympathectomies. This involves 85 patients.

Since the etiology is unknown and the nature of the pathologic process is not entirely clear, it is impossible to think of sympathectomy as a specific therapy. Indeed it is almost certain that remissions and exacerbation of the disease still continue unaltered, but that the symptoms are usually ameliorated. The release of vasoconstrictor impulses can affect only the undiseased collateral circulation. It is apparent, therefore, that the earlier in the course of the disease sympathectomy is performed, the more benefit should be derived. Whether sympathectomized and hitherto undiseased arteries and arterioles are protected to any extent from the encroachment of thromboangitis obliterans is a question that at the moment cannot be answered.

Results. A follow-up study has been made in the hope of shedding light on two important questions—namely, the influence of sympathectomy on preservation of the extremity and its effect on the relief of symptoms.

Of the 170 legs that have been sympathectomized, 23, or 13.5 per cent, were subsequently amputated. If cases in which amputation was performed less than three months after sympathectomy are excluded (and since in many of these cases sympathectomy was performed as a last resort it seems reasonable to exclude them), the amputation rate is lowered to 9.4 per cent. These figures are to be compared with the 67 (35.2 per cent) of the total 190 legs not subjected to sympathectomy that were amputated. The figures are not, of course, strictly comparable since the unsympathectomized groups to a large extent were treated early in the twenty-year period, before some of the more modern concepts of general therapy were evolved, and also because there has been a longer period in which further arterial obliteration might develop. Nevertheless, it appears probable that some legs have been preserved by sympathectomy.

In an attempt to evaluate the symptomatic relief following lumbar sympathectomy, it was obvious that evaluation, difficult enough in any case, had better be confined to a definite symptom such as pain. We turned our attention, therefore, to patients with intermittent claudication or steady pain in their extremities unassociated with an open ulcer at the time sympathectomy was done. This strict requirement gave us only a small group of 30 extremities belonging to 18 patients that we

carefully studied. The patients were personally interviewed and examined.

The results are summarized in Table 2, which shows that although only 60 per cent of the extremities that could be evaluated showed improvement in intermittent claudication, 86.6 per cent demon-

strated improvement in general comfort—that is, increased warmth, disappearance of numbness and so forth.

Some⁵ have believed that sympathectomy should be more efficacious in patients with less damage to the circulation as evidenced by palpable popliteal pulsations. Table 3 shows that we have not found this to be true. The good and poor results are about evenly distributed among the patients with and without palpable popliteal pulses.

The optimum extent of lumbar sympathectomy has always been debated. The debate has centered around whether the first lumbar ganglion should be removed along with the second and third or whether removal of the latter two alone is sufficient. Although evaluation of this point can never be finally made until postoperative testing of the sympathetic denervation is accurately done, we have some information derived from the operator's impression of the extent of the sympathectomy performed. Table 4 correlates the removal or non-

TABLE 3 *Correlation of Presence or Absence of Popliteal Pulse with Improvement in Intermittent Claudication (25 Extremities)*

removal of the first lumbar ganglion with the effect on intermittent claudication. Although the numbers are too small to be conclusive, there is no tendency for them to suggest that the additional removal of the first lumbar ganglion contributed markedly to the subjective result.

The danger of interfering with sexual function is always debated when the extent of lumbar sympathectomy is considered for patients in this age group. We were able to analyze the results on 16 patients who had had unilateral (5) or bilateral (11) lumbar sympathectomy. We found that none of the 5 patients who had had a unilateral lumbar sympathectomy of any degree (4 of our 5 included the first lumbar ganglion) had any trouble with potency or ejaculation. Of the bilateral lumbar sympathectomies the first lumbar ganglion was removed bilaterally in 6 patients, all of whom had some trouble with sexual function (3 with ejaculation, and 3 with potency). In 1 of these patients the trouble with ejaculation was only temporary, lasting for three months. In another, ejaculation was not abolished but decreased by 75 per cent. In the other 4 cases trouble was complete and permanent. Two of the patients with bilateral lumbar sympathectomies had the first lumbar ganglion removed on one side but not on the other. Both had complete and permanent loss of ejacula-

Totals	14	9

tory power. In 2 patients only of the bilateral group were the first lumbar ganglions spared on both sides. Neither of these showed any interference with sexual function. Poppen and Lemmon⁶ found that 39 per cent of males who had the first and second lumbar ganglion removed from above on both sides for arterial hypertension had trouble with sexual function. They postulated that lower lumbar ganglions often participate in the regulation of such function. From this point of view, therefore, as well as from that of the clinical result, it is concluded that it is rarely advisable or necessary to remove the first lumbar ganglion when a lumbar sympathectomy for thromboangiitis obliterans is performed in young men. It is also important, if a bilateral operation is to be performed, to warn the patient of possible trouble, since owing to the variable arrangement of ganglions in this region,⁷ it is not always possible to preserve the first lumbar ganglion.

Since only 5 of the 18 patients could be said to have definitely abstained since the diagnosis was first made, the effect of smoking on this group of

patients could not be accurately assessed. Of the 7 extremities in these 5 patients, 6 were improved in varying degrees, only 1 was unimproved. We are of the opinion, from talking to the patients who did not abstain, that there is a great individual variation in sensitivity to smoking in patients with thromboangitis obliterans. Separation of the sensitive from the nonsensitive persons can be made, however, only by a process of trial and error that, at best, is unsatisfactory. Furthermore, it is well known that even those who are most sensitive will often continue to smoke in the face of the threatened loss of a limb. We therefore consider that a strict edict should be issued to all patients with thromboangitis obliterans that they abstain from smoking for life.

It is important that the surgeon have some knowledge of when maximal improvement may be expected to follow sympathectomy. In 13 of the 16 patients who were improved after lumbar sympathectomy, the maximal improvement was immediately established in 6. In 3 the improvement was complete within two months. By the end of a year the remaining 4 had experienced all the improvement that they obtained.

Amputation

Ninety legs were amputated in 64 patients (26 patients had bilateral amputations). This is an incidence of 25 per cent legs lost. Many of these operations were performed soon after the patient was first seen at the hospital and so do not represent a failure of therapy, however, the incidence is high.

Of the amputations done above the level of the metatarsals, 18 were done at the point of election in the lower leg. Twenty-seven were low-thigh and the remainder or 45 were Gritti-Stokes amputations. Because of the relative youth in this group and the fact that in thromboangitis obliterans arterial obliteration tends to be more peripheral and the collateral circulation better than in arteriosclerotic gangrene, the Gritti-Stokes amputation is usually to be preferred over the more conservative low-thigh amputation. It gives a weight-bearing stump that is relatively easy to fit with a prosthesis and allow maximum activity.

However, it is probable that with modern therapies such as sympathectomy and chemotherapy more lower-leg amputations should be performed than we have thought permissible in the past.

Minor amputations. Minimal gangrene is frequently best treated by amputation of one or more toes. In our series 47 patients, or 26 per cent, had amputations that averaged three and three-tenths toes apiece.

Toe amputations should never be done until the level of gangrene has been clearly established and it appears probable that the resulting wound will heal. Crushing of the appropriate peripheral nerves as described by Smithwick⁸ continues to prove a

useful form of therapy. It is of great value in certain patients with painful open lesions when the sensory denervation may allow adequate daily dressings and the sympathetic denervation some additional beneficial release of vasoconstrictor impulses. At present, transmetatarsal amputation, as recommended by McKittick⁹ in diabetic patients, is considered as an alternative to multiple toe amputations. We have performed a few highly successful ones in patients seen since this series was concluded.

Although thromboangitis obliterans may be a generalized arterial disease, only 10 of our patients, or 6 per cent, have required amputation of fingers. No amputation above the level of the finger was required in the upper extremity. In these 10 patients a total of 40 fingers were amputated. In two patients who had lost almost all their digits as well as both legs, the finger stumps still showed nicotine stains indicating that smoking is indeed most difficult to give up.

Seventeen upper extremities were sympathectomized. It is impossible to draw conclusions about the result of these operations except that the subjective impression was favorable.

DISCUSSION

In reviewing this series of patients with thromboangitis obliterans, we are impressed by the severity and chronicity of the disease. That our therapy has improved is manifest by the decrease in length of hospital stay. The group as a whole required thirty-two days for each admission. In 1945 the average admission had become reduced to nineteen days. The patient today is far more likely to be economically self-supporting than he was a decade ago. This we attribute mostly to comfort or lack of pain brought about by sympathectomy.

That more must be accomplished therapeutically is obvious, but it appears unlikely that great strides will be made until a better understanding of the nature and cause of the disease is arrived at.

SUMMARY

Experiences at the Massachusetts General Hospital in the treatment of 180 patients with thromboangitis obliterans in the twenty-year period 1926-1945 are described.

The natural course of the disease is reviewed, and useful therapeutic measures are outlined.

Although 35 per cent of 180 patients required one or more major amputations, lumbar sympathectomy early in the course of the disease has materially reduced the incidence of major amputations and has proved to be the most valuable method of therapy in our experience.

PARENTERAL AND AEROSOL ADMINISTRATION OF ANTIHISTAMINIC AGENTS IN THE TREATMENT OF SEVERE BRONCHIAL ASTHMA*

HYMAN J RUBITSKY, M D,† ELLIOTT BRESNICK, M D,‡ LEON LEVINSON, M D,§
GEORGE RISMAN, PH D,¶ AND MAURICE S SEGAL, M D ||

BOSTON

IT IS a widely held opinion that bronchial asthma may be due to the liberation of free histamine from its usually bound state,¹⁻⁴ although many conflicting observations make this view far from universal. The oral administration of "antihistaminic" drugs (blocking agents) has proved of limited value in the management of bronchial asthma.⁵⁻⁷ Recent observations by other investigators and the results of protection studies performed in our laboratory have suggested that the parenteral use of these drugs may be indicated in the treatment of severe bronchial asthma.

Feldberg⁸ and Szczygielski⁹ have shown that histamine is capable of causing the release of epinephrine from the adrenal medulla. Staub¹⁰ and Farrerons-Co¹¹ have demonstrated essentially the reverse of this phenomenon — namely, that the intravenous injection of epinephrine or sympathin produces a marked increase in plasma histamine. This reciprocal relation has been termed the "histamine-sympathin see-saw." The epinephrine-fast state in intractable asthma may be a disruption of this "see-saw."¹²⁻¹⁴ In this condition large amounts of histamine are possibly present owing to allergic "shock,"¹⁵ anoxia¹⁶ and the further outpouring of histamine consequent upon continued epinephrine release from the patient's own adrenal medulla, and the repeated therapeutic administration of epinephrine. The "epinephrine-fast" patient may therefore present a situation similar to histamine being essentially unopposed. It is in this connection that the administration of specific antihistaminic agents would exhibit whatever value they may have in the clinical management of

asthma, by "balancing" the deranged histamine-sympathin "see-saw."

Yonkman and his associates¹⁷⁻¹⁹ described potentiation of the effects of epinephrine in the cat after the administration of tripeleennamine. This "adrenergic potentiation" was observed in both excitatory and inhibitory effector mechanisms. Similar potentiation of the vascular effects of epinephrine, after Antergan,²⁰ Benadryl^{21, 22} and Neo-antergan,^{23, 24} as well as tripeleennamine, has been reported by other observers. Experiments are in progress to determine whether antihistaminic agents have the ability to potentiate the protection afforded by sympathomimetic drugs, anticholinergic drugs and aminophylline against histamine-induced and methacholine-induced dyspnea and bronchospasm in patients with bronchial asthma.²⁵

Oral administration of antihistaminic agents may prove undependable. It has been shown that occasional patients, who demonstrated poor protection against histamine-induced dyspnea and bronchospasm when these drugs were administered orally, did show significant protection when the intravenous, rectal and aerosol routes were employed.²⁶ Taub²⁷ obtained clinical relief from various allergic phenomena following parenteral administration of antihistaminic agents after large oral doses of these drugs had proved ineffective. Rosenberg and Blumenthal²⁸ reported 4 cases of poison-ivy dermatitis in which immediate relief of pruritus followed intravenous injection of diphenhydramine. One subject was then placed on a maintenance dose of 50 mg orally every four hours and then 100 mg every two hours and experienced no relief. The authors concluded that "the only explanation felt plausible is that absorption from the gastrointestinal tract was impaired." Serafini,²⁹ McGavack³⁰ and Arbesman³¹ have also noted variable absorption rates of antihistaminic drugs from the gastrointestinal tract during the course of various studies.

COMPARATIVE PROTECTION STUDIES EMPLOYING DIPHENHYDRAMINE AND TRIPLENNAMINE BY VARIOUS ROUTES

An analysis of Figure 1 and 2, in which are summarized the degree of protection afforded by oral, intravenous, rectal and aerosol administration of diphenhydramine and tripeleennamine against histamine-induced and methacholine-induced dyspnea and bronchospasm in asthmatic subjects reveals

are reached within fifteen to thirty minutes by the rectal route. Somewhat greater protection against methacholine-induced dyspnea and bronchospasm is obtained by these agents administered by the intravenous and rectal routes. The intensity and duration of significant antihistaminic protection conferred by the aerosol route (about two hours) is remarkable considering the minute dose employed. The technics used in the assembling of these data, by which controlled conditions not

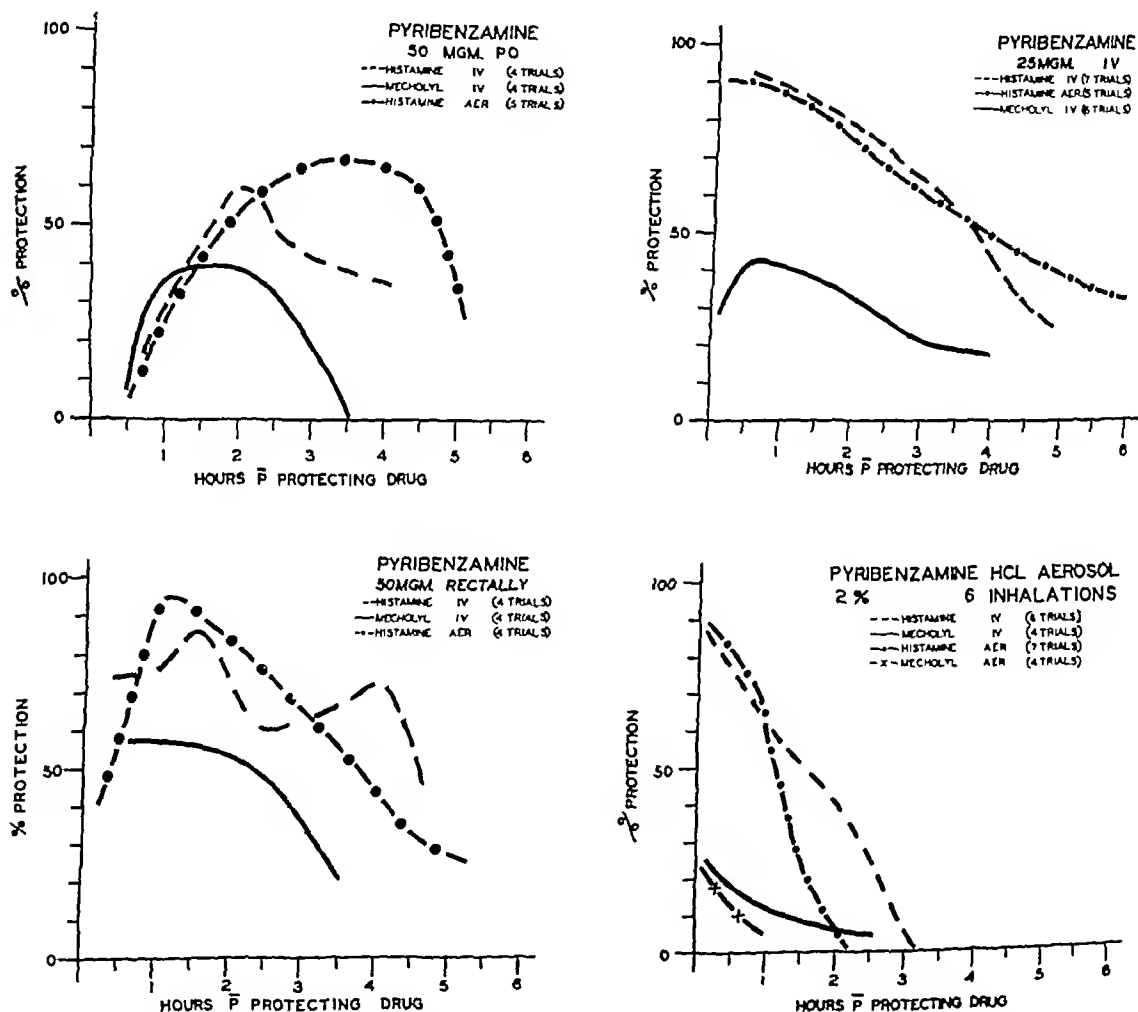

FIGURE 1 Protection Afforded by Oral, Intravenous, Rectal and Aerosol Administration of Tripeleennamine Hydrochloride (Pyribenzamine) against Dyspnea and Bronchospasm Induced by Histamine and Methacholine in Asthmatic Patients

the following significant features, which suggested the possible value of these agents in the management of the asthmatic patient

Significant protection (40 per cent) is not attained until sixty and ninety minutes with oral diphenhydramine and tripeleennamine, respectively. Immediate and almost complete antihistaminic protection is conferred by the intravenous and aerosol routes. High degrees of antihistaminic activity

usually present at the bedside can be achieved, have already been fully described.^{29, 33}

METHODS

We have used diphenhydramine* and tripeleennamine† in the treatment of 15 patients seriously ill with bronchial asthma. Doses ranged from 20

*Kindly supplied by G. D. Searle and Company, Chicago, Illinois.
†Kindly supplied by Ciba Pharmaceutical Company, Summit, New Jersey (Pyribenzamine).

to 50 mg of either agent and were administered intravenously at a rate not exceeding 10 mg per minute. To avoid chemical incompatibility, these drugs should not be mixed with solutions of aminophylline, if an infusion containing the latter drug is being administered, the antihistaminic agent may be injected into the rubber tubing close to the needle.

The most common side reactions observed in our patients were drowsiness and dizziness, par-

crease in the tenacity of the sputum were noticed several hours after the administration of tripele-namine, which McElin and Horton³¹ have also observed and which is possibly related to its anticholinergic properties.

Once having relieved the severe bronchospasm, we have successfully maintained many of our patients during convalescence with antihistaminic agents by the aerosol or rectal routes, or both, as supplements to other therapy. The aerosol route,

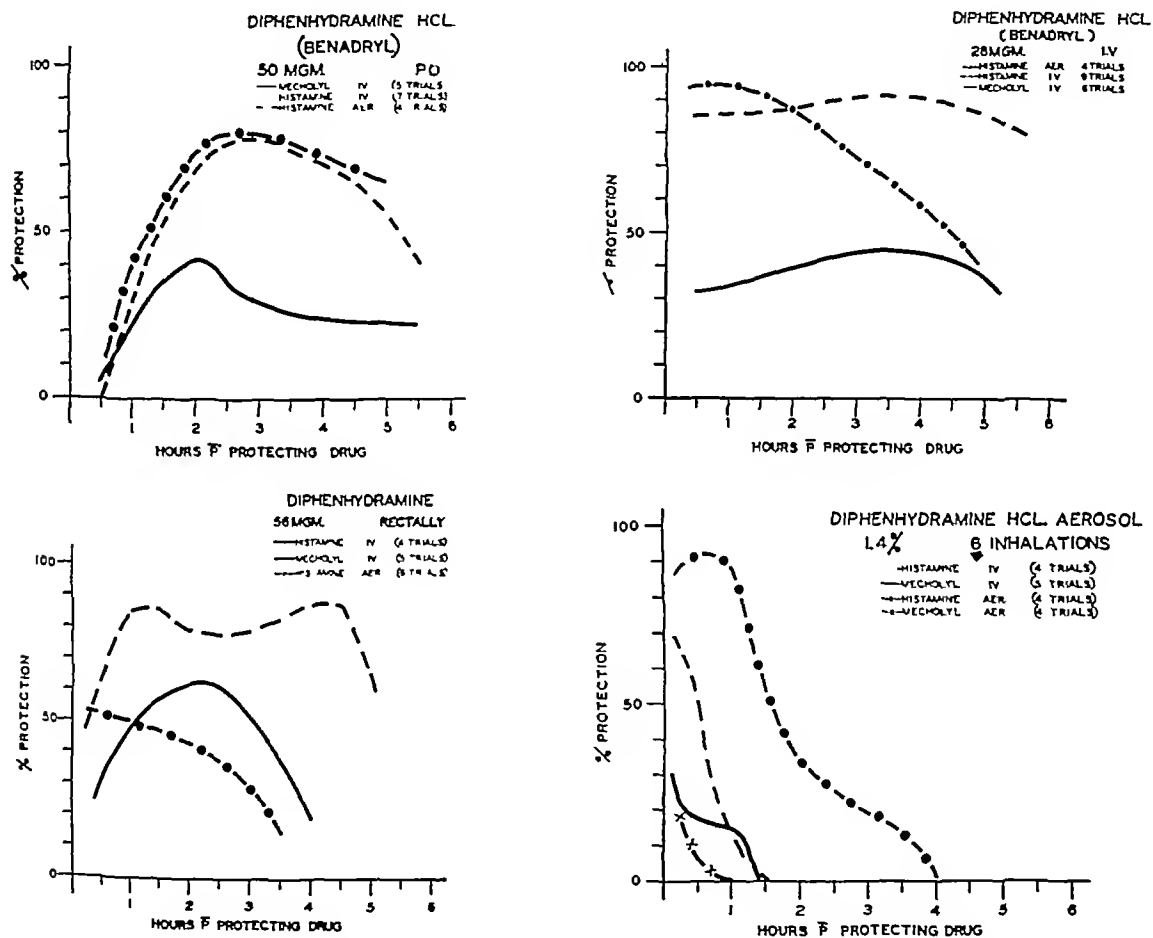

FIGURE 2 Protection Afforded by Oral, Intravenous, Rectal and Aerosol Administration of Diphenhydramine against Dyspnea and Bronchospasm Induced by Histamine and Methacholine in Asthmatic Patients

ticularly in the upright position, which usually disappeared gradually within one or two hours. Other less frequent effects noted in a total of 102 separate administrations of diphenhydramine were headache, transient chilliness, nausea, fatigue, palpitation, pallor, blurred vision, tachycardia and the "alert reaction." Essentially similar side reactions were encountered in 43 intravenous administrations of tripele-namine. In some cases a moderate diminution of expectoration and an in-

creasing a 2 or 5 per cent tripele-namine solution, either alone or mixed in equal parts with a bronchodilator, in a Vaponefrin nebulizer, has afforded gratifying relief. This is especially true when physical factors such as exposure to cold appear to play an important role. Rectal administration of tripele-namine or diphenhydramine (25 to 50 mg) has likewise been surprisingly efficacious over prolonged periods. For rectal instillation one may employ capsules of diphenhydramine, puncturing

the ends of the capsule before insertion into the rectum, or either drug may be given in solution, alone or in combination with aminophylline. Addition of diphenhydramine to solutions of aminophylline may result in the formation of a milky suspension, this reaction apparently does not interfere with the action of either drug given rectally.

The 15 patients in this series were selected after they had proved partially or completely refractory to either one or a combination of the following epinephrine subcutaneously, various bronchodilator aerosols, aminophylline intravenously or rectally, meperidine, helium-oxygen and "bronchial catharsis." Whenever possible, vital-capacity readings were taken in an attempt to obtain more objective evidence of improvement in pulmonary ventilation. Significant relief or restoration of epinephrine sensitivity was afforded in 10 cases.

CASE REPORTS

CASE 1 E S, a 26-year-old woman, had had eczema and perennial bronchial asthma all her life, necessitating eight previous hospitalizations. There was a history of familial allergy. She had had pneumonia at the age of 16. Decreases in her vital capacity of 1000 cc or more could regularly be induced during asthma-free periods by the intravenous injection of 0.01 to 0.02 mg of histamine. She had been maintained comfortably on bronchodilator aerosols for many months, many oral preparations and rectal administration of aminophylline had afforded no relief.

After an absence of 3 months, she returned to the clinic on September 10, 1948, with a history of increasingly severe bronchial asthma over the previous 4 days. She was greatly fatigued, somewhat tremulous and so dyspneic that it was impossible to obtain satisfactory vital-capacity determinations. She had been taking epinephrine subcutaneously every hour or so and bronchodilator aerosols even more frequently, with rapidly diminishing relief. Intravenous and rectal administration of aminophylline was likewise essentially ineffective and merely precipitated an "alert reaction." After six inhalations of Isuprel (1:200 solution) had proved ineffective, 25 mg of tripeleminamine was given intravenously. The dyspnea was greatly relieved after only 5 mg had been injected. By the time the total amount was given, she was no longer dyspneic, her vital capacity was 1800 cc. The only side effect noted was mild drowsiness. Ten minutes later, six inhalations of Isuprel 1:200 were again administered with an immediate rise of her vital capacity to 2200 cc, at which level it remained.

In the light of this patient's previous history, it is probable that were it not for the dramatic relief afforded by the intravenous injection of tripeleminamine, hospitalization would have been necessary. Although not so impressive as in the other cases reported, the restoration of sympathomimetic sensitivity resulting from the antihistaminic is nonetheless noteworthy.

CASE 2 M G, a 22-year-old single woman had had bronchial asthma for 11 years, at first seasonal but later perennial. Prior to being followed in our clinic, frequent hospital admissions had been necessary. She exhibited sensitivity to dust, mixed feathers and several foods, both clinically and by skin tests. When she was symptom free, predictable drops in her vital capacity of 1000 cc or more could be produced with 0.015 mg of histamine intravenously.

The effectiveness of intravenous antihistaminic therapy has been dramatically demonstrated in this patient on many occasions. On August 31, 1948, at the height of the ragweed-pollen season and during the course of a protection study in which histamine was being employed intravenously as the

bronchospastic agent, she experienced moderate asthma, lasting more than an hour. Her highest vital capacity was 2400 cc, whereas her usual control readings ranged from 3600 to 4000 cc. Isuprel inhalations were without effect. Tripeleminamine hydrochloride, 25 mg, was then administered by vein. Her vital capacity rose to the normal level (3500 cc) in 3 minutes, but dyspnea and falling vital capacity recurred, and the effects of tripeleminamine were no longer discernible 30 minutes later. Isuprel (1:200 solution, six inhalations) was given again at this time, with an increase in vital capacity to 4200 cc and relief lasting 80 minutes. Her asthma then recurred once more, and Isuprel (1:200 aerosol solution, nine inhalations) was ineffective. She was given 28 mg of diphenhydramine intravenously, diluted to 5 cc, with almost instantaneous relief after 1 cc had entered the vein. A vital capacity of 3400 cc was maintained for 30 minutes, and, as it began to drop, Isuprel (six inhalations) produced a further rise to 4000 cc. She remained at this level for 1 3/4 hours, and was discharged for the day, essentially asymptomatic. No side reactions from either drug were noted.

On September 9 the patient returned with severe bronchial asthma, which had been refractory to Isuprel aerosol, rectal administration of aminophylline, and epinephrine injected subcutaneously. She was perspiring profusely and extremely dyspneic, and was unable to blow up the vital-capacity apparatus. Diphenhydramine, 28 mg, was slowly administered intravenously. No sooner had the injection been begun than a profound relief again occurred and was objectively manifested by vital-capacity readings of 2000 cc within 5 minutes. Ten minutes after the diphenhydramine, Isuprel (1:200 solution, six inhalations) was given with even further relief. Her vital capacity rose to 3200 cc, at which level it persisted for 90 minutes. As before, no drowsiness or other effects were noted.

On November 12, after sudden changes in the weather, which had frequently precipitated asthmatic paroxysms in the past, she came to the clinic in severe bronchospasm that again was refractory to her usual therapy. She was given ten inhalations of an aerosol produced from a 1:4 per cent solution of diphenhydramine. Her vital capacity, which had been unobtainable, rose to 2800 cc, and after six inhalations of Isuprel 1:200 aerosol, it increased to 3200 cc, at which level it persisted for over 1 hour.

There is little doubt that parenteral antihistaminic therapy prevented not only hospitalization but also the progression of the asthma to the truly intractable state. Restoration of sensitivity to bronchodilator drugs with "adrenergic potentiation" was clearly and objectively demonstrated on the three occasions here reported and during several exacerbations since. It seems that diphenhydramine is the preferable drug in the patient, although no notable side effects occurred with either agent.

CASE 3 M K, a 55-year-old married woman, had suffered from bronchial asthma for 4 years. Until her present illness, the attacks had never been severe and had generally been relieved by epinephrine subcutaneously. Repeated skin tests were reported as negative. It was believed that emotional factors, as well as respiratory infections, contributed greatly to recurrences of the asthma. In April, 1948, a severe attack of asthma, which necessitated hospitalization, developed. On an extensive program of continuous aminophylline infusions (in 5 per cent glucose and water, meperidine and aerosols of a bronchodilator spray), she made a good recovery and was discharged within 10 days.

She then remained essentially well for 2 weeks, when she had a relapse and once again presented a picture of typical status asthmaticus. At this time she was entirely refractory to a continuous intravenous infusion of aminophylline, sympathomimetic amines by various routes, oxygen and numerous sedatives. She was then started on a program of intravenous injections of tripeleminamine, 50 mg every 4 hours. After the initial dose, bronchospasm became less marked, and the patient was considerably relaxed and somewhat drowsy. These injections were continued for the first 24 hours, and

*This case has previously been reported elsewhere.¹¹

the dose was gradually lowered to 40, 30, and 20 mg at intervals of approximately 1 day. The drug was entirely discontinued after 5 days of treatment.

Approximately 20 minutes after the initial intravenous dose of tripeleannamine she was given 0.3 mg of epinephrine subcutaneously. Subsequently, dyspnea and wheezing became still less marked. Furthermore, she did not complain of the troublesome palpitation and headache that epinephrine had produced previously. After the second injection of the antihistaminic agent, it was observed that she could once again return to aerosols of one of the sympathomimetic amines with considerable relief and without the side reactions previously observed. It was further noted that her tolerance for aminophylline returned under this program. She continued to make excellent progress, and after the 5th day, all intravenous therapy was discontinued and she was placed on a program of rectal administration of aminophylline and tripeleannamine and aerosols of one of the sympathomimetic amines. She has remained symptom free under this program.

These results are of particular interest because they demonstrate that restoration of epinephrine and aminophylline sensitivity can also be obtained in patients with "intrinsic" bronchial asthma with parenteral antihistaminic therapy. Several other favorable effects of this regimen that merit comment are the desirable sedative side reactions in such patients and the absence of the nausea and the "alert reaction" that aminophylline had previously produced.

CASE 4 J. S., a 24-year-old single unemployed veteran, had had hay fever and asthma for the past 2 years, occurring from May to the first frost. Prior to coming to the clinic, he had required injections of epinephrine and aminophylline every evening on the Accident Ward. With Hydrylin, Isuprel aerosol and rectal administration of aminophylline, he fared very well for 3 weeks during his usually worst season.

On September 7 he entered the clinic with severe bronchospasm. His vital capacity was 1600 cc., as compared with previous readings, which varied from 4600 to 5000 cc. Neither Isuprel aerosol nor rectal administration of aminophylline had helped. Epinephrine, 0.25 mg., was given subcutaneously. Only slight clinical improvement was noted with an increase in vital capacity to 2400 cc. 5 minutes later. His asthma recurred in a short time, however, and his vital capacity fell to 1300 cc. After the intravenous injection of 28 mg of diphenhydramine, marked relief was experienced with a rise in vital capacity to 3200 cc. Five minutes later, Isuprel (1:200 solution, six inhalations) effected a further increase of vital capacity to 3800 cc.; this state persisted for 45 minutes longer before he was sent home.

Here again, sensitivity to sympathomimetic agents following intravenous antihistaminic therapy was promptly restored. The patient experienced moderate drowsiness and drying of the pharynx and tracheobronchial tree, which subsided within two hours.

CASE 5 W. S., a 17-year-old boy, had had asthma for 15 years occurring concomitantly with hay fever from June to early August. He had been hospitalized three times with severe "epinephrine-fast" and "aminophylline-fast" asthma. Predictable bronchospasm could be produced with intravenous or aerosol administration of methacholine; the patient exhibited no change in vital capacity after 0.05 mg of histamine intravenously.

On September 6, 1948, he entered the clinic with moderately severe bronchospasm, his vital capacity being 1400 cc. (His usual readings varied from 4000 to 4900 cc.) Epinephrine, 0.25 mg subcutaneously, produced no clinical response, and 20 minutes later his reading was only 200 cc higher. Twenty-eight mg of diphenhydramine was administered intravenously, with no appreciable change in vital capacity, al-

though he did comment that his chest "felt lighter." When 0.25 mg of epinephrine was again injected 10 minutes later, almost complete relief of the dyspnea occurred, with a rise in vital capacity to 2400 cc., which persisted for 1 hour. He was then discharged, the slight drowsiness produced by the diphenhydramine having subsided.

In view of this patient's past history of resistance to epinephrine and aminophylline preceding his three previous hospital admissions, it seems that restoration of sensitivity to epinephrine avoided hospitalization and further distress. We have noted similar results from intravenous injection of diphenhydramine, particularly in elderly patients and patients who were relatively histamine-insensitive during protection studies, relief being forthcoming not so much from the antihistaminic per se as from the sympathomimetic agent after sensitivity had been restored.

CASE 6 I. C., a 24-year-old married woman, gave a history of seasonal bronchial asthma and hay fever of 6 years' duration. When first seen on the ward she was anxious, tense and moderately dyspneic after having received little or no objective relief from two injections of epinephrine and 0.5 gm of aminophylline given intravenously. Her vital capacity was 1300 cc. She was given 28 mg of diphenhydramine intravenously, with prompt relief of her dyspnea and a rise in her vital capacity to 2300 cc. Six inhalations of Isuprel (1:200 aerosol) 8 minutes later raised her vital capacity 500 cc. more, even though she was very drowsy at the time. Several minutes later she fell asleep. She experienced no further marked respiratory distress during the remainder of her hospital stay.

CASE 7 F. M., a 25-year-old married woman, had a 20-year history of seasonal asthma and hay fever, for which frequent hospital admissions had been required. In addition to eczema in childhood, there was a strong family history of allergy. Skin tests showed marked positive reactions to ragweed and dust. Predictable dyspnea was readily produced in the laboratory with 0.025 mg of histamine intravenously during her asthma-free intervals.

Although a regimen of oral administration of diphenhydramine and potassium iodide and Isuprel by inhalation kept her comfortable during the entire pollen season, she experienced moderately severe bronchospasm with the onset of the first cold weather, as she had done the year before, when hospitalization had been necessary. After 2 sleepless and distressing nights, during which Isuprel inhalation was required every 30 to 60 minutes and aminophylline suppositories (0.5 gm) were without appreciable relief, she came to the clinic. Her vital capacity was 700 cc. She was apprehensive, fatigued, tense and in severe respiratory distress. A marked nonproductive cough was present. Isuprel by inhalation was repeated but was again without effect. Diphenhydramine was administered intravenously, and after the injection of 2 cc. (approximately 10 mg) her dyspnea was greatly relieved. The only side effect noted was slight drowsiness. Ten minutes after diphenhydramine, her vital capacity was 1800 cc. Six inhalations of Isuprel (1:200 aerosol) further increased her vital capacity to 2400 cc.

Hospitalization was probably prevented in this patient by the prompt relief afforded by diphenhydramine and the restoration of sympathomimetic aerosol sensitivity it effected. She also noted, thereafter, that if she took an aerosol of equal parts of 5 per cent tripeleannamine and Isuprel (1:200 solution) prior to going out into the cold, the onset of an asthmatic paroxysm, which had been poorly controlled by bronchodilator aerosols alone, was prevented. The efficacy of the rectal

the ends of the capsule before insertion into the rectum, or either drug may be given in solution alone or in combination with aminophylline. Addition of diphenhydramine to solutions of aminophylline may result in the formation of a milky suspension, this reaction apparently does not interfere with the action of either drug given rectally.

The 15 patients in this series were selected after they had proved partially or completely refractory to either one or a combination of the following epinephrine subcutaneously, various bronchodilator aerosols, aminophylline intravenously or rectally, meperidine, helium-oxygen and "bronchial catharsis." Whenever possible, vital-capacity readings were taken in an attempt to obtain more objective evidence of improvement in pulmonary ventilation. Significant relief or restoration of epinephrine sensitivity was afforded in 10 cases.

CASE REPORTS

CASE 1 E S, a 26-year-old woman, had had eczema and perennial bronchial asthma all her life, necessitating eight previous hospitalizations. There was a history of familial allergy. She had had pneumonia at the age of 16. Decreases in her vital capacity of 1000 cc or more could regularly be induced during asthma-free periods by the intravenous injection of 0.01 to 0.02 mg of histamine. She had been maintained comfortably on bronchodilator aerosols for many months, many oral preparations and rectal administration of aminophylline had afforded no relief.

After an absence of 3 months, she returned to the clinic on September 10, 1948, with a history of increasingly severe bronchial asthma over the previous 4 days. She was greatly fatigued, somewhat tremulous and so dyspneic that it was impossible to obtain satisfactory vital-capacity determinations. She had been taking epinephrine subcutaneously every hour or so and bronchodilator aerosols even more frequently, with rapidly diminishing relief. Intravenous and rectal administration of aminophylline was likewise essentially ineffective and merely precipitated an "alert reaction." After six inhalations of Isuprel (1:200 solution) had proved ineffective, 25 mg of tripeleennamine was given intravenously. The dyspnea was greatly relieved after only 5 mg had been injected. By the time the total amount was given, she was no longer dyspneic, her vital capacity was 1800 cc. The only side effect noted was mild drowsiness. Ten minutes later, six inhalations of Isuprel 1:200 were again administered with an immediate rise of her vital capacity to 2200 cc, at which level it remained.

In the light of this patient's previous history, it is probable that were it not for the dramatic relief afforded by the intravenous injection of tripeleennamine, hospitalization would have been necessary. Although not so impressive as in the other cases reported, the restoration of sympathomimetic sensitivity resulting from the antihistaminic is nonetheless noteworthy.

CASE 2 M G, a 22-year-old single woman had had bronchial asthma for 11 years, at first seasonal but later perennial. Prior to being followed in our clinic, frequent hospital admissions had been necessary. She exhibited sensitivity to dust, mixed feathers and several foods, both clinically and by skin tests. When she was symptom free, predictable drops in her vital capacity of 1000 cc or more could be produced with 0.015 mg of histamine intravenously.

The effectiveness of intravenous antihistaminic therapy has been dramatically demonstrated in this patient on many occasions. On August 31, 1948, at the height of the ragweed-pollen season and during the course of a protection study in which histamine was being employed intravenously as the

bronchospastic agent, she experienced moderate asthma, lasting more than an hour. Her highest vital capacity was 2400 cc, whereas her usual control readings ranged from 3600 to 4000 cc. Isuprel inhalations were without effect. Tripeleennamine hydrochloride, 25 mg, was then administered by vein. Her vital capacity rose to the normal level (3500 cc.) in 3 minutes, but dyspnea and falling vital capacity recurred, and the effects of tripeleennamine were no longer discernible 30 minutes later. Isuprel (1:200 solution, six inhalations) was given again at this time, with an increase in vital capacity to 4200 cc and relief lasting 80 minutes. Her asthma then recurred once more, and Isuprel (1:200 aerosol solution, nine inhalations) was ineffective. She was given 28 mg of diphenhydramine intravenously, diluted to 5 cc, with almost instantaneous relief after 1 cc had entered the vein. A vital capacity of 3400 cc was maintained for 30 minutes, and, as it began to drop, Isuprel (six inhalations) produced a further rise to 4000 cc. She remained at this level for 1 3/4 hours, and was discharged for the day, essentially asymptomatic. No side reactions from either drug were noted.

On September 9 the patient returned with severe bronchial asthma, which had been refractory to Isuprel aerosol, rectal administration of aminophylline, and epinephrine injected subcutaneously. She was perspiring profusely and extremely dyspneic, and was unable to blow up the vital-capacity apparatus. Diphenhydramine, 28 mg, was slowly administered intravenously. No sooner had the injection been begun than a profound relief again occurred and was objectively manifested by vital-capacity readings of 2000 cc within 5 minutes. Ten minutes after the diphenhydramine, Isuprel (1:200 solution, six inhalations) was given with even further relief. Her vital capacity rose to 3200 cc, at which level it persisted for 90 minutes. As before, no drowsiness or other effects were noted.

On November 12, after sudden changes in the weather, which had frequently precipitated asthmatic paroxysms in the past, she came to the clinic in severe bronchospasm that again was refractory to her usual therapy. She was given ten inhalations of an aerosol produced from a 14 per cent solution of diphenhydramine. Her vital capacity, which had been unobtainable, rose to 2800 cc, and after six inhalations of Isuprel 1:200 aerosol, it increased to 3200 cc, at which level it persisted for over 1 hour.

There is little doubt that parenteral antihistaminic therapy prevented not only hospitalization but also the progression of the asthma to the truly intractable state. Restoration of sensitivity to bronchodilator drugs with "adrenergic potentiation" was clearly and objectively demonstrated on the three occasions here reported and during several exacerbations since. It seems that diphenhydramine is the preferable drug in the patient, although no notable side effects occurred with either agent.

CASE 3 * M K, a 55-year-old married woman, had suffered from bronchial asthma for 4 years. Until her present illness, the attacks had never been severe and had generally been relieved by epinephrine subcutaneously. Repeated skin tests were reported as negative. It was believed that emotional factors, as well as respiratory infections, contributed greatly to recurrences of the asthma. In April, 1948, a severe attack of asthma, which necessitated hospitalization, developed. On an extensive program of continuous aminophylline infusions in 5 per cent glucose and water, meperidine and aerosols of a bronchodilator spray, she made a good recovery and was discharged within 10 days.

She then remained essentially well for 2 weeks, when she had a relapse and once again presented a picture of typical status asthmaticus. At this time she was entirely refractory to a continuous intravenous infusion of aminophylline, sympathomimetic amines by various routes, oxygen and numerous sedatives. She was then started on a program of intravenous injections of tripeleennamine, 50 mg every 4 hours. After the initial dose, bronchospasm became less marked, and the patient was considerably relaxed and somewhat drowsy. These injections were continued for the first 24 hours, and

*This case has previously been reported elsewhere.¹¹

subsequent to the repeated use of epinephrine, suggested the possible value of these agents in the management of severe bronchial asthma.

Fifteen acutely ill asthmatic patients, 8 in the "intractable" state, were treated and maintained with intravenous, aerosol and rectal administration of diphenhydramine and tripeleminamine. The case histories of 7 patients are presented. Significant relief from bronchospasm or the prompt restoration of epinephrine sensitivity followed the intravenous administration of antihistaminic agents in 10 of the 15 patients.

The most favorable therapeutic results were obtained in patients who had previously been found to be "histamine sensitive" during protection studies. The poorest results occurred in patients with obstruction of the tracheobronchial tree by inspissated plugs of mucus, elderly patients with significant and irreversible cardiac and pulmonary disease and histamine-insensitive persons. Many of the patients in this series were satisfactorily maintained during remission with antihistaminic drugs both by the rectal route, alone or combined with aminophylline, and by the aerosol route, alone or combined with a bronchodilator.

Parenteral antihistaminics should be employed only as adjuncts to other effective therapy in the management of the patient acutely ill with bronchial asthma.

instillation of the aminophylline-diphenhydramine combination was also impressive

DISCUSSION

In this series of 15 cases of acute bronchial asthma, the intravenous administration of diphenhydramine or tripeleennamine resulted in clinical improvement in 10. In some cases marked amelioration of dyspnea directly followed the administration of the antihistaminic agent. In others the effect of the drug was indirect, by enhancing the bronchodilator powers of subsequently administered sympathomimetic drugs ("adrenergic potentiation"). The sedative action ("hyoscine effect") of diphenhydramine especially was also of value.

Several authors have commented upon the efficacy of parenteral administration of antihistaminic agents in asthma. Rosenberg and Blumenthal²⁸ treated 3 patients with severe acute attacks of bronchial asthma, employing doses of 30 to 40 mg of diphenhydramine intravenously. Although in 2 cases there was no appreciable change, the third patient exhibited immediate objective relief. Cohen²⁵ controlled an attack with as little as 8 mg of diphenhydramine intravenously. However, Jenkins and his co-workers²⁶ obtained indifferent results from diphenhydramine given intravenously in 8 cases. It has been our experience, particularly in elderly patients with asthma, that when direct relief from the antihistaminic agent is not forthcoming, the restoration of adrenergic response that may follow is often therapeutically important.

It appears, however, that the effectiveness of therapy with these agents is possibly attributable to some other factor than their ability to antagonize histamine. McGavack^{27, 28} and others^{22, 29} have demonstrated the marked anticholinergic and anti-barium chloride action of diphenhydramine, which we have confirmed in asthmatic patients (Fig 1 and 2) both for this drug and, to a lesser degree, for tripeleennamine.²⁶ Inasmuch as many investigators believe that cholinergic mechanisms in the etiology of asthma and other allergic phenomena are at least as likely as histamine mechanisms,^{32, 40, 41} this property assumes considerable possible clinical significance.

Whereas the side effects produced by intravenous injection of antihistaminics are frequently undesirable in the ambulatory patient, drowsiness, relaxation and sleep may be highly desirable in the severely ill patient. Mild drowsiness is also noted after the rectal administration of either agent. We have not observed any significant cumulative effects with parenteral administration of antihistaminic agents. The diminution of expectoration and increase in the tenacity of the sputum that may be observed later have not been troublesome when effective expectorant therapy is also given.

We have found the combination of aminophylline with either diphenhydramine or tripeleennamine given rectally two or three times daily to be effective in maintaining many patients after cessation of severe asthma. We have also encountered favorable results in several patients with an aerosol, employing a 2 or 5 per cent tripeleennamine solution, or 1.4 per cent diphenhydramine solution, either alone or mixed with equal parts of solutions of sympathomimetic amines. The use of these combinations is particularly effective as a prophylactic measure in patients whose asthma is precipitated by exposure to cold. Feinberg⁶ and Arbesman⁷ have also noted relief with tripeleennamine aerosol in individual patients.

Parenteral antihistaminic therapy is by no means a panacea for the management of the severely ill asthmatic patient, and we have encountered patients in whom no relief was forthcoming from these agents. Waldbott and Young⁴² have even observed an aggravation of asthma after the use of antihistaminic agents. This therapy is presented only as an effective adjunct to other proved procedures in the management of the seriously ill patient, with particular emphasis on physiologically directed therapy and "bronchial catharsis."^{43, 44} Our poorest results have occurred in patients with obstruction of the tracheobronchial tree by inspissated plugs of mucus, elderly patients with significant and irreversible anatomic disease of heart or lungs and histamine-insensitive persons. The last observation was particularly striking in 2 young patients (B L and E C) in whom bronchospasm could be induced during clinically asthma-free intervals only by methacholine. Both developed severe bronchial asthma accompanying acute bronchitis and exposure to cold, and required hospitalization. No significant relief was afforded by parenteral administration of antihistaminic agents in either of these patients, even when large doses were given. Of interest in this regard are the observations by Fuchs et al,⁴⁵ who point out that in only 1 of the 23 per cent of their asthmatic patients helped by oral diphenhydramine was organic heart or lung disease present, whereas in the 77 per cent not receiving relief, organic heart or lung disease or an active sinus infection was present in all.

SUMMARY

The relative ineffectiveness of "antihistaminic" agents in severe bronchial asthma when given orally is well known. We have demonstrated prolonged and high degrees of protection against histamine-induced, and to a lesser extent against methacholine-induced, dyspnea and bronchospasm after the intravenous and rectal administration of "antihistaminic" agents in the laboratory. These observations and those of other investigators, indicating that large amounts of histamine may be released in allergic "shock" and hypoxia, and particularly

five minutes, + when the sulfur powder sank to the bottom immediately but floated in a dilution of the urine with water of 1:1, ++ when the sulfur sank also in the urine diluted 1:1, and +++ when the powder sank in higher dilutions.

Studies of the excretion of cholic acids in the urine of alcoholic patients had the following results: of 660 specimens of urine of 600 patients examined, + tests were found in 13.94 per cent and ++ to +++ tests in 5.46 per cent. That means that liver-cell damage was demonstrable with this test in 19.4 per cent. This number of positive tests is considerably less than the figures of 30.07 per

cent that in the more chronic stage of liver damage the cephalin-flocculation test was still positive while the urobilinogen test and the cholic acid test were negative. The biopsies revealed the severe damage to the liver cells and the fast improvement after modern treatment.

The last test used in these studies was the methylene blue test for bilirubin in the urine (Franke¹⁰). This procedure is considered as very useful by a great number of investigators, though it is not specific for bilirubin. The technic of Gellis and Stokes¹¹ was followed. The test was rated as + when blue color appeared with 5 drops, when 6

TABLE 1 *Results of Liver-Function Tests in an Alcoholic Patient**

DATE	UROBILINOGEN	CHOLIC ACIDS	CEPHALIN FLOCCULATION at 48 hr	SERUM BILIRUBIN		REMARKS
				DIRECT mg/100 cc	INDIRECT mg/100 cc	
Nov. 14	+++ (1:650)	+++				
Nov. 15	+++ (1:540)	+++	+++	2.8	3.2	Direct diazo reaction biphasic; delayed liver edge extended to navel and was firm, with irregular surface; spleen not palpated; no ascites.
Nov. 18	++ (1:32)	+	++			
Nov. 19	++ (1:16)	+				Liver biopsy† showed acute stage of alcoholic cirrhosis with marked cellular necrosis and leukocytic reaction (chiefly polymorphonuclears); moderate amount of fat vacuolization; some fibrosis already present.
Nov. 20	+	±				
Nov. 27	±	+	+			
Dec. 4	—	±				
Dec. 20	—	±	++			Liver smaller; not so firm and not tender; second liver biopsy† showed that fat had largely disappeared and majority of liver cells appeared normal whereas very few had appeared normal on first examination; polymorphonuclears still present but markedly decreased in number; fibrosis remained unchanged.

*Treatment consisted of bed rest, high protein, high vitamin diet and cholinechloride.

†Performed by Dr. Wade Volwiler.

cent positive results with the urobilinogen test and of 37.86 per cent positive tests with the cephalin-flocculation method. Comparison between the cholic acid tests and the urobilinogen tests in these patients reveals equal tests in 77.88 per cent. Surprisingly, the cholic acid test was more sensitive than the urobilinogen test in 14.55 per cent, whereas the urobilinogen test was more sensitive in only 7.57 per cent of the cases.

It is of interest that in nonhabitual drinkers twelve to twenty-four hours after an excess of alcohol the modified Hay test and also the urobilinogen test may become positive. On the other hand, Hay tests on approximately 250 patients in my practice and in the Boston Dispensary Medical Clinic with the modified technic showed ± and even + results in patients without apparent liver lesion.

The serial examinations shown in Table 1 may demonstrate the value of the urobilinogen test and the cholic acid test in comparison with the cephalin-flocculation test, the blood bilirubin test, the clinical picture and liver biopsies. This case shows

drops or more were needed the test was rated ++.

Of 150 examined specimens on 150 patients 118 (78.67 per cent) were negative, 12 (8 per cent) were +, and 20 (13.3 per cent) were ++ (6 drops to 10 drops were needed). This means that in 21.33 per cent of the specimens examined slight bilirubinuria as a sign of damage to the liver cells was present although none of the patients had a visible jaundice. The methylene blue test gives almost the same percentage of positive findings in alcoholic patients as the cholic acid test. The comparison of the methylene blue test with the urobilinogen test made in the same patient shows a definite superiority of the latter.

SUMMARY AND CONCLUSIONS

In studies on large unselected groups of alcoholic patients at the Washingtonian Hospital parenchymal liver damage was demonstrable by the cephalin-cholesterol-flocculation test in 37.86 per cent of 140 specimens examined, by the quantitative urobilinogen test on the urine in 30.15 per cent of 2308 specimens examined, by the methylene blue

LIVER-FUNCTION TESTS IN ALCOHOLIC PATIENTS*

GEORGE M. LEPEHNE, M D †

BOSTON

IT HAS been believed for decades that chronic alcoholism damages the hepatic parenchyma and may finally lead to cirrhosis of the liver. Available statistics show alcoholism to be an etiologic factor in hepatic cirrhosis in 33 to 87 per cent of the cases. The extent to which the damage to the liver cells caused by alcohol is demonstrable by liver-function tests is of interest. Numerous authors, using the urobilinogen test, the blood bilirubin test, the bilirubin retention test, the bromsulfalein test, the galactose tolerance test and the cephalin-cholesterol-flocculation test found positive results in 20 to 50 per cent of uncomplicated cases of alcoholism. Almost all these reports are based on a relatively small number of cases.

It has been possible to study liver-function tests on a large number of unselected alcoholic patients of the Washingtonian Hospital, an institution specializing in rehabilitation and treatment of male alcoholic patients.

The patients came into the hospital in a state of acute intoxication, some of them after repeated admissions. In only a small percentage of cases was the liver palpable below the costal margin. None of the patients were jaundiced. Delirium tremens was encountered in only 3 per cent of the cases.

In the present study the cephalin-cholesterol-flocculation test of Hanger, the quantitative urobilinogen test in the urine of Wallace and Diamond, the Hay test for cholic acid excretion in the urine and Franke's methylene blue test for bilirubin in the urine were used.

One hundred and forty cephalin-flocculation tests were done on 140 patients with ripened emulsion (Mateer,^{1 2}), and readings were made after twenty-four and forty-eight hours. Twenty-five tests—that is, 17.86 per cent—were + in the forty-eight-hour reading, which is the decisive one, 28 tests, or 20 per cent, were ++ to ++++. *In toto*, in 37.8 per cent of examinations, evidence of damage to the liver was demonstrable by the cephalin-flocculation test. These figures are markedly higher than the figure of 20 per cent of positive tests in 40 alcoholic patients found by Wade and Ehrenfest-Richman.³ However, they stand in good agreement with the figures of former authors, who used various other liver-function tests in alcoholic patients.

The second test used was the quantitative estimation of urobilinogen in the urine (Wallace and Diamond⁴). The test was rated as + when the pink color was still seen in the dilution of 1:3 to 1:15,

and as ++ when the color disappeared in dilutions of 1:16 to 1:80. Higher necessary dilutions were recorded as +++.

Examinations of 2308 specimens of urine of 2070 patients gave the following results: in 30.16 per cent, the tests were indicative of liver-cell damage—+ in 18.15 per cent, ++ in 9.45 per cent and +++ in 2.56 per cent. These results are in agreement with the figures of positive urobilinogen tests in uncomplicated alcoholism found by other authors.

The largest amounts of urobilinogen seen were 1:300, 1:400, 1:450, 1:540, 1:650 and 1:750. It is surprising that in the cases with +++ reactions an enlarged liver was present in only 33.3 per cent. Serial examinations showed that in all groups considerable variations were sometimes noted from day to day. In 44 cases comparative tests were made of the morning and afternoon specimens. In 43.2 per cent the tests were the same at both times. In 36.3 per cent there was an increase in the afternoon specimen, and in 20.5 per cent there was a slight decrease. The afternoon increase could be as marked as follows: forenoon, ±, afternoon, 1:200; forenoon, 1:50, and afternoon, 1:200.

A comparison of the urobilinogen test and the cephalin-flocculation test made in the same patient shows a good correspondence in 54.64 per cent of the cases. However, it is surprising that in 36.08 per cent the urobilinogen test was positive whereas the cephalin-flocculation test was negative. In only 9.28 per cent the cephalin-flocculation test was positive, and the urobilinogen test was negative. The urobilinogen test seems to be more sensitive in acute transient damage to the liver cells, which apparently occurs often in alcoholic patients.

The third test used in this study was Hay's test for cholic acid excretion in the urine. This test is based on the lowering of the surface tension by cholic acids usually measured by the stalagmometric method. Simpler and for practical purposes equally accurate is the Hay test: dried sulfur depuratum powder strewn on the surface of the urine sinks to the bottom of the container when cholic acids are present. Mueller,⁵ Lepehne,⁶ Doumer⁷ and others recommended this test as very useful, though it is not a specific one. I modified the test by acidifying the urine with concentrated hydrochloric acid according to Morrison and Swalm,⁸ who recommended the addition of hydrochloric acid for their stalagmometric method. It was found that the Hay test became considerably more sensitive. The test was called ± when a small amount of the sulfur powder sank to the bottom within three to

CONJUNCTIVAL AND CORNEAL CALCIFICATION IN HYPERCALCEMIA*

Roentgenologic Findings

FELIX G FLEISCHNER, M D,† AND SEYMOUR R SHALEK, M D‡

BOSTON

DEPOSITION of calcium or true ossification in the eyeball has been known to the ophthalmologist and pathologist. These conditions occur most commonly in the choroid and are believed to be often caused by injury. Twining and Shanks¹ distinguished four groups of intraocular calcifications as seen roentgenologically: calcification of the lens, ossification of the vitreous, calcified atheroma of the ophthalmic artery and a shrunken calcified globe. Kautz and Schwartz² described, in detail, the x-ray appearance of the ring-shaped calcific deposits in the choroid and also listed and discussed the differential diagnosis of other opacities in the orbit and globe, such as calcium deposits in retinoblastoma in children, opaque and semi-opaque foreign bodies, vascular calcifications, phleboliths, orbital angioma and osteoma.

Walsh and Howard³ have found, by ophthalmologic methods, calcification of the eye in patients with hypercalcemia. In their report, describing their own experience over ten years at the Johns Hopkins Hospital and similar observations by Dr David Cogan⁴ of the Massachusetts Eye and Ear Infirmary, they list 16 cases in which 7 patients presented the clinical picture of hyperparathyroidism, 7 vitamin D poisoning, and 2 sarcoidosis.

FIGURE 1 Corneal and Conjunctival Calcifications As Found on Ophthalmoscopic Examination of the Left Eye

The lesions, identified with the aid of the slit lamp, are of two distinct types: one in the conjunctiva, and the other in the cornea (Fig 1). The conjunctival lesions appear as small glass-like particles within the conjunctiva of the palpebral-fissure region. These minute areas are crystal clear. They may be many or few. The second type of ocular abnormality occurs in the cornea. It consists of hazy, grayish, granular epithelial and subepithelial

opacities running concentrically with the limbus on either the nasal or the temporal side or both. The opacity is most dense at the periphery, fading out centrally. Its appearance is similar to that of band keratitis seen in association with intraocular inflammation or rarely as a primary disorder. Chemically, these deposits are identified by conjunctival biopsy as probably consisting of calcium phosphate. The roentgenologic visualization of these ocular calcifications is the subject of this report.

CASE REPORT

A. E. S., (B. I. H., M4364),§ a 42-year-old man, had had crippling polyarthritis for 20 years and had received vitamin D medication since 1942, including 2 or 3 Ertron capsules daily, 3 or 4 tablets of Darthrone daily for 6 months and Dolcin tablets for several months. In 1943 a right ureteral colic had occurred, with hematuria and passage of "gravel." There were several similar episodes in the following year. When the patient was seen on January 14, 1949, he complained of a dull pain in the left costovertebral angle and gross hematuria. X-ray examination of the abdomen revealed bilateral calcification of the kidneys. On the basis of the history and these findings he was admitted to the hospital for further study.

Physical examination showed an edentulous patient with moderate pallor of the oral mucosa and the skin. The thyroid gland was enlarged to about three times the normal size and contained several nodules. The chest roentgenograms revealed bilateral changes in both upper lobes, consistent with arrested tuberculosis of the hematogenous type and moderately advanced emphysema. Destructive joint changes consistent with advanced rheumatoid arthritis were found in the fingers, wrists, elbows, shoulders, knee joints, left hip and spine. There was marked generalized decalcification of the bones, especially the long bones, with loosening of the cortices, but without cyst formation. There was in addition evidence of marked muscular wasting.

The kidneys, which were rather small, were normal in shape and position. There was extensive mottled calcification throughout both kidneys, the individual calcium flecks being 3 mm and smaller. The distribution of the calcification followed the individual pyramids of the kidney, with less calcification in the left kidney. Intravenous urography and retrograde pyelography revealed delay in excretion, marked impairment of concentration and slight dilatation of the calyces. These examinations also confirmed the intraparenchymatous location of the calcific deposits. In a complete survey, no soft-tissue calcification was found in the extremities or the walls of the chest and abdomen.

An ophthalmologic consultant reported as follows (Fig 1)

There is no redness in either eye. The corneas and conjunctivas look normal microscopically. The anterior chambers, pupils and tensions are normal. The lenses and vitreous are clear. The disks, maculae and retinal vessels appear normal. Vision is about 20/25 in each eye. Slit-lamp examination reveals grayish-white, powdery opacities along the limbus of the cornea, both temporally and nasally, from about 2-5 and 7-10 o'clock. The opacities are not deep, with only rare superficial blood vessels and about 15 to 10 mm wide. Otherwise, the corneas are clear.

§A complete discussion of the metabolic and hormonal aspects of this case will be published elsewhere by Drs. Mark F. Lessem and S. L. Gargill.

*From the Department of Radiology, Beth Israel Hospital and Harvard Medical School.

†Instructor in radiology, Harvard Medical School; assistant professor of radiology, Tufts College Medical School; director, Department of Radiology, Beth Israel Hospital.

‡Resident in radiology, Beth Israel Hospital.

test for bilirubinuria in 21.33 per cent of 150 specimens examined, and by the sulfur test for cholic acids in the urine in 19.40 per cent of 660 specimens examined. These figures are consistent with the results of former authors who made various liver-function tests in alcoholic patients, and reveal clearly that there is no regular correspondence between the four tests. In the acute stages the urobilinogen test and the cholic acid test seemed to be more sensitive than the cephalin-flocculation test. Sometimes, the cholic acid test was more sensitive than the urobilinogen test. In the more subacute and chronic stages the cephalin-flocculation test was sometimes the only positive one. A good screening method for office practice to detect early disturbance of the liver is the simultaneous performance of the qualitative urobilinogen test, the modified sulfur test for cholic acids and the methylene blue test for bilirubinuria. The urobilinogen test should be done preferably in the afternoon specimen. Examination showed, confirming numerous previous observations, that in 36.6 per cent of cases the afternoon excretion of urobilinogen exceeded considerably the morning excretion.

Furthermore, it can be concluded that the liver dysfunction in alcoholic patients can be largely transient. Even serious damage as found in the liver biopsy described can subside within a month. The occurrence of marked cirrhosis is surprisingly rare among the patients of the Washingtonian Hospital. This corresponds well with the opinion that hepatic cirrhosis develops only if several different factors have been present. The combination of the modern treatment of alcoholism by the conditioned reflex and psychiatric methods with an early modern anticirrhotic therapy may prevent

the development of hepatic cirrhosis in these patients (Thimann¹²).

I am indebted to Dr. J. Thimann, medical director of the Washingtonian Hospital, for giving me the opportunity to make this study, and to Dr. Fred M. Meyer and Mr. J. Stimson for their valuable help in these examinations.

owski, Winkler and Peters,⁶ McLean and Lebo⁷ and Freeman, Roads and Yeager⁸) Similarly, Howard and Meyer⁹ noticed a recession of the ocular calcifications in 4 of 8 cases within one to sixteen months of withdrawal of vitamin D, often associated with, but not always parallel to, general clinical improvement

Dr Fuller Albright, who saw the patient in consultation, summarized his opinion as follows

There are at least three sequences that could have led to the present picture primary hyperparathyroidism, with hypercalcemia, nephrocalcinosis, renal insufficiency, rising serum phosphorus and falling serum calcium, rheumatoid arthritis, with immobilization, osteoporosis of disuse, hypercalcuria, nephrocalcinosis and so forth, and vitamin D overdosage, with rising serum calcium, nephrocalcinosis and so forth

The fact that stones antedated vitamin D therapy is against the third sequence and consistent with the first two The fact that abnormal calcium is confined to the eyes and kidneys is also somewhat against vitamin D overdosage. I favor primary hyperparathyroidism There is probably little to be gained by total removal of the parathyroid tumor, since the degree of renal insufficiency requires an increased compensatory production of hormone, greater than the tumor is now making The diagnosis can be made only by exploration

The patient was explored, but no parathyroid tumor was found in the neck

SUMMARY

A case of hypercalcemia is reported, the etiology of which is not yet certain Primary hyperparathyroidism, immobilization secondary to rheumatoid arthritis or vitamin D poisoning possibly played a role in the etiology

Roentgenologic examination of the anterior portion of the eyeballs revealed calcification of two different types corresponding to the two types described by Walsh and Howard, found by ophthalmoscopic examination, but not yet described in the roentgenologic literature

The bone-free x-ray technic used in this examination is described in detail

AGRANULOCYTOSIS FOLLOWING PYRIBENZAMINE*

Report of a Case

ALVIN M. CAHAN, M.D.,† EDWARD MEILMAN, M.D.,‡ AND BERNARD M. JACOBSON, M.D.§

BOSTON

THE effectiveness of Pyribenzamine (tripelenamine hydrochloride) in many allergic states and its apparent freedom from toxicity have led to its widespread use with little fear of serious reaction. Thus far only 1 case of depression of the granulocytic series after Pyribenzamine therapy has been reported.¹ The following case is believed to represent agranulocytosis resulting from the use of Pyribenzamine over a period of five and a half weeks.

CASE REPORT

A 39-year-old housewife entered the hospital complaining of sore tongue and mouth of 3 days' duration. The past history included migraine headache since the menarche, for which she had frequently used empiric compound. There was no history of eczema, hay fever, asthma or other allergic reactions to foods or drugs until 2 months before admission,

when she had noted a red, itching rash on the left forearm spreading to involve the trunk. This rash was diagnosed as a contact dermatitis. Seven weeks before entry she was treated with Benadryl, lotions and salves without effect. Five and a half weeks before admission the hemoglobin concentration was 15.7 gm per 100 cc., and the blood smear was normal. Medications were changed to Pyribenzamine, 50 mg three times daily, chloral hydrate for sleeplessness and Ergotrate (ergonovine maleate) for her headaches. On this program the rash and itching subsided. Three and a half weeks before entry the Pyribenzamine dosage was reduced to 25 mg three times daily.

She had used no medication except Pyribenzamine for at least a week preceding the onset of the present illness. Three days before admission she became ill with mild chills, malaise, generalized aches, prostration, sore mouth and a temperature of 100°F. On the next day she omitted the Pyribenzamine and took several empiric tablets. Two days before admission ulcerations appeared on her tongue, her gums became swollen, and she complained of an unpleasant taste. She had no sore throat. From then until admission the mouth and tongue became progressively more painful, and she took food and fluids with increasing difficulty. Treatment consisted of mouth rinses with salt, sodium bicarbonate and milk of magnesia. On the afternoon of admission the white-cell count was 1700, with 2 per cent neutrophils in the stained smear. She was given 300,000 units of penicillin in heeswax and oil intramuscularly, and was referred to the hospital. During the 5½ weeks preceding her illness, she had taken a total of 40

The bulbar conjunctivas in the interpalpebral spaces show occasional small, round and oval, glistening superficial, slightly elevated "cysts" or crystals. Some are single and isolated, others are grouped together. In addition to these shiny spots, there are rare nonglistening deposits under the conjunctiva, with no enlargement or newly formed blood vessels. These changes are identical in both eyes. This microscopical eye picture agrees with that described in patients with hypercalcemia.

Examination of the urine showed a +++ test for albumin, with a specific gravity of 1.010, ++ to +++ tests for calcium were repeatedly demonstrated by the Sulkowitch method while the patient received a low-calcium diet. Sputum and urine examinations for tubercle bacilli by smear, culture and guinea-pig inoculations were negative. Morphologic blood studies showed a moderate anemia, with a red-cell count of 3,500,000 and hemoglobin of 10.1 to 12.9 gm per 100 cc, and were otherwise normal. The nonprotein nitrogen of the blood ranged from 50 to 79 mg per 100 cc in 14 examinations. Five total-protein examinations were 6.15 to 7.45 gm per 100 cc. Seventeen calcium determinations ranged from 10.7 to 11.6 mg per 100 cc and dropped to 8.7 to 9.1 mg per 100 cc after treatment with stilbestrol, saline infusions and Amphojel. Twelve inorganic serum phosphorus determinations showed values of 4.5 to 4.7 mg per 100 cc before treatment and values of 2.9 to 2.3 mg per 100 cc after treatment. The alkaline phosphatase ranged from 2.4 to 3.1 Bodansky units.

Skull roentgenograms disclosed faint calcification in annular arrangement in the orbits (Fig. 2). With the bone-free technic,

FIGURE 2 Portion of a Posteroanterior Roentgenogram of the Skull

The white, curved lines in the orbits (arrows) represent the corneal calcifications. (The white spot above the left orbit is due to a buckshot beneath the skin.)

described below, these calcifications were brought into better relief. They were of two different types. When the scleral portion of the globe was hit tangentially plump, rod-like calcific deposits 2 mm in width and 3 or 4 mm in length in a curvilinear arrangement were seen. If the corneal limbus was hit tangentially a solid, homogeneous, dense calcific

FIGURE 3 Two Tangential Views of the Left Globe (Bone-Free Technic) Demonstrating the Corneal Calcification (A) and the Conjunctival Calcifications (B). (The white spot above the left orbit is due to buckshot beneath the skin.)

shadow of less than 1 mm in width and 7 mm in length was seen in the left eye (Fig. 3), and an interrupted similar shadow line 8 mm in length was seen in the right eye.

In the bone-free technic standard dental films are used. The patient, conveniently seated in a dental chair, presses the film with two fingers of the opposite hand close to his nose in the medial corner of the eye. The tube of the dental x-ray machine is centered toward the external canthus from behind in such a way that the beam covers as much of the eyeball as possible. The patient keeps his eye open and is directed to look steadily alternating to the side, straight forward and medially, in order that several tangential views of various parts of the anterior convexity of the globe may be obtained. The technical factors are the same as those for frontal teeth, 15 MA, 55KV and 1 second were the technical factors used with our equipment.

DISCUSSION

The roentgenologic findings of calcification of the conjunctiva and cornea in the palpebral fissure can easily be correlated with the ophthalmoscopic findings of Walsh and Howard,³ observed also in the case reported above. Roentgenologically, two types of calcification have been identified. The short, rod-like deposits are apparently identical with the crystal-clear, nodular deposits found in and beneath the conjunctiva, the linear shell-like deposits correspond to the calcification in the limbus. The observations of Walsh and Howard, as well as those of Cogan,⁴ were made exclusively in patients with hypercalcemia of various origin.

In this case, too, the ocular calcification is apparently a manifestation of hypercalcemia though the cause of the hypercalcemia is not definitely determined. Three causative factors were considered: hyperparathyroidism, vitamin D poisoning and immobilization due to rheumatoid arthritis.

Widespread metastatic calcifications have been observed in all three of these conditions (Mulligan⁵). However, the calcium deposits in many organs, such as the lung, heart, stomach, liver and spleen, can be recognized only by pathological examination of the tissues. Calcifications of the kidneys, periarticular structures and subcutaneous tissue, as well as arterial calcifications, of diagnostic value solely in young persons, have been the only ones accessible to roentgenologic exploration. Renal and vascular calcifications have been found with great frequency in all three of these conditions, whereas periarticular calcium deposits, rather common in excess of vitamin D, are but rarely reported in hyperparathyroidism and hypercalcemia secondary to bone and joint disease. The generalized moderate decalcification of the bones occurs in all three conditions and has no differentiating significance in the presence of considerable renal damage. Disappearance or marked diminution of massive deposits of lime salts have been observed after withdrawal of vitamin D medication with or without simultaneous reduction of calcium intake (Dan-

onset of menstruation was a predisposing factor in the precipitation of agranulocytosis. In the case reported above, it is interesting that the acute symptoms began two days after the beginning of the period.

SUMMARY

A case representing agranulocytosis following pyribenzamine is presented. This is the second case report of this condition subsequent to the administration of Pyribenzamine and calls attention to the advisability of performing white-cell counts on any patient receiving Pyribenzamine for prolonged periods who shows signs or symptoms of agranulocytosis.

Since the preparation of this report Drs George A McCormack and Richard G Whiting have informed us of a similar case treated at the Lawrence Memorial Hospital in Medford. Their patient took approximately 400 mg of Pyribenzamine for a month prior to the onset of agranulocytosis. On the sixth day after the onset of this patient's illness the white-cell count had declined to 1100, and the neutrophils had completely disappeared. The patient made an uneventful recovery.

MEDICAL PROGRESS

RH AND OTHER BLOOD GROUPS*

LOUIS K. DIAMOND, M.D.,† AND FRED H. ALLEN, JR., M.D.‡

BOSTON

THE Rh and other blood groups have achieved great importance in the last few years because of their relation to erythroblastosis fetalis. But numerically this disease may not emphasize the need for practical knowledge about blood groups as often as blood transfusion does—a therapeutic procedure that has become relatively simple and used, or sometimes possibly abused, probably several million times a year. In addition, genetic and anthropologic studies using blood-group characteristics have been revitalized by the discovery of the newer and now much more numerous blood agglutinogens. And finally, medicolegal problems, which formerly were unsolvable because of too few positive detectable characteristics for identification of any person's blood-group individuality, can now come closer to satisfactory resolution because of the possible permutations and combinations of the blood-group factors, making any blood more nearly unique.

By use of knowledge and technics now available, the safety of multiple transfusion of whole blood has been greatly increased. Relatively simple laboratory tests are now available to establish accurately the compatibility of the blood of the donor and the recipient.

The discovery of the Rh factor in 1939 by Levine and Stetson,¹ who found the Rh antibody in a parturient woman after a hemolytic transfusion reaction, and independently in 1940 by Landsteiner and Wiener,² who found the Rh antibody in a rabbit immunized by Rhesus-monkey blood, opened the door to re-exploration of blood groups. This subject has been reviewed recently.³⁻⁶ Seven different blood-group systems are now known in which the antigens are common enough to be useful in such studies, and these seven systems are probably controlled by seven different pairs of chromosomes.

This report briefly reviews the field of blood groups, giving only the basic information. The blood-group antigens and antibodies are discussed briefly, with emphasis on genetic and immunologic factors. Certain important clinical considerations will be discussed in relation to some of the antigens. The paragraphs on technic are brief. More complete studies have been published elsewhere.^{3,9} A later review will cover the clinical aspects of the subject.

ANTIGENS AND ANTIBODIES OF HUMAN BLOOD GROUPS

The blood groups are named for the specific antigenic substances (agglutinogens) in the red blood cells. These antigens are inherited factors, appearing early in fetal life and remaining unchanged throughout life. Table 1 lists most of the known antigens that are recognizable in the blood groups and subgroups. Certain rare antigens, and identifiable variants other than those listed below in-

gm of Pyribenzamine. She had had a normal menstrual period beginning 2 days before the onset of her illness.

Physical examination showed a well developed and well nourished woman complaining of a sore mouth but appearing only moderately ill. There were two small ecchymotic areas on the lateral surface of the right forearm. There were no petechiae. The eyes, ears and nose were normal, including funduscopic examination. The breath was not remarkable. There was generalized swelling of the gums, with several areas of hemorrhage and necrosis of the papillae. On the sides of the tongue were three deep, punched-out necrotic ulcerations measuring about 5 mm in diameter and covered with yellow exudate. There was no surrounding inflammation. The pharynx and tonsils were normal. There was an enlarged tender anterior cervical lymph node on the right. The heart and lungs were normal. The liver edge was palpable 4 cm below the right costal margin in the midclavicular line on deep inspiration, its upper border being in the sixth interspace, to percussion. It was nontender. The tip of the

enlarged. The patient was asymptomatic and had refrained from using any medication. The red-cell count was 4,630,000, with a hemoglobin of 14.3 gm, and the white-cell count 8700, with 73 per cent neutrophils, 20 per cent lymphocytes, 6 per cent monocytes and 1 per cent eosinophils.

DISCUSSION

During the five and a half weeks preceding her illness the patient had taken four medications: Pyribenzamine, Ergotrate, empirin compound and chloral hydrate. However, for a week or more before the onset of her illness, she had used nothing but Pyribenzamine, omitting the others because she felt so well. She did not use empirin again until a day after the onset of her sore mouth, when

spleen was felt below the costal margin on deep inspiration. The extremities were normal. Neurologic examination revealed no abnormalities.

The temperature was 102°F, the pulse 112, and the respirations, 18, the blood pressure was 118/70.

The urine was yellow, acid and clear, with a specific gravity of 1.020, and with negative tests for albumin, sugar, bile and acetone. Microscopic examination of the sediment showed normal results. A stool was brown and guaiac negative. A blood nonprotein nitrogen taken on the 2nd hospital day was 29 mg per 100 cc. The blood Hinton and Kahn tests were negative. A heterophil-antibody agglutination on the 3rd hospital day was negative in all dilutions. The prothrombin time was 16.7 seconds, with a control of 15.0 seconds. Four hemoglobin determinations (Sahli) ranged from 13.4 to 16 gm per 100 cc. Four red-cell counts ranged from 4,180,000 to 4,500,000. The platelets were normal. The white-cell count on the evening of admission was 3200, with but 8 per cent neutrophils and 6 per cent band forms. On the next day the white-cell count had risen to 5300, with 24 per cent neutrophils. Thereafter the total neutrophil count rose as shown in Table 1.

The patient received intramuscular injections of penicillin in doses of 100,000 units every 3 hours for 6 days, and 100,000 units every 8 hours for a total dosage of 4,800,000 units. Supportive treatment included a soft diet and 2 multivitamin capsules daily. On the 3rd hospital day folic acid, 10 mg daily, was added. The patient was febrile for the first 2 hospital days, the temperature reaching 101.4°F on the 2nd day, after which it remained normal. This fall in temperature was paralleled by a decrease in the pulse rate and coincided with marked improvement in the general well-being of the patient. The lesions in the mouth healed slowly but steadily so that at discharge, 8 days after admission, the gums were virtually normal and the ulceration on the tongue was clean, with epithelializing, small concavities. The spleen receded on about the 4th hospital day.

Examination two months after the acute illness revealed irregular depressions at the sites of the former ulcerations on the tongue. The spleen was not palpable. The liver was not

she omitted Pyribenzamine for the first time in five and a half weeks after having taken a total of 40 gm of the drug. On the basis of the history, Pyribenzamine seems to be incriminated. The depression of the granulocytes that occurred in this case only after prolonged exhibition of the Pyribenzamine seems analogous to the leukopenia seen after extended use of other drugs, such as the sulfonamides, thiouracil or propylthiouracil. In all these agents the effect on the granulocytic series is not manifest in the early days of the administration of the drug. Wintrobe² states that the granulocytopenia from sulfanilamide usually occurs after one to three weeks of treatment, and that from thiouracil usually after four to eight weeks. It seems that the analogous time for Pyribenzamine is four to five weeks. In the case previously reported¹ granulocytopenia occurred after eight weeks of Pyribenzamine.

Although folic acid was used in therapy, we do not believe that it played a role in recovery, since the rise in the white-cell count had begun before folic acid was started. The significant monocytosis observed initially and in subsequent examinations (Table 1) may be considered evidence of the onset of spontaneous recovery, according to the observations of Reznikoff.³

Thompson⁴ reported cyclic neutropenia just preceding the menstrual flow, and he believed that the

higher titer in serum medium than in saline solution or in albumin and is difficult to neutralize with soluble antigen.⁶ The immune anti-A antibodies so far described have been much more active against A₁ than against A₂ cells. A small proportion of the cases of erythroblastosis fetalis are caused by immune anti-A or anti-B, but it is definitely known that the Group A or O mother of a Group B fetus

wise, the genotype BB cannot be distinguished serologically from the genotype BO.

The CDE (Rh) System

Seldom has a subject caused so much confusion in the minds of both physicians and laity as that of the Rh factor. Much of the confusion appears to result from the rapidity of progress in the field

*Based on data of Race et al.¹¹ (the frequency of the R₂ gene is taken as 0.00005) and Fisher and Race¹² (the frequencies are approximately the same for American whites the proportion of D-negatives being a little lower — approximately 15 per cent).

can have immune anti-B in her serum without any observable ill effects on the baby.

Anti-A and anti-B typing serums. The apparent discrepancy between the number of identifiable phenotypes and known genotypes in the ABO system (Table 3) is explained by the limited number of specific antisera as follows. Anti-A serum agglutinates all Group A and Group AB cells. Anti-A₁ (anti-A serum absorbed with A₂ cells) does not agglutinate A₂ or A₂B cells, but does agglutinate A₁ and A₁B cells. Anti-B serum agglutinates only B and AB cells. The person of genotype A₁A₂ can be differentiated only by family studies, not by direct testing, from the A₁A₁ or A₁O person, and all three have therefore the same phenotype. Like-

and from the complex terminology. The antigens and antibodies are not confusing if they are considered one by one, employing the nomenclature of Fisher and Race, which is based on assigning letters (C, D, E, c, d, e) to the specific antigens of the Rh system (Table 4). Although it is recommended that the CDE nomenclature be adopted as standard,¹⁷ the Wiener abbreviations are indispensable in conversation, and must be known if much of the literature is to be understood.

Genetics of the CDE system. According to Fisher's theory there are three sets of allelic (alternative) genes, C, C*, and c, D and d, E and e — one set for each of three loci in one of the pairs of chromosomes. The loci are closely, or absolutely, linked,

crease the number of possible genotypes* to well over 100,000,000

The ABO System

Antigens The A₁, A₂, B and O antigens are inherited as Mendelian alleles. The A and B antigens of the red cells were discovered by Landsteiner¹⁰ fifty years ago. That O is actually an antigen has only recently been recognized.¹¹ The variant A₂ has been known for many years.¹² The curious facts that virtually all B-negative adults have anti-B antibodies and that virtually all A-negative adults have anti-A antibodies in

who have large amounts of the antigens A or B, or both, in their saliva and gastric juice are called "secretors," and inherit this characteristic as a Mendelian dominant. Eighty per cent of Europeans are secretors.

Antibodies Anti-A and anti-B antibodies are naturally occurring substances. They agglutinate

their serum have not been explained on either genetic or immunologic grounds, but they are obviously of enormous importance as far as blood transfusions are concerned. The specificity of anti-B is quite uniform from one person to another, but there is considerable variation in anti-A antibodies, their activity against A₂ cells often being weak. Occasionally, anti-A₁ is found in the serum of an A₂ person.⁸ An antibody that agglutinates all O and A₂ red cells has been variously called "anti-O" and "anti-A₂," its exact significance is a matter of dispute. The relations between the antigens and antibodies in the ABO system are shown in Table 2.

The A and B antigens are rather widely distributed in nature, especially A, which is found in various animals and plants. Both antigens are easily obtainable in pure water-soluble form from extra-human sources (for example, A is obtained in high concentration from hog gastric mucosa) and have been used in concentrated solution for experimental purposes or for the neutralization of anti-A and anti-B in human whole blood or serum.¹³ The A and B antigens are also found, in various amounts, in other human tissues than the red cells. Persons

red cells containing the corresponding specific antigens. Agglutination does not require complement, is most active at 4°C, is active at 37°C and occurs with red cells suspended in saline solution, serum or a solution of albumin.

Isohemolysis and isoagglutinins may occur in the same serum. They are not separable, and differ in that hemolysis requires serum complement. Isoagglutinins are accompanied by isohemolysis in only about 30 per cent of possible cases.⁸ They

are specifically neutralized by soluble A or B substance.

Immune anti-A and anti-B There is no evidence that natural anti-A or anti-B harms the fetus. In contrast to the natural anti-A and anti-B antibodies, "immune" antibodies have been described by Witebsky⁵ and found in numerous cases, as in a Group A or Group O woman carrying a Group B fetus. The immune anti-A or anti-B gives a

*Genotype is defined as the total gene pattern inherited from the parents, not necessarily identifiable by typing serum.

In this discussion of the peculiarities of the Rh antibodies, specific reference is made only to anti-D, since other antibodies in this group may behave in a similar fashion

An important contribution to the science of immunology was made by workers in the field of blood grouping when it was shown that agglutinins existed in different forms. It was first shown that certain anti-D antibodies might specifically coat D-positive cells without agglutinating them, to such an extent that the coated cells could not then be agglutinated by potent anti-D agglutinating antibodies^{20, 21}. Next, it was demonstrated that these antibodies, which were unable to agglutinate red blood cells in saline solution, the traditional medium for such tests, were able to agglutinate red cells in a medium of 20 per cent albumin²². Finally, it has been shown that albumin-active (saline-inactive) antibodies exist that are not "blocking" antibodies. This last type of antibody, representing perhaps a third "order" of antibodies, which coat but do not block red cells and do not agglutinate in saline solution, have been called "cryptagglutinoids"* by Hill, Haberman and Guy²³. Preliminary research by these authors²³ appears to show that the three "orders" of antibody are found in highest concentrations in three distinct protein fractions — gamma globulins (saline-active agglutinins), beta globulins (the albumin-active cryptagglutinoids), and euglobulins (blocking antibodies and cryptagglutinoids). "Agglutination" of red cells is observed, however, with all three "orders" of antibody, in saline solution, when the Coombs technic, using anti-globulin serums, is employed. The several varieties of anti-D antibodies are all specific in their relation to the D antigen and may all be present in the same serum. Their differences only accentuate the need for identifying them in serums presented for investigation. The *in vitro* activity of anti-D antibodies depends not on any quality of the particular D antigen involved, but solely on the antibody-forming mechanism of the sensitized person.

It is also suggested that the saline-active antibody cannot pass through the placenta, whereas the hyperimmune antibody readily passes through, to be found in the baby's serum (in the case of a D-negative baby) in concentration equal to that in the mother's serum.

The MNS System

The M and N antigens (mendelian alleles) were discovered by Landsteiner and Levine^{24, 25} in 1927. The S antigen is a recently discovered one²⁶ that is genetically linked to M and N. Since each of the three MN types may be positive or negative with respect to anti-S, there are six phenotypes, when anti-M, anti-N and anti-S are all used. Since an anti-s serum has not been discovered, the SS genotype

*O-₊ synonyms are hyperimmune antibodies, incomplete antibodies, fixators and blockers. Saline-active antibodies are also known as easily immune antibodies, complete antibodies and agglutinins.

type can be distinguished from the Ss genotype only by family studies. Even if anti-s were available, one could not distinguish except by family studies the two genotypes MS/Ns and Ms/NS (Table 5).

In human beings M, N, and S are relatively poor antigens. Natural anti-M and anti-N are observed occasionally in low titer. Such antibodies are usually if not always, agglutinins effective in the cold. Immune anti-M has been found in a number of cases in which Type N persons have been given transfusions of M or MN blood. The immune anti-M is active at 37°C, and may be the cause of a severe hemolytic transfusion reaction. Anti-S

has not been identified as a natural agglutinin and has not been produced in animals. Several examples of immune anti-S in S-negative persons have been reported. In one such case the antibody failed to cause agglutination of S-positive cells, but did "coat" them as could be demonstrated by the Coombs test. Anti-M and anti-N typing serums are obtained by immunization of rabbits with human Type M and Type N blood.

Since clinical problems involving M, N and S are so uncommon, typing with anti-M, anti-N and anti-S is not necessary in routine examinations, although they must be kept in mind whenever clinical problems cannot be solved with the use of A, B and Rh serums.

The P System

The antigen P was discovered by Landsteiner and Levine²⁸ in 1927 when they found in the serum of a rabbit, immunized with human blood, an antibody that agglutinated about 75 per cent of all human red cells irrespective of their ABO and MN blood groups (Table 6).

No serum corresponding to the predicted anti-p has as yet been identified.

Anti-P is reported to be fairly frequent in P-negative human beings, as a naturally occurring weak

and crossing over has not yet been observed. The number of possible combinations that may occur is quite large (Table 4). The genes are given the same names as the antigens of the red cells. It is important to emphasize that the inheritance of these genes is as though they were all *mendelian dominants*. To state it more correctly, there is *no dominance*.

The C^w antiserum¹⁸ and the genotypes having this antigen have not been included in Table 4, since they are of no real clinical importance and their inclusion would complicate the table. The C^w antigen is an uncommon, but serologically and genetically distinct, variant of C. The antigens C, C^w and c are genetically related in the same way that A, B and O are related, as Mendelian allelomorphs. Therefore, all human beings can be divided into six genotypes — CC, CC^w, Cc, C^wC^w, C^wc and cc. It is only when the possible combinations at the C locus are multiplied by the possible combinations at the D locus (DD, Dd and dd), and then by the possible combinations at the E locus (EE, Ee and ee) that the system appears complicated.

Only when it becomes important to determine whether a person is homozygous for D (DD) or heterozygous (Dd) is it necessary to consider the Rh antigens as a group. This is necessary because no anti-d typing serum is available. Anti-C, anti-D, anti-E and anti-c serums are generally available, and can be used to determine with fair accuracy the "zygosity" for D of any given person. A brief examination of Table 4 will indicate how this is done. Predictions must be based on the statistical table unless blood relatives of the person in question are available for examination.

Immunologic considerations of the CDE (Rh) system. The antigens in the Rh system vary considerably in their antigenicity. Only D is a really effective antigen. Between 50 and 75 per cent of D-negative human beings develop immune anti-D antibodies if the attempt at immunization is sufficiently prolonged. About 50 per cent are immunized by a single transfusion of D-positive blood. About 5 per cent are immunized by pregnancies involving D-positive fetuses. The corollary to this last statement should be emphasized — namely, that 95 per cent of D-negative women with D-positive husbands (and D-positive fetuses) are never immunized (sensitized) to D, their infants will not have erythroblastosis.

The other antigens of the Rh system are very much less antigenic, although antibodies to each of them have been found in human serums at one time or another. A still unexplained phenomenon is the frequent occurrence of anti-C in a human serum that also contains anti-D, and the extreme rarity of occurrence of anti-C in the serum of a D-positive, C-negative person. This phenomenon suggests some basic immunologic relation between the anti-

gens D and C, so that the presence of the D antigen is protective against immunization to the C antigen. There is a similar, but less striking, relation between anti-D and anti-E antibodies, in that anti-E has been found in many D-positive, E-negative persons (though in most cases it is present along with anti-D), suggesting that the immunologic relation between D and E is less close than that between D and C. The relatively close relation of D to C has been postulated by Fisher on genetic grounds also. It is evident that the protective effect of the D antigen is not shared by either C or E, since D-negative persons having C or E or both appear to be as readily immunized by D as persons lacking both C and E. This problem deserves further study.

The over-all relative effectiveness of the Rh antigens is indicated by the fact that of all persons immunized by one or more of the Rh antigens, over 95 per cent have anti-D, a few have anti-c or anti-E, or both, and an extremely small fraction have anti-C alone, or anti-e or anti-d.

The D antigen, besides being the most important from the immunologic viewpoint, is also most variable. D-positive red cells from most persons are agglutinated by all anti-D typing reagents. About 1 per cent of D-positive red cells, however, are agglutinated by some anti-D serums and not by others. This 1 per cent comprises an apparently unlimited variety of peculiar D antigens. The symbol D^u has been given to this group of irregular D antigens,¹⁹ although the single symbol does not imply any specific immunologic or genetic characteristic of the antigen. Since the D^u variants are antigenic, they are clinically important, especially because they are difficult to recognize by routine typing methods. A fatal hemolytic transfusion reaction has resulted from the administration of such blood, thought to be D-negative, to a D-negative person who had previously been immunized by D. The D^u variants are inherited just as the other antigens of the Rh system are, and "breed true" genetically. The D^u antigens are, for clinical purposes, best considered as identical with the D antigen.

The D antigen has been demonstrated with certainty only in the red blood cells and in red-cell stroma. Experiments indicating that D is present in certain other body cells or fluids have not been confirmed.

The antibodies of the CDE (Rh) system. Isoagglutinins for the Rh factors do not occur naturally. When found in human serum, they result from active isoimmunization, either by transfusion of blood or by pregnancy. Anti-Rh isoagglutinins are developed apparently without anti-Rh hemolysins. Anti-D antibody can be produced artificially in rabbits and some other animals by injection of Rhesus blood or human D-positive blood, but Rh antibodies other than anti-D have not been produced in animals.

but were invariably in low titer. Hemolytic transfusion reactions have not been reported as the result of sensitization to the Lutheran antigen, nor has it been found responsible for any cases of erythroblastosis fetalis.

Summary of the Blood-Group Antigens

Seven different, genetically unrelated and immunologically distinct blood-group systems have been well established in human beings. Other antigens have been identified by occasional serums without sufficient study being possible for definite characterization, because of lowness of titer of the antibody, or rarity of the antigen. Many more, undoubtedly, are waiting to be identified. Of all the antigens described, only A, B and D are of enough clinical importance to warrant routine procedures concerning them — A and B because natural antibodies are universal in human beings lacking the antigens in their red cells, and D because of its considerable antigenicity and the consequent danger of transfusion reactions or erythroblastosis fetalis, or both, when D-negative persons are exposed to D-positive blood.

(To be concluded)

and Race¹⁸ in England About 8 per cent of red cells of Britishers are agglutinated by anti-Lutheran (anti-Lu^a) Anti-Lutheran has been found in the serum of Lutheran-negative recipients deliberately transfused with Lutheran-positive blood³³ The antibodies were active in saline solution at 37°C

a diagnosis. The rather short duration and rapid progress of the symptoms favor this diagnosis over some of the others, and this would be my first choice. Furthermore, by the law of averages I favor a malignant tumor. In my experience most of these tumors have been left-sided, so I would guess a left-sided tumor.

The second possibility I would consider is hyperplasia of the reticular cells of the adrenal cortex. This is a very interesting condition. It occurs mostly in females, and there is often a family history in the siblings. The typical story in females is usually as follows: together with certain characteristic changes in the external genitalia, the child is born with a large clitoris, she grows normally for the first one to eight years, she then develops axillary and pubic hair and grows rapidly, which suggests that androgen is being produced in excess somewhere in the body, finally, because of early epiphyseal union secondary to the excess of androgen, she stops growing at an early age. The net result is that her final height is about normal.

The reticular cells of the adrenal cortex have an interesting life history as worked out by the great Dr Sam S. Blackman, Jr.¹ The fetal reticular zone is well developed and apparently functioning, in the first two weeks of postnatal life it retrogresses but leaves behind some cells that give origin to the postnatal reticular zone, these cells lie dormant until about puberty, when they again show signs of activity and produce reddish-brown granules.

The life history of the reticular zone in cases with hyperplasia of the reticular cells is modified. In the first place the fetal reticular zone is increased, in the second place the cells that give rise to the adult reticular zone lie dormant only one to eight years, rather than up to the usual time of puberty.

We are now in a position to interpret the clinical manifestations. The anatomic changes at birth are undoubtedly the result of increased androgen production by the hyperplastic fetal reticular zone, the failure of axillary and pubic hair to develop in the first few months is due to the latent period when the fetal reticular cells lie dormant, finally, the rapid growth of axillary and pubic hair and of the external genitalia, if it does occur, is evidence of the recrudescence of the reticular cells.

The reticular-cell hyperplasia not only is much less frequent in the male but also runs a somewhat different course. It is very apt to be associated with Addison's disease, because of the encroachment of the reticular cells on the other layers of the adrenal cortex.

Against the diagnosis of hyperplasia in this particular case are the failure of the genitalia to be enlarged at birth and the absence of any clinical or laboratory findings suggesting Addison's disease (for example, the serum electrolyte values and electrolysate values for sweat). On the other hand the onset of pubic hair and of rapid growth at six years

of age is about the right time one would expect if this were the diagnosis. Furthermore, there must be cases in the male in which the activity of the fetal reticular zone is not sufficient to cause noticeable enlargement of the male genitalia. Finally, there must be male patients who do not have Addison's disease. Adrenocortical hyperplasia is my second choice.

I will now turn to possible disorders of the Leydig cells. First, a word about testicular function: the hypothalamus, by way of a neurohumeral pathway, stimulates the anterior pituitary body to release follicle-stimulating hormone (FSH) and luteinizing hormone (LH). These hormones, in turn, stimulate the testes, FSH leading to tubular development and LH controlling production of testosterone by the Leydig cell.

The first possibility we might consider here as a cause of increase in androgen production is a tumor of the Leydig cells themselves. This is very rare. No such tumor was felt. In the only case I know of with this diagnosis, the 17-ketosteroid excretion was over 1000 mg as compared with 66 mg per 24 hours in this case. I think we can dismiss this diagnosis as possible but unlikely.

One might consider a tumor of the pituitary body giving off too much LH. Such a diagnosis would seem reasonable, but I never heard of a pituitary tumor that did this.

The next possibility to consider is a disturbance in the hypothalamus, releasing FSH and LH and stimulating all functions of the testes. One meets this condition in the so-called "pineal syndrome." It is initiated, not by the hormone of the pineal body, but by any tumor in the region of the pineal body. Against such a diagnosis in the case at hand is the failure of the testes to be enlarged. The size of the testes is dependent almost entirely on the size of the tubules, and in the pineal syndrome development of the tubular, as well as the Leydig cells, occurs. There are no findings to suggest an intracranial lesion, and I think we can dismiss this diagnosis.

Finally, one comes down to the possibility of a selective overproduction of LH without FSH. This might cause stimulation of Leydig cells without stimulation of tubules. I had never heard of such a syndrome until recently when Dr Nathan Talbot mentioned it. I leave this for him to discuss. Such a diagnosis would seem to be compatible with the findings in this case, and I might put it down as a third choice.

It is now the vogue to divide adrenocortical hormones into three functional types, one for each layer of the gland. The innermost reticular layer is thought to produce the gluconeogenic, "sugar" or "S" hormone, the outermost glomerulosa layer is thought to produce the salt and water, sodium or "Na" hormone. It may be of interest to see what evidence there is for overproduction of each

CASE 35481

PRESENTATION OF CASE

A six-and-one-half-year-old boy was admitted to the hospital because of rapid weight gain, growth of pubic hair and enlargement of the penis.

On routine examination nine months before admission, he had been found in good health, with normal development, weighing 44 pounds. The blood pressure was 100 systolic, 60 diastolic. The genitalia were noted as normal. Approximately six months before admission, however, he began to gain weight rapidly and to develop pubic hair and penile enlargement. He was otherwise completely asymptomatic and had been very energetic and active, with good muscular strength. He had a good appetite without special preferences, although he ate a great deal of meat and potatoes. There was no special craving for salt or sugar. There were no voice changes, development of axillary hair, acne or other skin changes.

The past history revealed that he was born in breech presentation at term and weighed 6 pounds, 10 ounces. Weight gain and development were normal.

A review of the systems was negative except for an episode of "abscessed ears" and tonsillectomy eighteen months previously for frequent upper respiratory infections. He rarely wet the bed, and there were no other genitourinary symptoms.

Physical examination showed a well developed boy. The weight was 65½ pounds, and the height 46 inches. He seemed very plump, with prominent abdomen and hips. The neck and cheeks were fat. Examination of the head, neck and chest was negative. The heart was slightly enlarged to the left. The rate was normal, and there was a Grade II pulmonic systolic murmur. An electrocardiogram gave a normal tracing. The abdomen was plump and full, but no masses were palpable. There was

definite, kinky pubic hair. The penis measured 7.6 cm in length and 6.3 cm in circumference. The testes were small and measured 1.9 cm in cross section. The skin was clear, and there was no acne or unusual pigmentation. There was no axillary hair. Neurologic examination was negative.

The temperature was 99.2°F, the pulse 100, and the respirations 22. The blood pressure was 132 systolic, 96 diastolic.

The urine had a specific gravity of 1.022. The tests for sugar and bile were negative. There were rare red cells and white cells in the sediment. The blood hemoglobin was 14 gm, and the white-cell count 7700, with 78 per cent neutrophils, 14 per cent lymphocytes and 8 per cent monocytes. The eosinophil count was 112 cells per cubic millimeter. The serum chloride was 106 milliequiv, the sodium 140.4 milliequiv, the carbon dioxide 25.5 milliequiv and the potassium 3.9 milliequiv per liter. The nonprotein nitrogen was 17 mg, and the fasting blood sugar 86 mg per 100 cc (the blood sugar of a specimen taken two hours after breakfast was 97 mg). A sample of sweat contained less chloride and more potassium per liter than normal. The urinary 11-17 oxycorticosteroid was 0.2 mg per 24 hours. The 17-ketosteroids were 6.6 mg per 24 hours.

X-ray films of the right hand and wrist indicated a bone age of seven years. Films of the skull failed to show any significant changes; the bones were of normal texture and density. The pituitary fossa was intact. Chest films showed clear lung fields. The heart was at the upper limit of normal size. The aorta was prominent. Anterior and posterior views of the abdomen showed normal appearance of the left kidney, spleen and liver. The right kidney was obscured by intestinal contents. There was no evidence of abdominal tumor.

On the fourth hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. FULLER ALBRIGHT* This seems like a straightforward case, but one never knows in these exercises.

We know that this patient was producing too much androgen. The rapid somatic growth and the early development of the genitalia are evidence of this. Besides, the 17-ketosteroid excretion was 6.6 mg per 24 hours, which is very high for a child of this age (normal value, 0 mg). There are two tissues in the body that produce androgen: the reticular cells of the adrenal cortex and the Leydig cells of the testes. We therefore expect to find some disorder in one of these two tissues.

I will first discuss the reticular cells of the adrenal cortex. The first possibility I would consider is a tumor, benign or malignant, of the adrenal cortex. Everything in this case is compatible with such

*Physician, Massachusetts General Hospital

tered have been on the left side. Left-sidedness to me makes no sense so I am always equally suspicious of the right. This is the second right-sided tumor of our series. Left-sidedness is presumably a statistical fluke, and I suspect that with time and increased experience the left-sided predominance will also disappear.

Careful search was made at operation for evidence of malignant spread of the tumor. Grossly, the capsule of the tumor was unbroken. No invaded lymph nodes were encountered. The tumor was excised in toto.

The tumor was transected after removal at the operating table. On the gross examination I made a diagnosis of cancer because of the unevenness of consistence in one area and distortion of the stroma. These gross findings have been present in other malignant adrenocortical tumors and consistently absent in the small, apparently benign, tumors that have been resected from patients with Cushing's disease. My experience is too limited for me to be certain but I have a hunch that in such tumors the gross pathology is more reliable than the microscopical. I am therefore fearful of recurrence in spite of my negative search for lymph-node metastases.

DR TRACY B. MALLORY: The tumor was a well encapsulated nodule of quite variable color with many bright-orange-yellow spots in it, indicating

FIGURE 1

that in portions of the tumor considerable lipoids were present (Fig. 1). The microscopical section showed a very variable picture (Fig. 2). Cells could be found that corresponded to all the various layers of the adrenal cortex. There were numerous lipid-filled cells corresponding to the fascicular layer, and also many of the big rather homogeneous eosinophil cells that are found in the reticular layer. There was not a great deal of pigment in the cells in this case. The question comes up whether this tumor was benign or malignant. Encapsulation would be in favor of its being benign. In some parts of the tumor very atypical cells with giant multiple nuclei were found, which anywhere else in the body would certainly be evidence of a highly malignant tumor. Our experience in adrenal tumors has in-

dicated that marked cellular atypicality of this type may be present in tumors that run a benign course. I think it very probable that if these slides were shown to a group of pathologists they would split fifty-fifty as to whether it was benign or malignant. My impression is that the outlook is relatively

FIGURE 2

favorable although we did call it carcinoma. That may perfectly well be an error.

CASE 35482

PRESENTATION OF CASE

A sixty-nine-year-old housewife was admitted to the hospital because of a "nervous breakdown." She had suffered from a chronic nonproductive cough most of her life, and nine months before admission, coincident with an emotional strain, her cough became worse and her appetite failed.

one of these hormones by the tumor that I have diagnosed. We have already discussed the androgenic hormone. Against overproduction of the glucocorticogenic hormone are the failure of the eosinophils to be decreased, the normal value for 11-17 corticosteroids and the rapid growth. In favor of some overproduction of the "Na" hormone is the hypertension and the low chloride and high potassium values in the sweat. It would seem, therefore, that this tumor was producing a large amount of androgenic hormone, a normal amount of the glucocorticogenic hormone and a slightly increased amount of the "Na" hormone.

DR NATHAN B TALBOT Our preoperative diagnosis was the same as that just given by Dr Albright. In the differential diagnosis the condition of greatest interest was a syndrome that we have now seen in a number of young boys. It is characterized by precocious masculinization, starting in early life. The testes are of normal size for age. The urinary 17-ketosteroid output is either normal or slightly elevated, and the urinary gonadotropin (FSH) assay is apt to be negative for 3 and 6 mouse units per 24 hours. Exploration of the adrenal glands of such patients fails to reveal either a tumor or bilateral hyperplasia. On the other hand, testicular biopsy reveals marked development of the interstitial cells of Leydig without more than minor evidences of testicular tubular development. It is believed that the precocity is due to a production of androgenic hormones by the Leydig cells and that these in turn have been precociously developed and activated by pituitary interstitial-cell-stimulating hormone (ICSH). It is further believed that the pituitary body has been activated to ICSH production by some sort of hypothalamic disturbance. Since most of these patients have shown no neurologic evidences of an intracranial lesion, it seems probable that the hypothalamic disturbance is of a functional nature rather than an organic, structural defect. Parenthetically, it may be added that the testicular interstitial cells occupy but a small volume, hence, it is possible for extensive interstitial-cell hyperplasia to occur without a clinically definite increase in gross testicular size. It is growth of spermatid tubules that accounts in the main for the increase in testicular size during adolescence.

So far as testicular size and masculine development were concerned, the patient under consideration corresponded to patients with the condition just described. On the other hand, he differed in the age at onset of precocity, which in his case was much too late for the above syndrome. He also differed in water and electrolyte status, for he had signs (questionable edema of the face, slight hypertension and cardiac enlargement) suggestive of a pathologic increase in the production of adrenocortical hormones of the type that cause sodium and water retention and potassium diuresis. To gain some objective information concerning the

present patient's adrenocortical "Na-K" hormone status, Dr William Locke applied a sweat electrolyte test on which he has been working recently. It might be interesting to hear the results of these studies.

DR WILLIAM LOCKE Methods for estimating the rate of secretion of the "Na-K" hormone are not so satisfactory as the methods for the other cortical hormones, as Dr Albright and Dr Talbot have said. In this case the hypertension may have indicated some overproduction of that hormone. The patient did not have hypochloremic alkalosis, which is sometimes associated with Cushing's syndrome and which has been attributed to an overproduction of the "Na-K" hormone in that condition. We have been studying variations in the electrolyte concentrations in sweat, with a view to using them as an index of "Na-K" hormone production. This subject was first studied by Dr J W Conn,² who showed that desoxycorticosterone acetate has somewhat the same effect on sweat as it has on urine composition—that is, it reduces the concentration of chloride and sodium, and increases the concentration of potassium. In this case the sweat chloride was 100 milliequiv, and the potassium 13.2 milliequiv per liter. Under the conditions of this test one would expect the chloride concentration in the sweat from a normal child to be perhaps three times what it was in this case and the potassium concentration to be approximately half what it was in this case. So we considered our findings to be suggestive evidence of an excessive production of the "Na-K" hormone.

CLINICAL DIAGNOSIS

Carcinoma of adrenal cortex

DR ALBRIGHT'S DIAGNOSIS

Carcinoma of adrenal cortex

ANATOMICAL DIAGNOSIS

Carcinoma of adrenal cortex

PATHOLOGICAL DISCUSSION

DR OLIVER COPE This patient had a tumor of the adrenal cortex. Why were the roentgenograms reported as showing no evidence of a tumor? The answer is that the tumor was small, not more than 3 cm in its greatest diameter and scarcely large enough to cast a shadow. The roentgenograms were excellently clear, and a shadow was present on either side just above the kidney consistent with that cast by the adrenal gland. The shadow on the right was denser than that on the left. In making the incision we anticipated that if a tumor were present it would be on the right side. This proved to be the case.

It is a curious thing, as Dr Albright has pointed out, that the overwhelming majority of the hyperfunctioning adrenocortical tumors we have encoun-

pelvis (Fig 1) A residue of barium was caught in a sigmoid diverticulum and in the appendix.

The patient was placed on complete bed rest, digitalized and given Hykinone, elixir of ferrous sulfate, 10 per cent hydrochloric acid and liberal supplements of vitamins with a salt-restricted diet. The temperature fluctuated between 100 and 101°F for the first seven days and then fell to normal (the weather was exceedingly warm during this period). After three days the pulse fell to normal limits.

FIGURE 1

Over the first three days she received 0.4 cc of Mercupurin in divided doses, with a 6-pound weight loss and slight relief of orthopnea. A total of 4000 cc of whole blood and the packed erythrocytes from 1500 cc were given during the first fifteen days. One transfusion was followed immediately by a febrile reaction, the temperature reaching 102°F. This subsided promptly without jaundice or hemoglobinuria. There was a steady rise in hemoglobin from 3.5 to 9.0 gm following the first seven transfusions. Three subsequent 500-cc transfusions in the ensuing four days failed to produce further elevation. A hematologic consultant was unable to determine the cause of the anemia, which he classified as normocytic and slightly hypochromic. As the blood count rose the cardiac status improved. There was subsidence of peripheral edema and great diminution in the pulmonary rales. No

cause for the wide variation in the blood non-protein nitrogen was established. On the twenty-first hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR W. PHILIP GIDDINGS* This history concerns an elderly woman with symptoms and signs suggesting disorder of nearly all the major body systems. Perhaps some of these are interrelated, and we can reduce the problem to simpler terms.

It is obvious that she was severely anemic, and the evidence all indicates a so-called secondary anemia. One immediately suspects chronic blood loss, but we are given no apparent source of bleeding. It is both regrettable and amazing that no stool examinations for occult blood are recorded.

After her anemia, the next apparent difficulty is that she was in cardiac failure. The suggestion by history of possible rheumatic fever at the age of twenty is not borne out by the electrocardiogram; at least she did not have evidence of rheumatic heart disease, nor was the murmur described suggestive of a specific lesion. With diuretics and correction of her anemia the cardiac status improved, and it is justifiable to conclude that her heart failure was largely if not wholly due to the anemia. At least that is my conclusion.

The next striking fact is that her renal function was impaired: she showed albumin, casts and red cells in the urine. The specific gravity did not rise above 1.013, phenolsulfonephthalein excretion was about half of normal, and she did not concentrate intravenous dye sufficiently for x-ray visualization of the upper urinary tract. All this bespeaks a diffuse renal lesion, which I take to have been independent of her other difficulties. I suppose she had a chronic glomerular nephritis, and shall ascribe the albumin and nonprotein nitrogen levels to this.

Let us now consider her liver. Here again we find evidence of functional impairment. The albumin-globulin ratio was decreased, bromsulfalein retention, alkaline phosphatase and prothrombin time were all elevated, though none of them to a very marked degree. Cephalin flocculation was ++ at forty-eight hours. Urinary urobilinogen and van den Bergh values were normal. In my limited knowledge of such matters, I should conclude that although a diligent search was made for evidence that some sort of biliary-tract disease underlay the clinical picture, the findings did not suggest a major hepatic disorder. I do not know whether or not her severe anemia, nephritis, cardiac failure and probable malnutrition could produce this picture in the liver, but I suspect that they might.

I should mention in passing her chronic cough. I see no cause for this in the history, physical examination or x-ray findings, except that its increased severity recently was due to pulmonary edema.

*Assistant in surgery, Massachusetts General Hospital.

A visit to her family doctor disclosed that she had lost weight and that her "blood was down to 70." She was given "iron pills," which, after a month, "raised her blood to 80." Six months before admission she noted the onset of weakness, increasing ease of fatigability, shortness of breath and increased anorexia. After two months she again consulted her doctor, who gave her ten injections of liver extract and prescribed liver pills, which she took religiously until the time of admission. No significant improvement in her symptoms followed this medication. One month before admission she first noted orthopnea, followed in two weeks by swelling of the ankles and legs. Constipation became troublesome at approximately the same time, and her stools became smaller in size. There was one brief episode of abdominal cramps, and it became necessary for her to take cathartics. Over the nine-month period there was progressive weight loss totaling 40 pounds. She had never experienced dysphagia, vomiting, hematemesis, melena, rectal bleeding or jaundice, and there had been no dysuria or gross hematuria.

At the age of twenty she suffered an attack of pneumonia complicated by "muscular and inflammatory rheumatism." The left breast was removed because of an "adenoma" thirty years previously. "Polyps" were removed intravaginally at thirty-five and sixty-nine years of age.

On physical examination the mucous membranes were generally pale. The tongue was red, with atrophy of the marginal papillae. The left breast had been removed by simple mastectomy. Tiny, firm, shotty lymph nodes were palpable in the left axilla. There was moderate kyphosis of the thoracic vertebra, and respiratory expansion was diminished. Breath sounds were distant, the percussion note was hyperresonant, and scattered coarse rales were heard over both pulmonary bases. At 30° elevation the neck veins became distended and pulsating. The heart was enlarged to the left, and there was a Grade II precordial murmur. A++ pitting edema of the lower extremities extended upward to the knees. A large, hard, smooth mass was palpable in the right lower quadrant of the abdomen extending downward into the pelvis. One examiner believed that he could outline the lower border of the lesion by dipping the palpating fingers into the pelvis. The lesion was movable to palpation but unaffected by respiration. The liver and spleen could not be felt. On rectal examination there was palpable fullness in the right posterior quadrant, but a rectal shelf was not encountered. Vaginal examination was not completely satisfactory, and the uterine fundus was not outlined.

The temperature was 102°F, the pulse 100, and the respirations 20. The blood pressure was 110 systolic, 60 diastolic.

Examination of the blood showed a red-cell count of 1,160,000, with a hemoglobin of 3.5 gm, and a

white-cell count of 9000, with a normal differential ratio but with 8 metamyelocytes and normal appearing platelets. The erythrocytes were hypochromic. No normoblasts were seen. Except for continued hypochromia subsequent blood smears were not remarkable. The hematocrit reading was 20 per cent. Reticulocyte counts were 0.6 per cent and 0.4 per cent respectively. A sternal-marrow aspiration was reported as not remarkable. Repeated urinalyses were consistently acid, with specific gravities between 1.008 and 1.013. Albumin varied from a trace to ++. The sediment contained 4 or 5 white blood cells per high-power field and 2 or 3 red blood cells per high-power field on one occasion. Occasional granular casts were seen. Twelve-hour urine concentration studies yielded a specific gravity of 1.012. The phenolsulfonephthalein excretion was 34 per cent in two hours. A urine culture grew a few colonies of colon bacilli. The total serum protein varied from 6.18 to 7.19 gm per 100 cc, the albumin from 3.23 to 3.35 gm, and the globulin from 2.95 to 3.84 gm. Four successive nonprotein nitrogen determinations gave readings of 31, 68, 30 and 68 mg per 100 cc. Successive prothrombin determinations were 52, 44, 57, 48 and 70 per cent of normal. A van den Bergh reaction was less than 0.4 mg per 100 cc on direct and indirect tests on one occasion, and 0.2 mg direct, 0.4 mg indirect, on another. The alkaline phosphatase varied between 20.1 and 16.9 units per 100 cc. The cephalin-flocculation test was + at twenty-four and ++ at forty-eight hours. Urinary urobilinogen examinations were 0.25 and 0.29 Ehrlich units respectively. Bromsulfalein excretion studies showed 14.2 per cent retention of the dye in forty-five minutes.

A cytologic examination of smeared vaginal secretions was negative. An electrocardiogram was within normal limits. A barium enema showed lateral and upward displacement of the cecum, ascending colon and proximal transverse colon by a large, smooth mass lying in the right lower quadrant. The deformity was that of a pressure defect, with no evidence of involvement of the wall of the colon.

A chest x-ray examination revealed increased linear markings throughout both lung fields. The heart was slightly enlarged in the region of the left ventricle. The aorta was moderately tortuous and calcified in the region of the arch.

Films of the skull and lumbar spine were negative for evidence of metastases.

In an intravenous pyelogram there was an insufficient amount of opaque material on either side to warrant adequate visualization of the urinary passages. The right kidney could not be traced. The left seemed lower than usual but within normal limits. There was an impression of a rounded, soft-tissue mass occupying the right side of the

is one of the first places to look in searching for the cause of an obscure secondary anemia (The next is the stomach) So far as I know, the precise reason for the anemia is not known

In spite of the x-ray findings, I am constrained to make a diagnosis of carcinoma of the cecum. It fits the picture too well for me to consider any other. An obvious diagnosis to consider is metastasis to the peritoneal cavity from a carcinoma of the breast removed thirty years previously. I see no way to support such a diagnosis. The question arises whether or not her liver difficulties could have been due to metastatic disease. Although cancer of the right colon typically metastasizes late, this was a large tumor and could well have spread through the portal system. I am certain that we cannot answer this question definitely, but I should not be surprised to learn that she had liver metastases.

I do not know whether an intramural tumor of the wall of the bowel at this level, such as a neurofibroma, would give this picture. It does not look at all like a lipoma. Neurofibrosarcoma would produce the same effect in the way of anemia as the classic carcinoma of the bowel, but I do not know whether or not it would still leave the mucosal pattern intact. I am going to guess that she had a primary neoplasm of the right colon of some sort.

DR WYMAN: From the x-ray standpoint I do not think it is tenable to place the primary tumor especially carcinoma, in the right colon. I wonder if Dr Giddings would consider a papillary cystadenoma or cystadenocarcinoma of the ovary?

DR GIDDINGS: It is conceivable that the mass is a little lower in the film than I judged it to be from the physical examination as recorded. Ovarian tumors are usually capable of being bimanually palpable.

DR WYMAN: We have seen them as high as and higher than this in many cases.

DR DANIEL S. ELLIS: Are the x-ray findings consistent with a dermoid cyst?

DR WYMAN: It should be of less density because it contains fat. This seems to be of increased density.

CLINICAL DIAGNOSIS

Carcinoma of ovary

DR GIDDINGS'S DIAGNOSES

Tumor of cecum

Secondary anemia

Cardiac failure

Chronic glomerular nephritis

Metastases to liver?

ANATOMICAL DIAGNOSIS

Renal-cell carcinoma of right kidney

PATHOLOGICAL DISCUSSION

DR SOMERS STURGIS: This woman looked older than her stated age, and she was moribund on admission. When the service first saw her she was desperately sick, and it was very questionable in their minds whether they could ever get her in shape for surgery. The gynecologic service favored an ovarian lesion and rather suspected that she had a diffuse carcinomatosis to account for the anemia and lack of much guaiac in the stool. It was on that basis and with that diagnosis in mind that she was operated on.

The laparotomy was done, and a large, smooth, nonadherent, encapsulated tumor was found retroperitoneally, lying behind the ascending colon. The pelvis was normal. The uterus was small, and both ovaries were atrophic. It was obvious that this was a renal neoplasm. It was dissected off without difficulty from the ascending colon.

DR MALLORY: The resected specimen was an enlarged kidney, enlargement being due to a characteristic renal-cell carcinoma, which had not invaded the renal pelvis. This explains why there had not been, at any time, hematuria. The tumor had not extended into the renal vein as they so often do. The patient made a good operative recovery and left the hospital comparatively well.

We shall pass it over — possibly unwisely — as an unexplained and irrelevant matter

We now come to the crux of the story, the mass in the right lower quadrant of the abdomen. This was probably a surgical lesion and is the reason for my having been assigned this case. I must confess, with apologies to my medical colleagues, that now for the first time I feel on familiar ground.

The tumor was large, smooth and hard. We immediately think of the cecum, kidney, liver, gall bladder and ovary as possible origins of such a mass. That it was not inflammatory is evidenced by its mobility, implied lack of tenderness, normal leukocyte count and absence of sustained fever. Nonmalignant hard tumors are unusual unless calcified, which is the reason that I suspect this was cancer.

Was it ovarian? One observer demonstrated it to be out of the pelvis, and it was not definitely palpable on vaginal examination. I do not think it was in the ovary. The physical examination and x-ray films do not agree with the behavior of hepatic or cholecystic tumors, and I believe we can rule out the liver and gall bladder. Nor could it have been kidney: a movable renal mass would have descended with respiration, and this did not.

In a patient with anemia of this degree and a mass at the right lower quadrant, one would like to know the guaiac reaction on the stool.

DR TRACY B. MALLORY: Three specimens were examined: one was negative, one was +, and one was + or —.

DR GIDDINGS: I might say, it is rather surprising that a retrograde pyelogram was not done, since the mass in the right lower quadrant was sufficient in size to displace the major viscera. One would think the surgeon would want to know the precise relation of the ureter to the mass, but I gather that the investigation there was not done. I would also question once and for all whether this could have been a renal tumor. I do not think it was.

That leaves us with the cecum, unless we consider such rarities as mesenteric tumors. This would be a good time to see the x-ray films.

DR STANLEY M. WYMAN: The chest film taken in the supine position is that of an elderly woman with an enlarged heart, apparently chiefly left ventricular, with a tortuous arteriosclerotic aorta. The lung fields, themselves, reveal no definite active localized disease, but there does appear to

be considerable emphysema, as shown by increased anteroposterior diameter of the chest. The films from the barium enema demonstrate quite conclusively a large mass lying in the right lower abdomen over the sacrum, lumbar spine and iliac crest (Fig. 1). This displaces the right colon as described. The pressure is chiefly on the ascending colon, and to a lesser degree on the cecum and on the hepatic flexure. There is no evidence of intrinsic involvement although the mass may be adherent to the colon. The cecum itself is quite well seen in this film and lies lower and more medially than usual, in keeping with the pressure from the mass. There is a definite area of dense calcification seen in the right midabdomen, better seen on several other films. This does appear to be important and is not consistent with a calcified lymph node.

DR GIDDINGS: Could it be a vessel?

DR WYMAN: I do not believe so. The patient does have tortuous arteriosclerotic vessels in the pelvis, and probably higher up than I can demonstrate in the aorta. There is some calcification to the left of the spine — possibly, in the splenic artery. The mass is better seen in films of the attempted pyelogram. It lies below the right kidney. The kidney on the right is not outlined, but what seems to be its lower pole is not grossly remarkable. The left kidney is definitely small, measuring perhaps a quarter of the usual size. The calcification is present in all these films, and it occupies essentially the same position. To me, that is one of the more interesting features of these films.

DR ALFRED E. KRANES: How about the visualized bones? Do they show any changes of metastatic involvement?

DR WYMAN: They seem diffusely osteoporotic, in keeping with the patient's age. I do not see any gross metastases, but we know that with osteoporosis we can miss extensive metastases with great facility.

DR GIDDINGS: That does not make me feel any better. I am at a loss to explain the calcification here. It was not mentioned before.

Of course, the diagnosis that immediately suggested itself to me was carcinoma of the cecum. This is a classically insidious tumor that frequently grows to large size before its detection. One of its most characteristic features is an accompanying severe anemia of the hypochromic variety. As Alvarez and others have pointed out, the cecum

The Autocrat of the Breakfast Table would also have enjoyed reading Luyk's lucid exposition of his subject, "Progress without Statistics." In the judgment of the *Journal* his analysis is adequate.

INDUSTRIAL MEDICINE — A NEW PROGRAM

A BLUEPRINT for the expansion and improvement of industrial medicine in Massachusetts will be offered on December 14 at 2:00 p.m. at the Hotel Statler, in Boston, by the Committee on Industrial Health of the Massachusetts Medical Society. This venture is a logical outgrowth of the Massachusetts Health Conference in February, on which occasion it became evident that a fresh outlook and a renewed effort were needed. The interest was present, but the initiative seemed then to be lacking.

Since that meeting the Committee on Industrial Health has been reorganized with new and enthusiastic membership, and a section on industrial health has been established in the Society. It is under such auspices that the program of December 14, published elsewhere in this issue of the *Journal*, will be presented.

Massachusetts is a highly industrialized state in which many physicians who devote their full time to the medicine of industry have done excellent work, and in which many others, engaged in part-time activities, have discharged their functions with varying degrees of competence and effectiveness.

The actual practice of industrial medicine is, fortunately, an area in which there can be little real conflict between labor and management. Management, when properly informed, is as eager to improve existing programs or institute new ones for the health and safety of workers as labor is to cooperate in attaining the same high objectives. The physician, as the working agent, is equally respected by both sides.

In this effort to bring together representatives from management, labor, industrial nursing and industrial medicine to discuss common problems and work out effective solutions, the interest of all physicians is sought.

INFECTIONS WITH THE "COXSACKIE VIRUS"

THE discovery by Dalldorf and Sickles^{1,2} of a new virus from human cases resembling poliomyelitis and the subsequent isolation of this virus by Melnick, Shaw and Curnen³ from cases that were diagnosed as nonparalytic poliomyelitis, aseptic meningitis or fever of unknown origin were recently reviewed in these columns.⁴ The latter workers found the new virus to be widespread in this country during the summer of 1948. Certain new and significant observations have been added by the original discoverers^{5,6} and deserve mention in view of the interest stimulated by their work and because of the extensive epidemics of poliomyelitis that have occurred in and around Boston during the past summer.

The new virus was originally isolated by the Albany workers from 2 young boys who suffered from what was believed to be paralytic poliomyelitis during August, 1947. The authors usually referred to it as the "suckling mouse virus" because it was originally isolated by intracerebral inoculation of mice three to seven days old. They have now chosen to call it the "Coxsackie virus" after the village in upstate New York where the first human cases were recognized.⁶

Dalldorf⁵ later isolated his virus from 5 out of 21 fecal specimens collected during a rather large epidemic of poliomyelitis that occurred in 1947 in Wilmington, Delaware. This epidemic was noteworthy because other investigators had failed to isolate the classic poliomyelitis virus from the patients, so that the new virus was considered as probably causally related to some of these cases. Some of the clinicians and epidemiologists who investigated this outbreak considered the disease to be atypical in two respects: the unusually large number of multiple cases in families and the transient nature of the paralysis in many patients.

Additional studies were carried out by the Albany workers during 1948 in the course of which they isolated the new virus from 10 out of about 130 specimens collected from "poliomyelitis" patients in upstate New York.⁵ These isolations were from widely scattered outbreaks and from isolated cases,

SUBSCRIPTION TERMS: \$7.00 per year in advance, postage paid for the United States (medical students \$4.00 per year); Canada \$8.00 per year (Boston funds); \$9.50 per year for all foreign countries belonging to the Postal Union.

MATERIAL should be received not later than noon on Thursday three weeks before date of publication.

THE JOURNAL does not hold itself responsible for statements made by any contributor.

COMMUNICATIONS should be addressed to the *New England Journal of Medicine*, 8 Fenway, Boston 15, Massachusetts. Telephone KE 6-2094.

OLIVER WENDELL HOLMES AND BIOSTATISTICS

A CENTURY ago when a patient died from puerperal infection, the physician (and doubtless the patient) was considered merely unlucky. Holmes, however, was not content to stomach this kind of ill luck. He gathered the facts, quantitated them and proved statistically that the doctor was more than unlucky. He was a "pestilence carrier (who) must look to God for pardon for man will never forgive him."

Holmes "had the chances calculated that a given practitioner shall have sixteen fatal cases in a month." By comparing this "unlucky" series of sixteen births with the total number of births in the community not complicated by infection, he found that "there was not one chance in a million

million millions that such a series should be noted" as a purely fortuitous phenomenon.

During the intervening hundred years, while the controversial aspects of puerperal sepsis were being settled, the mathematicians have been busy, first with whittled pencils and then with slide rules and calculating machines perfecting modern biostatistics. It is not necessary to wait for odds of a billion billion to one in order to demonstrate the significance of an observation, and the textbook on biostatistics is today part of the research-minded physician's vade mecum, whether he likes it or no.

The "or no" reaction, however, is so common as to be almost instinctive among the majority of physicians, who have no occasion to use the binomial theorem when computing doses of sulfadiazine or cutting for the stone. To those who enjoy a kind of statisticophobia, who nevertheless are compelled by the inner spirit of curiosity and research to study a series of operations, autopsies, blood counts, x-ray examinations or whatnot in order to find the solution to some challenging medical problem, a recent progress report by Luykx* will be found worthy of thoughtful reading. The purpose of Luykx's contribution is to give "the reader of medical and scientific literature, the medical 'common man'" an appreciation of the need for, and the purposes of, proper presentation and analysis. "The student of medicine must have some knowledge of technics of handling quantitative data (1) in order to understand a correct presentation and (2) in order to form a judgment as to whether a given exposition or analysis is adequate or not."

Although electric calculators have made Einsteins of office secretaries, Luykx makes it abundantly clear that there is more to a formula than grinding it through the machine. Practicing physicians will be cheered by the statement

The technic of calculating the mean and standard deviation will not be discussed here. This is a matter of the proper use of a calculating machine or a slide rule. Much more important is a correct understanding of the meaning of these parameters.

*Luykx, H. M. C. Progress without statistics. Council on Pharmacy and Chemistry. *J. A. M. A.* 141:195-201, 1949.

and the studies show that the agent was widely disseminated in New York State during that summer. Furthermore, at least one antigenically distinct strain and possibly others identified differ in the nature of the disease they produce in mice.

The earlier strains were incapable of infecting monkeys and had the unique property of causing disease only in very young mice and hamsters although this may later be modified experimentally. In mice they caused lesions of the muscles rather than of the central nervous system. They were thus distinct from the classic monkey-pathogenic poliomyelitis virus, which produces central-nervous-system lesions in monkeys and shows no antigenic relation to the new virus. Certain of the new strains, however, appear to produce lesions in both the muscles and the central nervous system. Thus far, even these new strains have failed to cause lesions that resemble those of poliomyelitis.

Pathological studies of patients have, to date, been quite limited because the only fatal cases have apparently been caused by classic strains of poliomyelitis virus. This leads one to suspect that the new agent is less malignant for human beings than the monkey-pathogenic strains. Studies in the experimental disease have also indicated that the serologic diagnosis of infections with the new agent may be quite difficult.

In the mice the outstanding lesion has been the destruction of muscle that becomes a rich source of virus. The muscle degeneration suggested the possibility that studies of creatine and potassium balance might be used as a diagnostic aid. Infected mice were found to develop quite rapidly a marked creatinuria coincident with a loss of muscle potassium and creatinine.⁶ It was therefore suggested that similar studies might be useful in human cases.⁵

In discussing these findings, Gifford and Dalldorf⁶ cite reports from the literature of creatinuria following paralytic poliomyelitis. The muscle findings in reported cases of poliomyelitis, however, have been variable and obviously require re-examination in the light of the more recent findings in experimental infections with the Cocksackie virus. Furthermore, the reports of cases of poliomyelitis in which muscle groups that apparently were totally

paralyzed have rapidly and completely recovered; their function likewise require re-evaluation. It is hoped that future observers will have available more extensive studies of muscles from cases of suspected poliomyelitis, with and without paralysis. It is necessary to determine whether the muscle lesions caused by the classic poliomyelitis virus and by the new viruses have distinctive clinical and histologic features and also what the pathogenic potentialities of these tissues may be. This is particularly important in view of the finding of central-nervous-system lesions produced by some of the new strains.

HEAT VERSUS VIGOR

THE importance of temperature as perhaps the leading environmental factor determining the success of man's attempts at life on this planet is stressed by Mills,* writing for *Science*. His analytic essay, emanating from the Laboratory for Experimental Medicine of the University of Cincinnati, suggests that it's not so much the humidity that counts as it is the heat — although the humidity also plays its part.

If the animal body is considered somewhat in the light of an internal combustion engine, the working efficiency of men, horses and dogs ranges between 20 and 25 per cent, and even this degree of efficiency depends on the rapid dissipation of its waste heat. Diesel did better, having achieved a working efficiency of 40 per cent for his well known engine.

In view of such a summer as New England and other parts of the world have recently experienced, it is easy to agree with Mills that the lowered com-

*Mills, C. A. Temperature dominance over human life. *Science* 110 267-271 1949.

from fundamental contributions of various authors are appended to the various chapters, which also include extensive bibliographies. For the literature previous to 1920, the reader is referred to Vol. II of the *Handbuch der speziellen pathologischen Anatomie und Histologie, Jage*, Berlin, 1928-1937. The book is well published but sparsely illustrated for its type. It should be in the reference collections of all medical libraries and available to ophthalmologists.

Foundamentals of Internal Medicine. By Wallace M. Yater, M.D., M.S. (in Med.), director Yater Clinic, Washington, D.C. Third edition. 8°, cloth, 1451 pp., with 315 illustrations. New York: Appleton-Century-Crofts, Incorporated, 1949. \$12.00.

This new edition of a standard treatise has been thoroughly revised and brought up to date. Eighteen collaborators have written certain chapters of the text. A new and enlarged article on electrocardiography has been included. Sections on chemotherapy and therapy with antibiotics and on inhalation therapy have been added. The drug dosage has been given in the metric system and the old apothecary system discarded. A comprehensive index concludes the text. The book is well published and should be in all medical libraries and available to the practicing physician.

International Digest of Health Legislation. Vol. I No. I, 1948. 8°, paper 144 pp. Geneva, Switzerland: World Health Organization, 1948.

This new periodical succeeds the first section of the *Bulletin mensuel de l'Office International d'Hygiène Publique*, which ceased publication in December, 1946. It comprises the orders, decrees and regulations for the governments in the World Health Organization. It is published in two languages, English and French, and issued as separate or bound numbers. This is the English edition in bound form.

Diseases of the Liver, Gallbladder and Bile Ducts. By S. S. Lachman, M.D., assistant professor of clinical medicine, Cornell University Medical College, assistant attending physician, New York Hospital, adjunct physician, Mt. Sinai Hospital, and assistant in postgraduate medical instruction, University Extension, Columbia University. Second edition. 8°, cloth, 1135 pp., with 147 illustrations and 2 color plates. Philadelphia: Lea and Febiger, 1949. \$18.00.

The text of this second edition of a standard work has been completely revised. The chapter on infectious hepatitis has been completely rewritten. Large bibliographies are appended to the various chapters. There is a comprehensive index. The book is well published and is recommended for all medical libraries and to all persons interested in the liver and its diseases.

Tumors of Bone. By Charles F. Geschickter, M.D., professor of pathology, Georgetown University School of Medicine, consultant in pathology, United States Naval Medical School, consultant in pathology, Mt. Alto Veterans' Administration Hospital, and pathologist-in-chief, Gallinger Municipal Hospital, Washington, D.C., and Murray M. Copeland, M.D., professor of oncology, Georgetown University School of Medicine, consultant in surgery, Gallinger Municipal Hospital, Washington, and special consultant, Federal Security Agency, Public Health Service, Cancer Control Branch, Washington. Third edition. 4°, cloth, 810 pp., with 642 illustrations. Philadelphia: J. B. Lippincott Company, 1949. \$17.50.

The previous editions of this standard treatise were published in 1931 and 1936. The third edition has been thoroughly revised, and the subject brought up to date. Chapters on fibrous dysplasia, osteoid osteoma, tumors of the spine, endocrine changes in bone and rare diseases of bone have been added. The chapters on embryology, chondroblastomas, and treatment of bone sarcoma have been entirely rewritten. The tabulations of bone tumors, on which the book is based, have been extended to include more than 500 additional cases. The illustrations have been revised by the addition of more than a hundred new ones and the deletion of a large number of the old ones, with the object of presenting the best possible reproductions of representative roentgenograms,

gross specimens and photomicrographs. Lists of selected references are appended to the various chapters. There is a good index. The publishing is well done, and the illustrations are excellent. The book, although justifiably expensive, should be in all medical libraries, and available to pathologists, orthopedists and surgeons.

The Temporal Bone and the Ear. By Theodore H. Bast, Ph.D., professor of anatomy, University of Wisconsin Medical School, and Barry J. Anson, Ph.D., professor of anatomy, Northwestern University Medical School. 8°, cloth 478 pp., with 165 illustrations. Springfield, Illinois: Charles C. Thomas, 1949. \$12.00.

This monograph presents a comprehensive study of the development and the adult anatomy of the ear and the temporal bone. Concerning the pathology of the ear only such information is given as relates to development. The text has been organized on a developmental basis, beginning with the otic labyrinth, after the first chapter on the general anatomy of the temporal bone and the ear. The following chapters discuss the periotic labyrinth, the otic capsule, histologic variations and pathologic processes, bone dysmorphies, the origin and development of the middle ear and related air spaces, and the auditory ossicles. The final chapter presents a historical survey of the structure and function of the internal ear, covering the period from 550 B.C. to the present. Bibliographies are appended to the various chapters. There are good indexes of authors and subjects. The book is well published, and the illustrations are excellent. Considering the large number of expensive figures and plates, the price of the book is not excessive. The volume should be in all medical libraries and in the libraries of otologists and anatomists.

Nutrition and Diet in Health and Disease. By James S. McLester, M.D., professor of medicine, University of Alabama School of Medicine. Fifth edition. 8°, cloth 800 pp. Philadelphia: W. B. Saunders Company, 1949. \$9.00.

This standard treatise was first published in 1927 and the last edition was printed in 1945. In this new edition much of the text has been rewritten, and the work now conforms to the knowledge gained during the war years. A section on folic acid has been added, and the material on the vitamins and their functions on deficiency diseases and on protein has been revised. The more liberal diet now used in peptic ulcer and the high-protein regimens used in cirrhosis and other diseases of the liver are discussed, data on the low-salt diet for congestive heart failure and the sodium-free diet for arterial hypertension have been added. New food tables have been included in the text. The chapters on the feeding of infants, by Dr. Philip Jeans, and on nutrition in industry, by Dr. Robert S. Goodhart, have been entirely rewritten. There is a new chapter on the feeding of surgical patients by Dr. Charles C. Lund, of Boston. There is a comprehensive index, and the book is well published in every way. The use of a lightweight paper has resulted in a book light in weight for its size. The volume should be in all medical libraries and should prove valuable to the practicing physician as a standard reference text.

A Primer of Electrocardiography. By George E. Burch, M.D., Henderson Professor of Medicine, Tulane University School of Medicine, senior visiting physician, Chaney Hospital, consultant in cardiovascular diseases, Ochsner Clinic, and visiting physician, Touro Infirmary, New Orleans, and Travis Winsor, M.D., assistant clinical professor of medicine, University of Southern California School of Medicine, director of Nasb Cardiovascular Foundation, Hospital of the Good Samaritan, junior attending physician, Los Angeles County Hospital, and junior attending physician, Children's Hospital, Cardiac Department, Los Angeles. Second edition. 8°, cloth, 245 pp., with 265 illustrations. Philadelphia: Lea and Febiger, 1949. \$4.50.

This primer, intended for the beginner, has been revised in certain particulars. The bipolar precordial leads have been replaced by the unipolar leads, and it is recommended that they be employed exclusively with the standard leads in clinical electrocardiography. The book is well published, and the illustrations are excellent.

Dinner Meeting 6 p.m. Chairman, Arthur W. Allen, M.D., president, Massachusetts Medical Society

Remarks by Mr. Andrew B. Holmstrom, vice-president and general manager, Norton Company, Worcester, Massachusetts, Mr. Albert G. Clifton, legislative agent, Congress of Industrial Organizations, and Mr. Kenneth J. Kelley, secretary-treasurer and legislative agent, Massachusetts Federation of Labor "Rehabilitation of the Chest Patient" Dwight E. Harken, M.D., assistant clinical professor of surgery, Harvard Medical School, visiting thoracic surgeon, Boston City Hospital, and senior associate in thoracic surgery, Peter Bent Brigham Hospital

CORRESPONDENCE

A PHYSICIAN DISAGREES

To the Editor Fair-minded physicians who are members of the American Medical Association must feel ashamed of the official statement put out by the Board of Trustees of the Association in the October 15 issue of the *Journal*. In this statement the Trustees accuse the Department of Justice of the United States of waging a campaign to discredit American medicine and terrorize physicians into abandoning their opposition to compulsory health insurance. A careful perusal of the complete statement fails to show any concrete evidence to support this claim. A series of assumptions apparently forms the basis for this attack upon the integrity of the Justice Department of the United States.

In view of the past history of the American Medical Association and the evidence of persisting activities on the part of various groups in organized medicine, in violation of existing laws, to interfere with the development of plans to improve the delivery of medical care it seems that the Trustees are not in a very satisfactory position to try to besmirch the activities of the Department of Justice.

Actually, in 1938 the American Medical Association was convicted for breaking certain laws in the celebrated case of the Group Health Service in the District of Columbia, and this conviction was eventually upheld by the Supreme Court of the United States. In this instance it was the American Medical Association that was trying to discredit a group of physicians and to terrorize physicians from developing a plan to deliver medical care. Since then the Department of Justice has been receiving complaints from physicians and lay groups that similar tactics are being employed by organized medicine throughout the country. Investigation has provided enough evidence of disregard of the law by organized medicine to make the Department of Justice decide to bring suit in two instances. It seems only fitting in view of these facts that the Department should investigate further the numerous complaints that are made to it. To claim without evidence that such actions are aimed at terrorizing physicians rather than to compel them to obey the law seems quite unworthy of men honored by the medical profession to hold the high office of Trustees of the American Medical Association. I believe the national medical society should urge individual physicians and organized groups of physicians to obey the laws as they exist.

If any group does not believe in the existing laws it is fitting that attempts should be made through authorized methods to change them. The profession and the public should realize that there are thousands of reputable physicians who believe in the development of a national health program to be financed in part by compulsory health insurance such as President Truman favors.

CHANNING FROTHINGHAM, M.D.

101 Bay State Road
Boston

NOTE Further perusal of the statement issued by the Board of Trustees discloses the following paragraphs, relating to the alleged threatening of medical societies by Administration leaders: "On February 28, 1949, for example, one of the National press associations carried a dispatch from Washington quoting Government officials as stating that anti-trust actions would be started against 'several' medical societies soon after the Compulsory Health Insurance drive was started in Congress [italics ours]." — Ed

BOOKS RECEIVED

The receipt of the following books is acknowledged and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Food Poisoning By G. M. Dack, Ph.D., M.D., professor of bacteriology and director, Food Research Institute, University of Chicago School of Medicine. Revised edition. 8°, cloth, 184 pp., with 13 tables. Chicago: University of Chicago Press, 1949. \$3.75.

This second edition of a special work has been revised, and the subject brought up to date. The various chapters include chemical poisoning in food, poisonous plants and animals, botulism, staphylococcal food poisoning, salmonella, alpha type streptococci (*Streptococcus faecalis*) in relation to food poisoning, significance of other bacteria and infections to be differentiated from food poisoning. Lists of references are appended to the chapters. There are indexes of authors and subjects. The small book is well published and should be in all medical libraries.

Public Health in the World Today Edited by James S. Simmons, dean, Harvard School of Public Health, assistant editor, Irene M. Kinsey. With a foreword by James B. Conant, president of Harvard University. 8°, cloth, 332 pp. Cambridge, Massachusetts: Harvard University Press, 1949. \$5.00.

The papers presented in this volume were delivered during 1947-1948 at the public-health forums, conducted by the Harvard School of Public Health. Twenty-three eminent persons in their particular fields participated in the forums. The material is divided into various aspects of public health as follows: the profession of public health, public health in the United States today, public-health programs and problems abroad, and public health in a new era. The volume is excellently published but is marred by the lack of an index. It should be in all collections on the subject.

Natural Products Related to Phenanthrene By Louis F. Fieser and Mary Fieser, Department of Chemistry, Harvard University. Third edition of the monograph previously entitled *Chemistry of Natural Products Related to Phenanthrene*, by L. F. Fieser. 8°, cloth, 704 pp., illustrated. New York: Reinhold Publishing Corporation, 1949. \$10.00. (American Chemical Society Monograph No. 70.)

The authors have revised this standard reference book to bring it up to date. The first and second editions were published in 1936 and 1937. Despite its formidable title, the work is definitely of medical interest. Some of the chapters discuss the quinone and opium alkaloids, sterols and bile acids, sex hormones, adrenal cortical hormones, steroid metabolism and cardiac active principles. The pertinent literature is cited in footnotes on the appropriate pages. There are comprehensive indexes of authors and subjects. The printing is well done with a good type on light-weight paper, producing a volume light in weight for its size and yet conserving space. The volume is a good example of publishing in which some consideration is given the prospective reader. The book should be in all medical, physiologic and chemical libraries and in commercial laboratories.

Histology and Histopathology of the Eye and Its Adnexa By I. G. Sommers, M.D., assistant professor (ophthalmology), College of Medical Evangelists, and medical officer (E. E. N. T.) United States Public Health Service, Los Angeles, California. 8°, cloth, 784 pp., with 69 illustrations. New York: Grune and Stratton, 1949. \$12.00.

This new book is based on the lecture courses given by the author over many years to his students. The text is divided into three parts: normal histology, embryology and senescence, general pathology (in relation to the eye), and histopathology of the eye. Under the heading "Reading of Source Material," extensive lists of short pertinent excerpts

TRANSFUSION TREATMENT OF SHOCK DUE TO MYOCARDIAL INFARCTION*

FRANKLIN H. EPSTEIN, M.D.,† AND ARNOLD S. REIMAN, M.D.†

BOSTON

THE pathogenesis and treatment of the vascular collapse often attending myocardial infarction have perplexed investigators for many years. Particularly vigorous in recent years has been the debate over the safety and efficacy of treatment with transfusions of blood or plasma. Although a few case reports of such treatment have appeared in the literature^{1, 2} and many opinions have been given pro^{3, 5} and con,⁶⁻⁸ no series of cases has yet been published.

At the New Haven Hospital transfusion of patients in shock after myocardial infarction has both advocates and opponents. During the past six years some of these patients have been given only the usual nonspecific supportive measures, without vasopressor or stimulant drugs, and others have received infusions of blood or plasma. The records of both groups have been reviewed in an attempt to evaluate therapy with transfusion and to form a clearer picture of the natural history of shock due to coronary occlusion.

METHODS AND MATERIALS

The records of all patients given the diagnosis of myocardial infarction since 1943 were studied. Only those with unequivocal clinical and electrocardiographic evidence of recent infarction, or those with autopsy proof of infarction, were selected for this report.

For the purposes of this study, a patient was considered to be in shock whenever the systolic blood pressure remained below 90 for at least an hour, during which the classic signs of peripheral vascular collapse (weakness or stupor, cyanosis and cold, moist skin) were present. The large group with the appearance of shock but with systolic blood pressures above 90 was not studied, even when the arterial pressure was considerably below its usual level. A few patients who looked well, although their systolic blood pressures were below 90, were not considered to be in shock. This distinction seemed to be justified by the fact that such

patients uniformly did well, whereas, as shown below, the mortality was very high among patients with the signs of vascular collapse as well as hypotension.

Tests for statistical significance were those described in Snedecor's⁹ textbook.

RESULTS

From January, 1943 to January, 1949, 325 patients with unequivocal myocardial infarction were seen in the New Haven Hospital. Some of the characteristics of the entire group are presented in Table 1 and are compared with those reported in three recent reviews.^{10, 12} It can be seen that our patients resemble those in other series in their average age, sex distribution and the incidence of diabetes and previous hypertension. Thirty-eight per cent of 120 patients selected at random showed signs of congestive heart failure. It is impossible to compare this figure with that given by other authors since the criteria for this diagnosis are not uniform. In this series, patients were considered to be in heart failure whenever they had persistent basal rales, peripheral edema or venous distention and hepatomegaly. The over-all mortality in the present group, 44 per cent, was somewhat higher than that reported by others. This may reflect the stringency of our criteria for the diagnosis of myocardial infarction, which resulted in the elimination of all doubtful, and often less serious, cases from the study.

In confirmation of many previous observations, it was found that patients with diabetes† or congestive failure had a much higher mortality than the group as a whole, whereas previous hypertension did not seem to affect the prognosis. Patients over seventy years of age had a significantly higher death rate than younger patients. The mortality was significantly higher in females than in males. This was noted previously by Mintz and Katz,¹⁰ but not by Master and his associates¹¹ or by Rosenbaum and Levine.¹² Closer examination of our data revealed that the higher mortality among women

*Only one diabetic patient was in acidosis. This patient was also in shock. The disease in all other diabetic cases in this series was well controlled.

*From the Department of Internal Medicine, Yale University School of Medicine.

†Assistant in medicine, Evans Memorial, Massachusetts Memorial Hospital; formerly assistant in medicine, Yale University School of Medicine.

Poliomyelitis Papers and discussions presented at the First International Poliomyelitis Conference Compiled and edited for the International Poliomyelitis Congress 4th, cloth, 360 pp with 92 illustrations and 52 tables Philadelphia J B Lippincott Company, 1949 \$5 00

This volume constitutes the transactions of the first world conference on poliomyelitis. There were ten sessions, and the papers read covered the whole field of the subject. The volume is essential to all medical libraries. The book is well published.

Diseases of Children Volume II Edited by Donald Paterson, M D (Edin), F R C P, consulting physician, Hospital for Sick Children, Great Ormond Street, and consulting physician in charge of diseases of children, Westminster Hospital, and Alan Moncrieff, M D (Lond), F R C P, Nuffield Professor of Child Health, University of London physician, Hospital for Sick Children, Great Ormond Street, and consulting physician, Children's Department, Middlesex Hospital. Fourth edition 8^{vo}, cloth, 1033 pp, with 380 illustrations. Baltimore: Williams and Wilkins Company, 1949 \$10 00

This second volume of a well known British treatise on pediatrics is the joint work of twenty-four contributors, specialists in their particular fields. The material covered in this volume comprises diseases of the nervous system, congenital mental defect in childhood, diseases of the eyes, diseases of the muscles, bones and joints, orthopedic surgery, diseases of the genitourinary and digestive systems and the peritoneum, rheumatism, diseases of the cardiovascular system and of the blood, infectious diseases, venereal disease and diseases of the skin, and malignant lesions in childhood. There is a good index. The text was printed in Great Britain. The treatise should be in all pediatric collections in medical libraries.

Doctors of Infamy The story of the Nazi medical crimes By Alexander Mitscherlich, M D, head of the German medical commission to Military Tribunal No 1, Nuremberg and Fred Mielke. Translated by Heinz Norden. With statements by three American authorities identified with the Nuremberg medical trial. Andrew C Ivy, M D, vice-president, University of Illinois, and medical scientific consultant to the prosecution, Military Tribunal No 1, Nuremberg, Telford Taylor, brigadier general, United States Army, Chief of Counsel for War Crimes, and Leo Alexander, M D, psychiatrist, consultant to the Secretary of War and to the Chief of Counsel for War Crimes, and a note on medical ethics by Albert Deutsch (including the new hippocratic oath of the World Medical Association) 8^{vo}, cloth, 172 pp, with 16 pages of photographs. New York: Henry Schuman, 1949 \$3 00

This book is mainly a translation of *Das Diktat der Menschenverachtung*, published by the two principal authors at Heidelberg in 1947. It constitutes the story of the famous Nuremberg medical trial of 1946-1947, before Military Tribunal No 1. The two German authors attended the trial as delegates chosen by a group of German medical societies and universities. They were treated with the utmost courtesy and accorded the same privileges as the working press, with free access to all documents and testimony. They have rendered in the main part of this book a fair and impartial report on the proceedings of the trial. The defendants comprised 20 physicians of high rank in the German organization and 3 high-ranking civilian aids, 2 of whom were formerly attached to Hitler and Himmler. The text concerns the medical experimentation carried on at various concentration camps, the collection of skulls of Jews and the euthanasia program. Seven of the defendants were acquitted and freed, 7 were sentenced to death, and 9 received prison sentences of varying lengths.

The Uses of Penicillin and Streptomycin By Chester S. Keefer, M D, Wade Professor of Medicine, Boston University School of Medicine, and director of Evans Memorial and physician-in-chief of the Massachusetts Memorial Hospitals. 8^{vo}, cloth, 72 pp. Lawrence, Kansas: University of Kansas Press, 1949 \$2 00. Porter Lectures, Series 15.

In this small volume are gathered the three Porter lectures given by Dr Keefer under the auspices of the University of Kansas School of Medicine. They present a summary of the latest knowledge on two important therapeutic agents. The first lecture is entitled "Penicillin in Medical and Surgical

Practice," the second "Streptomycin in the Treatment of Infections," and the third "Antibacterial Agents from Microbes." The last lecture comprises a short history of the subject. Dr Keefer is recognized as an outstanding authority on penicillin and similar agents. Rather surprisingly, there is a good index to the small volume. The book is well published and should be in all medical libraries.

NOTICES

BOSTON CITY HOSPITAL HOUSE OFFICERS' ASSOCIATION

A Tuesday evening lecture sponsored by the Boston City Hospital House Officers' Association will be presented in the Dowling Amphitheater, Boston City Hospital, on December 13 at 7 p m. Dr Harry Eagle will speak on the subject "The Factors of Time and Dosage in the Therapeutic Use of Penicillin." The discussion will be led by Drs Maxwell Finland and Chester S. Keefer.

All interested physicians are invited to attend.

SOUTH END MEDICAL CLUB

A luncheon meeting of the South End Medical Club will be held at the headquarters of the Boston Tuberculosis Association, 554 Columbus Avenue, Boston, on Tuesday, December 20, at 12 noon. Dr Duncan E. Reid will speak on the subject "Experiences with a Recent Medical Mission to Germany."

Physicians are cordially invited to attend.

BOSTON LYING-IN HOSPITAL OBSTETRIC ROUND TABLE

The following schedule of obstetric round-table conferences for visiting physicians will be held at the Boston Lying-in Hospital at 7 p m on the dates indicated:

December 19, 1949 Early Trimester Bleeding (Clinical, Pathological and Hormonal Aspects) Drs H. Bristol Nelson, Arthur T. Hertig and George Van S. and Olive W. Smith.

February 20, 1950 Toxemia of Pregnancy (Obstetric Management and Treatment of the Complications of Oliguria and Anuria) Drs Duncan Reid and John Merrill.

April 17, 1950 Problems of Labor in the Potentially Infected Patient (Tests of Labor, Methods of Delivery and Chemotherapy) Drs Samuel B. Kirkwood, M. Fletcher Eades and Maxwell Finland.

Visiting physicians are invited to avail themselves of the Boston Lying-in Hospital cafeteria until 6 p m.

INTERNATIONAL SOCIETY OF HEMATOLOGY

The Biennial Congress of the International Society of Hematology will be held at the University of Cambridge, Cambridge, England, August 21 through 26, 1950.

The program committee is in the process of receiving titles for papers and scientific exhibits to be presented at the Congress. Material to be submitted for consideration for the program may be sent to Dr I. Davidsohn, Mt. Sinai Hospital, Chicago, Illinois, or Dr S. Mettler, University of California, San Francisco, California. Those desiring to present scientific exhibits should make application as soon as possible.

COURSES IN RADIOISOTOPE TECHNICS

Some vacancies still remain for the winter series of three courses in radioisotope technics offered by the Special Training Division of the Oak Ridge Institute of Nuclear Studies. Interested persons who can attend a course during the winter months are urged to make application for one of these courses in view of the heavy load of applications from university people for participation in the summer courses. The courses will begin on January 2, January 30 and March 6, 1950. Applications should be made as soon as possible. Eleven of the courses have already been given. Thirty-two participants can be accommodated in each of the three four-week courses. Requests for application and additional information should be addressed to Dr Ralph T. Overman, chairman, Special Training Division, Oak Ridge Institute of Nuclear Studies, P O Box 117, Oak Ridge, Tennessee.

(Notices concluded on page xi)

hypotension (average, seven hours) Two of these died suddenly, two and three days after emerging from shock and 3 patients survived Fifteen patients (75 per cent) died without improvement after one hour to four days in shock (average, nineteen hours), two thirds of these (10 patients) died within twelve hours

When shock was first noted, 11 (55 per cent) of the 20 patients who were not given transfusions

in 4 and improved in 3 Signs of failure followed transfusion in 2 other cases At the onset of shock, 7 patients who improved had congestive failure which, coincident with transfusion, increased in 3 and improved in 2, who were also given digitalis After receipt of 300 cc of p'lasma in twenty minutes, transient pulmonary edema developed in another patient Twelve of the 19 patients unimproved by transfusion were in congestive failure at the

including 2 of the 3 who survived, showed signs of congestive heart failure, usually left sided Nine of the 15 patients who died without improvement had congestive failure at this time, which improved in 1 and became worse in another In another case pulmonary edema occurred after the onset of shock In still another patient, who improved, signs of congestive failure appeared and increased temporarily before the patient recovered

The course of events was not very different in the 30 patients who received transfusions An average of 700 cc of blood or plasma was usually started three or four hours after the appearance of shock and given at the rate of 250 cc per hour Eleven of the thirty patients (37 per cent) rallied within three or four hours of the beginning of the transfusion, with an increase in systolic pressure of 10 to 60 and an improvement in general condition usually lasting until death or discharge Eight of these patients died two hours to six days after emerging from shock In 2 cases the blood pressure fell again to shock levels for a few hours before death, severe congestive failure and auricular fibrillation, with a rapid ventricular rate, developed in 1, another patient suffered a rupture of the myocardium, and 4 died suddenly of unknown cause Three patients continued to improve, 2 after repeated transfusions, and were discharged well Nineteen cases were not improved by transfusions The average survival after the beginning of shock in this group was sixteen hours This was similar to the course of patients in the "control" group who did not improve spontaneously

When transfusion was started, 19 patients (63 per cent) had congestive failure, which increased

onset of shock In only one of these did the signs of failure increase Heart failure occurred only after transfusion in another patient, who died in shock and pulmonary edema

As shown in Figure 1, more blood or plasma was given to patients who improved than to those who did not improve, however, some of the largest transfusions were not followed by improvement

FIGURE 1 Relation of the Amount of Blood Given and the Time of Administration to Improvement in Shock

There seemed to be no relation between the presence of congestive failure and the likelihood of improvement in shock with transfusion (Table 3) Fifteen of 19 patients with congestive failure at the onset of shock had no increase in failure with transfusion Indeed, congestive failure increased almost as often in patients who were not given transfusions (15 per cent) as in those receiving transfusions (20 per cent)

was apparently due to the greater age of our female patients and their higher incidence of diabetes. There was no significant difference in the mortality of the two sexes when only nondiabetic patients or diabetic patients in the same age group were compared.

Fifty patients, or 15 per cent of the series, satisfied the arbitrary criteria for shock outlined above. This figure is not comparable with those in the other

The average age and the incidence of previous hypertension in the patients in shock who received transfusions resembled those in patients in shock who did not get blood or plasma. As judged by the frequency of congestive failure, recurrence of pain after admission, occurrence of arrhythmia or intraventricular block and the average white-cell count and average temperature, the two groups did not differ significantly in the severity of the

series because no precise definition of shock is given by their authors. The mortality in this group was 88 per cent—more than twice that of the other patients not in shock. Thirty of the patients in shock were given transfusions of blood or plasma, and the remaining 20 were not. Table 2 compares certain features of the patients in shock with those not in shock and also compares the 30 pa-

myocardial insult. Their selection differed strikingly in that all diabetic patients in shock were given transfusions, comprising nearly half the transfusions. This factor must be considered when the results in the patients receiving transfusions are compared with their "controls" because the presence of diabetes (even though regulated) carried an extremely high mortality regardless of the presence of shock.

tients receiving transfusions with the 20 treated by more conventional methods.

Patients in shock had essentially the same age and sex distributions and the same incidence of previous hypertension as those not in shock. However, they had twice the incidence of diabetes and of congestive failure. The patients in shock had a significantly higher average white-cell count and lower temperature than the rest of the series.*

*The highest white-cell count and the highest temperature occurring during the first three days of hospitalization were recorded. Temperatures were usually taken by rectum but sometimes (and perhaps more often in the sickest patients) by mouth.

From the 20 patients who went into shock and were not given transfusions it was possible to form a picture of the natural history of the shock of myocardial infarction under the usual treatment. Table 3 summarizes the clinical course in the two groups.

At any time up to 12 days after the onset of chest pain (but within twenty-four hours in three quarters of the cases), the patients who were not given transfusions exhibited the signs and symptoms of peripheral vascular collapse. Five patients (25 per cent) improved after two hours to three days of

hypotension (average, seven hours) Two of these died suddenly, two and three days after emerging from shock, and 3 patients survived Fifteen patients (75 per cent) died without improvement after one hour to four days in shock (average, nineteen hours), two thirds of these (10 patients) died within twelve hours

In summary, from a purely statistical comparison of two small groups, no benefit from transfusion could be demonstrated. These figures are weighted by the fact that nearly half the patients receiving transfusions had diabetes, and presumably a worse initial prognosis than those not transfused, none of whom had diabetes. However, in this condition, in which every case is unique and the natural mor-

The situation had not changed 3 hours later, when an infusion was started. A liter of whole blood, a liter of 10 per cent glucose solution and 300 cc of physiologic saline solution were administered over the next 12 hours. Four hours after the transfusion had begun, when 500 cc of blood had been given, the blood pressure rose to 138/110. After the administration of another 500 cc of blood it was 150/110, and the patient looked and felt better. There was no increase in dyspnea or pulmonary rales. Four hours after the infusion had been stopped, the blood pressure began to drop again, and 3 hours later it was 100/86. Eight hours after transfusion

tality very high, statistical summaries may be less informative than a careful study of individual cases. Despite the statistical similarity between the transfused and "control" groups, transfusion seemed to be responsible for the clinical improvement in some patients. The following case reports are representative of 11 cases in which transfusion was accompanied by improvement in the shock syndrome.

A M (B60512), a 57-year-old man with hypertension, mild heart failure and one previous myocardial infarction, was admitted to the hospital after several hours of agonizing chest pain. The electrocardiogram was typical of recent anterior myocardial infarction. The blood pressure was 100/70. The first day of hospitalization was complicated by a nodal tachycardia, which subsided after large doses of quinidine. Thirty-two hours after admission, the arterial pressure dropped to 80/60, the patient became semistuporous, and his skin was cyanotic and clammy. He had not voided since admission. After 4 hours in this state, 1000 cc of plasma was given intravenously over a period of 2 hours. The blood pressure rose to 90/70. Even though the venous pressure rose from the equivalent of 210 mm to 340 mm of water, there was no increase in dyspnea or pulmonary rales, and the patient looked improved. Six hundred cubic centimeters of urine was obtained shortly after the infusion was completed. The blood pressure remained at 90/70 until 16 hours later, when it again fell to 80/60 and another 500 cc of plasma was infused. The venous pressure rose from the equivalent of 240 mm to 300 mm of water, but the patient seemed more alert and was able to void adequate amounts of urine. The blood pressure rose to 105/70 and was maintained at that level until discharge, 4 weeks later, when the signs of congestive failure had cleared.

A I (A57425), a 50-year-old diabetic man with hypertension and polycythemia, who had suffered a previous myocardial infarction, was admitted because of increasing dyspnea of 1 week's and vomiting of 1 day's duration. The arterial pressure was 150/120. He was digitalized because rales were present at the lung bases. Eighteen hours after admission severe, squeezing pain in the anterior portion of the chest developed, his blood pressure dropped to 80/40, and his extremities became cold and clammy. The concentration of glucose in the blood was not determined at this time, but hypoglycemia was considered unlikely because he had been given only 15 units of crystalline insulin 16 hours previously, and this had been followed by an infusion of glucose solution

had been stopped, the patient died. Autopsy confirmed the presence of a recent myocardial infarction.

DISCUSSION

Profound shock eventually results in widespread, irreversible disorganization of bodily function.¹⁴ In the presence of recent myocardial infarction, shock is particularly pernicious because existing cardiac damage may be aggravated by further reduction of coronary blood flow.^{14, 16} Most authorities agree, therefore, that this situation calls for prompt measures aimed at raising arterial pressure.

When shock follows experimental coronary occlusion in dogs, cardiac output is usually lowered but often not in proportion to the changes in arterial pressure.^{17, 18} By contrast with traumatic shock, the blood volume and central venous pressure are not reduced.^{17, 18} The meager data available on the hemodynamic changes occurring in man also indicate that, although the cardiac output may be reduced, neither the blood volume nor the central venous pressure is low.¹⁹ However, in some cases, there is evidence of peripheral venous collapse.^{20, 21} Two cases of shock and congestive failure following myocardial infarction have been reported in which the cardiac output was within normal limits in the presence of an elevated filling pressure.^{22, 23} Obviously, much more data of this sort is needed to clarify the mechanism of coronary shock in man.

Some authors^{6, 24} argue that the most rational therapy is the use of cardiac stimulants and vasoconstrictor drugs, but few cases of their successful employment have been reported.^{2, 24} One might expect blood transfusions to be of value if this type of shock were associated with pooling of blood in the splanchnic vessels and diversion of the circulation from more vital areas. There is evidence that this does occur in experimental hemorrhagic shock.

in dogs^{25, 26} and in shock due to mechanical limitation of blood flow²⁷

Transfusion might improve the circulation if further elevation of an already high venous filling pressure could increase the output of an infarcted heart. It has been shown that this occurs in a dog's heart failing during post-hemorrhagic shock after replacement of blood volume, although such a heart is less capable of responding to a given increment in filling pressure than it was before hemorrhage.^{28, 29} The blood pressures of 8 patients in this study rose during transfusion despite the presence of congestive failure. This suggests that some of these patients responded to augmented cardiac filling with an increase in cardiac output or peripheral resistance.

Many authors warn against transfusion of patients in shock when heart failure is present.³⁰⁻³² In only 2 of 21 such cases did pulmonary edema follow transfusion, and in one of these the symptoms subsided within half an hour, and the blood pressure rose. Signs of heart failure increased among the control patients almost as often as they did in those given transfusions. These data therefore suggest that transfusions can be given with relative safety.

It should be emphasized, however, that most of our patients received smaller quantities of blood at slower rates than are usually necessary to treat hemorrhagic and traumatic shock. For this reason the present study is inconclusive. Although more vigorous therapy might have improved the results, it is also possible that pulmonary edema would have been a more frequent complication. A more definitive investigation should include detailed hemodynamic studies on patients treated with larger and more rapid infusions than those employed in the present report. That such an effort is feasible is suggested by the infrequent development of pulmonary edema after transfusion in this series.

SUMMARY

Clinical observations on the effect of transfusions in 30 patients with shock following coronary occlusion are compared with the natural history of the disease in 20 patients not given transfusions.

Although transfusion seemed to be of benefit in a few cases there was no significant difference between the two groups in mortality and recovery from shock.

Transfusion did not seem to increase the incidence of pulmonary edema or the severity of congestive failure.

Shortly after this paper was submitted for publication, Sampson and Singer³³ reported their experience with small transfusions in the treatment of 11 cases of coronary shock. In spite of transient improvement in 8 cases only 1 patient survived his illness. Maximum improvement seemed to be dependent on early and fairly rapid transfusion. One patient with an initially high peripheral venous pressure died in pulmonary edema, but all others with congestive heart failure tolerated the transfusions well.

B.C.G. TUBERCULIN AS A TESTING MATERIAL*

ELI FRIEDMAN, M D,† AND IRVING SILVERMAN, M D ‡

BOSTON

WITHOUT going into a lengthy discussion on the significance of a positive skin reaction to tuberculin and its limitations, it is fair to state that few laboratory tests are as satisfactory and as widely used by the medical profession. Any additional contribution to the safety and efficiency of the test should be of value.

It is well known that the allergic response to tuberculoprotein, as indicated by the intensity of the reaction to tuberculin, varies in different persons. Thus, a given amount of tuberculin may elicit a mildly positive reaction in one subject and yet, in a more sensitive person, may cause a severe local reaction with vesiculation and necrosis, as well as constitutional symptoms such as malaise, chills and fever. The possibility, furthermore, of focal reactions with reactivation of a latent focus of tuberculosis, though very rare, must be kept in mind.

To avoid these severe reactions, it has been customary to start with a small initial dose, and, so that positive reactions in less sensitive persons will not be overlooked, this initial dose is followed by one or more tests with larger amounts of old tuberculin (O.T.) or purified protein derivative (P.P.D.). O.T., as is well known, is a steam-concentrated, glycerin-broth culture of human tubercle bacilli passed through a porcelain filter. P.P.D. is the heated protein of tubercle bacilli that has been precipitated from human tubercle bacilli cultured on protein-free mediums. The initial dose of O.T. is usually 0.1 cc. of a 1:1000 dilution (0.1 mg.). The second test is with 0.1 cc. of a 1:100 dilution (1.0 mg.). The dosages of P.P.D. as now marketed are as follows: first testing dose, 0.00002 mg., and second dose, 0.005 mg.

There is, however, an upper limit on the amount of tuberculin one can use. Smith et al.¹ carried out studies demonstrating that false-positive reactions, or "pseudoreactions," are obtained in as many as 15 per cent of cases when large doses (10 mg.) of O.T. are used. Some observers believe that any dose of O.T. over 1.0 mg. is unreliable because of the high incidence of false reactions. Furcolow et al.,² working with P.P.D., reported pseudoreactions in 50 per cent of cases when the usual second test dose (0.005 mg.) was used and the remarkably high figure of 96 per cent false reactions with the use of 1.0 mg. Vollmer³ states that, even

with the Patch test, pseudoreactions are more common when the concentration is increased.

It is obvious that the ideal tuberculin would be one that is free from severe positive reactions as well as pseudoreactions. In an effort to inhibit severe positive reactions, we tried antihistamine drugs⁴ and found them to be unsatisfactory.

It then occurred to us that a tuberculin prepared from B.C.G. vaccine might be an improvement over previous tuberculins. The bacilli in B.C.G. vaccine are sufficiently attenuated to be nonpathogenic and yet have not lost their ability to convert nonreactors to positive reactors. It was therefore decided to study the efficiency of B.C.G. tuberculin as compared with commercial tuberculin.

MATERIALS AND METHODS

This study was carried out with children aged four to twelve years at the Prendergast Preventorium in Mattapan, Massachusetts. Dr. Konrad Birkhaug, of the Division of Laboratories and Research of the New York State Department of Health, kindly prepared and supplied us with B.C.G. and O.T. The latter was prepared on a 5 per cent glycerolated broth, whereas the B.C.G. tuberculin was produced from an eight-week-old culture of B.C.G. grown on Sauton's (protein-free) synthetic medium. The concentration of these two tuberculins, according to Dr. Birkhaug, was comparable.

The children were tested intracutaneously with similar amounts of both O.T. and B.C.G. tuberculin. The same location (midvolar surface of the left and right forearms) was used for all injections. Alternate arms were used for B.C.G. and O.T. on every other subject so as to avoid any possible difference in reactivity of the right and left arms. The reactions were read at intervals of twenty-four, forty-eight and seventy-two hours, and those showing an induration of 5 mm. or more in diameter at the end of forty-eight hours, in addition to varying amounts of erythema, were considered positive reactions. (This is a criterion for reading a positive test as recommended by the Massachusetts Department of Public Health).⁵ The length and width of the indurations were measured with a millimeter rule. The product of these two measurements was considered as the area of the reaction and sufficiently accurate since the error would be approximately the same in all readings.

RESULTS

Of 91 children tested simultaneously with both 1:10,000 O.T. and 1:10,000 B.C.G. tuberculin, 43

were positive with both testing materials, and 48 were negative with both agents. The positive reactions were much more severe with OT in all but 8 cases of the 43 (Table 1). These 8 cases showed an equally mild reaction on both arms. Vesiculation occurred in 6 cases with the use of OT, whereas the opposite arm with BCG showed a definite positive reaction but without severity or vesiculation.

The 48 negative reactors were retested with a 1:100 dilution of both tuberculin on opposite arms

*Vesiculation.

Here again BCG proved to be as accurate as OT. Three subjects were found to be mildly positive to both. Pseudoreactions were much more common with OT and took forty-eight hours or more to fade, whereas with BCG these false-positive reactions were much less frequent and less severe and faded much more quickly.

In the final phase of the study 10 known positive reactors were tested with 1:100 dilution of OT, after which they were retested with a 1:100 dilution of BCG tuberculin. The difference in reactions was marked (Table 2). In 6 of the 10 OT-tested children vesicles, mild necrosis with markedly sore

arms and temperatures ranging from 101 to 104°F developed. The tests with BCG were all definitely positive, none were borderline, but were without

vesiculation and were unaccompanied by fever or other constitutional symptoms.

DISCUSSION

BCG tuberculin proved to be as accurate as OT since, despite the greater severity of the reactions with the latter, the tests all ran parallel in regard to positiveness or negativeness. In the dilution of 1:100 the reactions to BCG tuberculin were so definitely positive that there was no question of interpretation and no need for further testing with still larger doses. It is possible that a smaller dose of BCG tuberculin would be even more satisfactory as an initial and single testing strength material, thereby reducing still further the incidence of severe positive reactions and pseudoreactions. An optimum dose for routine intracutaneous testing, depending of course, on further observation and standardization, probably lies in a dilution between 1:1000 (0.1 mg.) and 1:200 (0.5 mg.). From our observations thus far, a dilution of 1:500 (0.2 mg.) appears to be the preferred dose.

The difference between the two tuberculin cannot properly be explained on the basis that BCG tuberculin is derived from bovine and OT from human tubercle bacilli, because it has been demonstrated by numerous observers that bovine and human tuberculin share a common antigen.

Nor can one ascribe all the differences in the severity of the reactions to the dissimilarity in the mediums used in the preparation of the two tuberculin. It is true that Magnusson and Lithander⁵ found that the glycerolated broth, which is the medium used for the preparation of OT, will give larger and more frequent reactions than Sauton's (protein-free) synthetic medium, which is used for the preparation of BCG tuberculin, but it is doubtful if this has any perceptible effect upon the real tuberculin reactions read in forty-eight to seventy-two hours.

It is very likely that the difference between the two tuberculins is qualitative as suggested by the work of Magnusson and Lithander.⁵ They found that in BCG-vaccinated children BCG tuberculin will provoke reactions considerably earlier and more frequently than OT. A better understanding of this qualitative difference may give more insight into the relation between allergy and immunity in tuberculosis.

SUMMARY AND CONCLUSIONS

From preliminary observations, it is fair to conclude that BCG tuberculin is a reliable and safe testing material. With similar dosages, given intracutaneously, BCG tuberculin produced much less severe positive reactions without undesirable local and constitutional manifestations and fewer

pseudoreactions than were seen with the use of OT.

Pending further standardization of the proper dosage, BCG tuberculin should prove to be suitable as a single-strength tuberculin for routine testing. This, it is hoped, would obviate, except in rare cases, the necessity for the present method of repeated testing.

OBSERVATIONS ON THE SYMPTOMATIC TREATMENT OF CHRONIC VASCULAR HEADACHE WITH CAFERGONE (ERGOTAMINE TARTRATE AND CAFFEINE)*

SHELDON G. COHEN, M.D.,† AND LEO H. CRIEF, M.D.‡

PITTSBURGH, PENNSYLVANIA

THE migrainous patient is grateful for any medication that will afford him symptomatic relief. Until recently, about the only medication capable of offering him any appreciable degree of comfort was ergotamine tartrate. Within the past year, a new preparation, Cafergone,§ has become available. This product contains a combination of ergotamine tartrate and caffeine.

Ergotamine is a natural alkaloid derived from ergot, a fungus found growing upon rye and other grains. Its pharmacologic actions¹ in man can be briefly outlined as follows: increase in contractions of the uterus by direct stimulation of the uterine musculature, constriction of smaller blood vessels, which is probably due to a direct peripheral action on the vascular muscle and consequent increase in the blood pressure, bradycardia, which may be a reflex response to vasoconstriction or a result of the ability of ergotamine to inactivate cholinesterase, a variable and minor effect on the central nervous system, a damaging effect on capillary endothelium with resultant vascular stasis, thrombosis and tissue gangrene—the mechanism of this action is not completely understood but may be secondary to extreme vasoconstriction and slowing of the blood stream with subsequent endothelial injury (Yater and Cahill² found that gangrene

was due to occlusion of the medium-sized and small arteries and arterioles by severe constriction and thrombus formation, intimal proliferation also possibly playing a role), and an adrenergic blocking effect³ on the sympathetic nervous system through paralysis of the excitatory responses (and possibly the inhibitory responses also) to epinephrine and adrenergic nerve impulses. Ergotamine does not prevent the liberation of the chemical mediators (adrenin or sympathin) but prevents the effector cells from responding to this substance.¹ Its action in providing symptomatic relief in migraine is so specific that this therapeutic response is often used as a diagnostic sign of migraine. It exerts no sedative or analgesic action so that it is only rarely that other types of headaches will be relieved by this drug. The most probable explanation of its therapeutic effect is based upon the concept of migraine as expressed by Wolff,⁴ in that the pain associated with migraine is due to dilatation and distention of relaxed cranial arteries, primarily branches of the external carotid artery. The therapeutic effect of ergotamine tartrate depends upon its specificity of action in its ability to constrict these relaxed and distended vessels.

Caffeine (1,3,7 trimethyl xanthine) is a derivative of coffee seeds and tea leaves. Its pharmacologic actions¹ can be briefly outlined as follows: stimulation of the central nervous system, especially the cortex (psychic and sensory functions and motor activity) and the medulla (respiratory, vasomotor and vagal centers), stimulation of the myocardium

directly resulting in tachycardia, increased cardiac output and a slight rise in blood pressure or a reflex bradycardia by inhibition of the medullary vagal nuclei, dilatation of peripheral blood vessels by a direct effect on the vascular musculature or constriction of these vessels by central stimulation of the medullary vasomotor centers^{1,5}, relaxation of coronary blood vessels, relaxation of smooth-muscle spasm, especially that of the biliary tract and bronchi, stimulation of skeletal muscles, slight increase in the basal metabolic rate, and a diuretic effect. The action is not completely understood, but the drug is believed to accomplish this by decreasing tubular reabsorption of fluid. Caffeine has been reported to be occasionally effective in headaches and migraine. This may be related to changes that the drug produces in the cerebral circulation.¹ Wolff⁴ reports that a mixture of caffeine and sodium benzoate administered intravenously acts as a vasodilator, whereas when given orally with a slower rate of absorption it may act as a vasoconstrictor. Thus, it may afford relief in migraine through its vasoconstricting action, for Wolff⁴ has found that other agents, which decrease the amplitude of pulsations of the cranial arteries, may lessen and abolish the headache of migraine when they reduce the amplitude to a degree comparable with the reduction produced by ergotamine tartrate. Goltman,⁶ by directly observing the bulging edematous brain during a migraine attack in a patient with an operative skull defect, and Redisch and Pelzer,⁷ who examined the capillaries in the skin at the cuticle base and in the mucosa of the lower lips in patients during migraine attacks induced by forced water intake, present evidence that migraine may be associated with changes in water metabolism and retention of fluids. The diuretic action of caffeine could therefore furnish one explanation for its therapeutic effect in cases of migraine. Dreisbach and Pfeiffer⁸ have demonstrated a "caffeine withdrawal headache" which may result from distention of the cranial arteries. The basic mechanism of this painful vasodilatation is obscure but may in some way be related to the sudden withdrawal of a central vasoconstricting agent, or accompanied by a relative increase in the effective blood volume.

Patients suffering from migraine have found that black coffee will enhance the effect of ergotamine tartrate or afford a certain degree of relief by itself. This, together with the known pharmacologic vasoconstricting and diuretic action of caffeine, resulted in the combination of ergotamine tartrate and caffeine for use in the symptomatic treatment of migraine. Friedman and Brenner,⁹ in studying 94 patients with migraine treated with various agents, report that combinations of ergotamine tartrate with caffeine proved to be more effective in relieving the migraine attack than ergotamine tartrate alone. Horton, Ryan and Reynolds,¹⁰ re-

porting 55 cases of headache, state that 56 per cent of patients obtained excellent results and 24 per cent obtained some relief with E C 110 (Cafergone) and that practically all the patients studied believed that E C 110 was more effective than ergotamine alone.

The following report deals with our results obtained with the use of this preparation.

CLINICAL MATERIAL

Fifty patients with chronic vascular headache were given a therapeutic trial with Cafergone. This was administered in oral tablets (E C 110) and in the form of a rectal suppository (E C 112). The oral preparation contained 100 mg of caffeine and 1 mg of ergotamine tartrate. The dosage was three tablets immediately during the aura or at the first warning of an impending headache and then one every half hour as needed for three subsequent doses, the total dosage not exceeding six tablets. In this group of patients there was a young boy, eleven years of age, to whom the drug was effectively administered in half this dosage. For patients who had extreme nausea and vomiting as a side effect of ergotamine or as part of the migrainous attack and who could not retain an oral preparation, the medication was supplied in the form of a rectal suppository. Each suppository contained 100 mg of caffeine and 2 mg of ergotamine tartrate. One suppository was used immediately upon the first warning of the onset of the headache, and then one every half hour as needed for two subsequent doses, the total dosage not exceeding three suppositories. A course of therapy was not repeated more often than once every ten days. Each of the patients was given at least two trials of therapy before definite evaluation was established.

Results were evaluated and tabulated as follows: none — no relief obtained, doubtful — doubtful

TABLE 1 *Results of Treatment of 50 Patients with Chronic Vascular Headache*

relief after a complete course of medication, mild — mild relief after a course of medication, moderate — moderate relief after a partial course of medication or definite relief after a complete course of medication, and marked — marked and definite symptomatic relief after two or three tablets or one suppository, each time the medication was employed.

Table 1 summarizes the findings.

Histaminic Cephalgia

Cafergone was administered to 2 patients with typical histaminic cephalgia as described by Horton¹¹ The symptomatology of this syndrome was characterized by unilateral headaches, of short duration, with sudden onset and cessation, often occurring at night, and associated with rhinorrhea, lacrimation, flushing and sweating of the forehead on the same side. One patient achieved an effective response varying between mild and marked, and in the second case marked relief of symptoms was noted.

Allergic Headache

Cafergone was given to 4 patients with typical allergic headache as described by Eyermann¹² The criterion for diagnosis of this condition was a non-migrainous type of vascular headache, with diffuse head pain, brought about as a result of the ingestion of a food or drug in a sensitive patient often suffering with an associated allergic disorder. In this group, 1 patient obtained no relief with this preparation, whereas the other 3 noted moderate relief with both the oral and suppository forms. One patient in this group also had Ménière's syndrome of allergic etiology associated with the cephalgia. It is interesting to note that Cafergone resulted in complete relief of the headache but did not affect the symptomatology of the Ménière syndrome.

Migraine

In this series of patients there were 44 cases of migraine. Thirty-six patients had the typical vasodilating type of migraine with the characteristic

TABLE 2 Degree of Relief Obtained with Cafergone in 44 Patients with Migraine

RELIEF	NO OF PATIENTS
None	7
Doubtful	2
Mild	5
Moderate	17
Marked	13

paroxysmal, periodic, recurrent, unilateral headaches, throbbing in nature, preceded by an aura and scotomas and associated with nausea, vomiting and photophobia. In 8 cases one or more of these features of the classic pattern were lacking, so that the established diagnosis was atypical migraine. Thirty-four patients were females, and 20 males were included in this series. Their ages ranged from eleven to fifty-nine years. The condition had been present from two and a half years to fifty years. The etiology of the migraine in these patients varied, with 25 cases due to allergy in this

group. This in no way reflects the true incidence of allergy as the cause of the migraine, for allergy usually produces this syndrome in a much smaller percentage of cases. It should be pointed out that the reason that the migraine could be attributed to allergy in such a large percentage of our patients

was that they were attending an allergy clinic, by reason of referral from another department that had suspected an allergic etiology or because they were allergic persons receiving treatment in this clinic for associated allergic diseases.

The therapeutic results achieved with Cafergone in this series of patients are summarized in Table 2, 3, 4 and 5.

In the total series of 44 patients with migraine, 37 noted relief of symptoms with the use of Cafergone.

22	8	3

4 experienced no relief after a course of Cafergone. It is noteworthy that one patient in whom Cafergone was effective reported that the only thing that had given her relief prior to this was black coffee. Another stated that antihistaminics were

more effective than either ergotamine or Cafergone. It is also interesting to point out that in 1 case in which a marked therapeutic effect was achieved with Cafergone, the patient reported an accompanying diuresis each time this preparation was employed.

Eight patients exhibited side reactions with the oral medication. Five who manifested gastrointestinal reactions noted absence of these side effects when switched to the rectal-suppository form, and only 3 of these patients also had side reactions to the suppository as well. Among the side effects listed were nausea, vomiting, irritability, feverishness, paresthesias and weakness. These side reactions, especially nausea and vomiting, were effectively controlled with 0.4 mg (1/150 gr) of atropine sulfate, administered by hypodermic injection or with tincture of belladonna (10 to 15 drops) when symptoms were less severe.

DISCUSSION

From the data presented above, it appears that preparations containing ergotamine tartrate combined with caffeine are effective in the symptomatic treatment of migraine. The addition of caffeine to the ergotamine tartrate in all probability exerts a synergistic action through either its vasoconstrictor or its diuretic effect. It appears that some patients who find no relief with ergotamine tartrate taken orally may achieve some degree of symptomatic relief with Cafergone. Many patients who find the oral preparation of ergotamine effective in the treatment of their migraine now find that Cafergone affords them a still greater degree of relief of symptoms. Some patients who obtain symptomatic relief only with ergotamine tartrate administered subcutaneously now find that Cafergone will achieve a similar therapeutic response, and it is therefore preferred by many of these patients because of the elimination of the necessity of a hypodermic injection. However, there are still many patients suffering with migraine who find that ergotamine tartrate by hypodermic injection is the only medication that will afford any appreciable degree of symptomatic relief. Like ergotamine, Cafergone is most effective when given during the period of aura or at the first warning of an impending headache rather than after the symptoms of migraine are well established. Its chief value lies in aborting the syndrome in its early stages. It is of no value in vasoconstrictive ("white") migraine, in which the indicated therapeutic agent to be employed is a vasodilating drug. Its side actions are essentially similar to those of ergotamine. Nausea and vomiting are effectively controlled with atropine sulfate, administered subcutaneously, and the muscle pains and weakness of the extremities are relieved by the intravenous administration of 10 cc of 10 per cent calcium gluconate. Often, when the patient can tolerate nothing by mouth

because of extreme nausea and vomiting, simply switching to the rectal suppository form of this preparation will result in symptomatic relief.

The contraindications to the use of Cafergone are essentially similar to those of ergotamine. Prolonged usage and overdosage can lead to the symptoms of ergot poisoning, and for that reason a total of 6 tablets or 3 suppositories should not be administered more often than every ten days. Because of its action in producing vasoconstriction and affecting damage to blood vessels the drug is contraindicated in coronary-artery and peripheral vascular diseases. Owing to its hypertensive effect, it should not be used when an associated hypertension exists. It is also contraindicated in pregnancy because of its direct stimulating action on uterine musculature. There is some evidence that increased sensitivity to ergot alkaloids may accompany febrile and septic states, hyperthyroidism and disease of the liver or kidneys, and its use is therefore precluded in these conditions. The dosage of caffeine included in this preparation is below the toxic level of 10 gm, and untoward reactions are usually not produced with doses under 1 gm. The side effects of caffeine, which are usually referable to the central nervous and circulatory systems, consist of insomnia, restlessness, excitement, tachycardia, extrasystoles and diuresis. These are usually well controlled by short-acting drugs of the barbiturate series.

SUMMARY

A series of 50 patients with chronic vascular headache were given a therapeutic trial with Cafergone, a new preparation containing a combination of ergotamine tartrate and caffeine.

The data presented suggest that the synergistic action of caffeine when added to ergotamine tartrate is more effective in some patients with migraine than ergotamine alone, when given orally, and is occasionally as effective as ergotamine tartrate when administered hypodermically.

The indications and contraindications for its use and the side actions produced are essentially those of ergotamine tartrate.

The pharmacology of ergotamine and caffeine, their therapeutic actions in the symptomatic treatment of migraine and the treatment of side effects produced are discussed.

MYCETOMA*

Report of a Case of Actinomycotic Variety

EMMETT B. REILLY, M.D.,† AND HOWARD H. STEEL, M.D.‡

VAN NUYS, CALIFORNIA, AND PHILADELPHIA, PENNSYLVANIA

MYCETOMA is a chronic granulomatous infection usually involving the feet, rarely affecting the hands¹ and still more uncommonly the leg, knee, neck, and trunk.² It is caused by a number of fungi, although the clinical and pathological picture is much the same regardless of etiologic agent. The disease most commonly occurs in males of the working age group with an agricultural background.³ There is no definite racial susceptibility, although certain racial groups, because of their occupational capabilities, are more frequently afflicted.

Mycetoma, or Madura foot, if one uses the geographicoanatomic nomenclature, is most prevalent in the warmer climes. The original reports were from India, but since then numerous cases have been reported from Africa, Europe and South and Central America and certain portions of North America. The majority of the cases in the United States involved people indigenous to the Southern and Western areas. No reports of the occurrence of the condition in Australia have been found.

NOMENCLATURE

According to Castellani and Chalmers,⁴ natives of Ballary knew Madura foot as "ghootloo mahdee" or "eggs of insects" because of the resemblance of the tubercular irregularities on the surface of the foot to ovum.

The vernacular terms "keereenagoah" and "kirinigras" are used in the Punjab and Rajputana respectively to describe mycetoma. Both words mean "dwelling house of worms" and came into use because the sinus tracts were considered to resemble cavities often occupied by larvae of flies.

Other local Indian terms are "slipada" (Bengalese) and "hatty-ka-poung" (Deccan) applicable to both elephantiasis and mycetoma and meaning "elephant leg."⁵

Some descriptive terms used to delineate the condition are endemic degeneration of the bones of the foot, elephant foot, eggfoot, ulcer grave, podalcoma and morbus pedis entophyticus.⁶ The eponym Ballingall's disease, synonymous with mycetoma, persists in the literature.

HISTORY

Madura foot was first noted by Indian physicians and is elucidated in early Sanskrit medical works. By many Kämpfer,⁶ a Pondichery missionary, is credited with being the first to describe the condition. In 1712 he used the term "perical," which means "leg of an elephant" and is applicable to any enlargement of the foot, but his description of the condition is classic for mycetoma. There is, however, some doubt about other very early cases because of laxness of terminology.

Madura foot was frequently misdiagnosed as tuberculosis by early authors. Godfrey,⁷ in 1844, described a probable case of mycetoma as "morbus tuberculosis pedis," believing it to be tuberculosis of the foot with incidental black deposits.

In 1842 Gill in the dispensary of Madura, a city in the southern part of the Madras province of India, called attention to a peculiar affection of the foot. It remained for Colebrook,⁸ Gill's successor, to introduce the term "Madura foot" into the literature in 1846.

In 1860 Van Dyke Carter⁸ established the fungous nature of the disease and proposed the name mycetoma ($\mu\upsilon\kappa\eta\varsigma$, fungus, and $\omega\mu\alpha$, tumor). He also proposed the earliest classification of the disease based on the color of the grains.

Reports have been numerous since that time, especially in the literature of nations founding empires, describing cases found in tropical and subtropical colonies. In 1894 Vincent,⁹ in Algiers, isolated an actinomycete from ochroid grains. In 1898 Wright,¹⁰ of Boston, isolated a hyphomycete from the black-grained variety. In 1906 Brumpt¹¹ reviewed the literature and provided an important mycologic study on the subject.

About that time much work was done in the analysis and classification of the causative organ-

isms In 1913 Pinoy¹² proposed that cases of Madura foot caused by an Actinomyces be called actinomycoses and those caused by a true mold be designated mycetomas This suggestion was modified by Chalmers,⁷ who, in 1916, used the term mycetoma as synonymous with Madura foot and distinguished actinomycotic and maduromycotic varieties of mycetoma This is the nomenclature accepted today

Mycetoma has been recognized in the United States since 1876, when Kemper and Jameson¹³ reported a case in a resident of Indiana, though some question of the accuracy of the diagnosis has been raised Hyde and Senn,¹⁴ in 1896, reported a case in an Iowa dental student

Since that time a number of cases have been recorded in the literature as having originated in the

is associated with the development of sinuses into the deeper tissues

On section of the involved member a profusion of scarring, discoloration and necrosis is noted Sinus tracts extend to involve any or all of the deeper tissues Abscesses connecting with the sinus tracts may extend along the tendons In advanced cases involvement of osseous tissue is usually present.

Microscopically the fungous grains are seen to be surrounded by polymorphonuclear leukocytes, many of which are undergoing degeneration Lymphocytes, plasma cells and macrophages are present as one proceeds peripherally Varying amounts of fibrous tissue are present An accumulation of large numbers of lipid-bearing macrophages is described in some specimens Eosinophils and pigment-bearing macrophages are also observed

MYCOLOGY

In earlier considerations of Madura foot the disease was usually classified on the basis of the color of the grain found in a given specimen Thus, a pale or ochroid variety, a melanoid variety and an uncommon, red variety were distinguished On microscopical examination the granules were seen to be composed of mycelia, pigment granules and leukocytes

However, it has been shown that each color may be produced by a number of different fungi and that a given species may produce grains of different color⁹

On microscopical examination of the grains, after softening in potassium hydroxide, individual hyphae may be studied

In the maduromycoses the grain is seen to be composed of a central mass of segmented branched hyphae with well defined walls and chlamydospores of various sizes About the periphery the hyphae assume a radiating appearance and terminate in chlamydospores

Grains from the actinomycotic variety are seen to be composed of a mass of more delicate, thin-walled, nonsegmented hyphal filaments Chlamydospores are absent The ends of the hyphae are surrounded by a gelatinous sheath, which gives a club-shaped appearance to the ends of the filaments

Cultural characteristics vary with the causative agent Sabouraud's agar produces the most satisfactory growth Animal inoculations have been tried by numerous authors^{9 12 42 43} On the whole, these have been unsatisfactory, although local, nonprogressive lesions have been produced

Gammel,⁹ in his study on the etiology of the mycetomes in the United States listed thirteen species of the genus Actinomyces as well as nineteen species belonging to two classes (*Fungi imperfecti* and Ascomycetes) and eight genera His list has been modified and brought up to date by Conant⁴⁴

PATHOLOGY

Most commonly the lesion involves the foot Much less often the hands or other portions of the body are affected Characteristically, the disease remains localized to the extremity, although local tissue destruction may be far advanced

The afflicted member is markedly swollen, the amount of swelling corresponding to the progress of the infection Necrosis of the overlying skin

DIAGNOSIS

The diagnosis of mycetoma is not a difficult accomplishment if the condition is kept in mind. A fairly typical set of symptoms and physical findings is present in most cases.

The patient is usually a male of the working age group with an agricultural background and an antipathy toward wearing shoes. There is usually a history of trauma, perhaps slight and far removed in time. A local lesion, either nodular, vesicular, pustular or ulcerative, appears. This is slow to heal, but since it causes little pain, the patient does not seek medical advice. The lesion drains sero-sanguinous or purulent fluid for a time and then heals, at least externally, only to return again at a later date. The involved extremity continues to swell. The condition is for a long time annoying rather than disabling, but it is always progressive.

After several months, perhaps several years, the patient presents himself to a physician.

The patient is by this time in fair general condition, perhaps evidencing some weight loss. Temperature and pulse are within normal limits. There is swelling that involves a large part or all of his foot. The surface of the swelling is marked with nodular, sinus-tract openings and ulcerations. Scar tissue is present, and there may be pigmentary changes. A probe can be inserted through the sinus tracts into the deeper tissues.

The blood count is usually normal, though a mild secondary anemia may be present. If granules are present in the drainage from the sinuses, direct examination under the microscope, as well as culture on appropriate mediums, is very helpful in establishing the fungal origin of the disease. If granules are not so readily available, a biopsy specimen may be taken for histologic examination and for culture.

X-ray study is helpful in establishing the presence of bone involvement. When such involvement is present the picture is that of marked osseous degeneration of both infectious and osteoporotic nature.

DIFFERENTIAL DIAGNOSIS

Tuberculosis can produce local lesions quite similar to those seen in mycetoma. However, systemic symptoms are usually more marked with tuberculosis. In tuberculosis a pulmonary lesion may be present. Tuberculin skin test and culture and guinea-pig inoculation of suppurative material would be helpful in the differentiation from tuberculosis.

Syphilis should be differentiated. Here the history, serologic changes and response to treatment help elucidate the true nature of the condition.

Diabetes can produce a strikingly similar picture, and again the laboratory will aid in diagnosis with tests for hyperglucosuria and hyperglycemia.

The possibility of other fungous diseases such as coccidioidomycosis, blastomycosis and sporotrichosis should be entertained in occasional cases. These should be distinguished by serologic methods, skin tests and identification of the fungus if the clinical picture is not sufficiently clear cut.

The differentiation of Madura foot from yaws and elephantiasis might cause some confusion. Yaws, however, is characterized by a greater systemic response, the occurrence of secondary lesions and the presence of rather definite racial predisposition. Elephantiasis is a lymphangitis involving usually an entire extremity rather than a peripheral portion of one as in mycetoma. Mycologic studies would rule out both these possibilities.

Malignant neoplasm could present a similar local picture. This can be readily separated by mycologic study and biopsy.

TREATMENT

To date no satisfactory therapeutic agent, except surgery, has been devised for the treatment of mycetoma, although numerous ones for both local and systemic use have been tried.

Local application of iodides was advised by Woolrabe⁴⁵. Audrain⁴⁶ suggested mercurochrome. Numerous other local germicides have been tried without favorable results. Chemical or thermal cauterization likewise has been unsuccessful. Tyrothrycin and gramicidin were used in the case reported below.

A long list of medications for internal use has been advocated. Woolrabe⁴⁵ recommended oral administration of iodides. Palmer⁴⁷ advised bismuth, sodium tartrate and copper citrate, reporting good results with this combination. Thymol⁴⁸ and oil of cinnamon⁹ have been suggested, but little success has followed their use. Arspenamine⁴⁹ has not been effective. Sodium propionate has been shown to be effective in vitro in large concentrations, but its clinical use⁴⁸ has not been successful. The sulfonamides have been credited with cures of the actinomycotic variety.^{48, 49} More recently, penicillin has been advocated⁵¹ and streptomycin was used in the case presented here. It is felt by many that the chief effect of these last three agents is on the secondary invaders.

X-ray therapy has been tried⁵² but does little more than slow the progress of the disease.

Amputation or surgical excision is the treatment of choice at this time although a trial of less radical therapy is always indicated.

Prognosis, so far as life is concerned, is good without treatment. Patients have lived for more than fifteen years with the disease without treatment. Prognosis for the cure of the lesion without treatment is extremely poor. An insidious, progressive course with remissions and exacerbations is the rule.

CASE REPORT

W. M., a 51-year-old Negro veteran was admitted to the Lake City Veterans Administration Hospital on May 20, 1947, complaining of swelling of the left foot ulceration and constant pain. About August, 1946, he had first noticed what he called "athlete's foot of both feet" more severe on the left side. By December the symptoms had become very severe, and the patient was plagued by almost continual itching. He believed that he had probably scratched it in his sleep. His physician advised topical medications to the foot. By March the patient was unable to work. He went to bed and remained there continuing to apply local medications to the foot. The skin broke down and numerous small sinus tracts appeared exuding a foul-smelling purulent material. The skin of most of the dorsum of the foot sloughed away and the tendons became visible beneath the necrotic ulcer base. The patient stated that when he lay in bed he could find relief from nagging pain in his foot only by placing a pillow beneath his knee. This was responsible for a 25° permanent deformity of the knee existing at admission.

The patient had always worked as a janitor except for 12 months in the Army as cook's helper. There was no history of agricultural employment. He had never left the state of Florida. There was no history of venereal disease. No history of injury to the foot could be elicited. The patient had lost 15 pounds in weight. There was no history of right sinusitis. There was a history of shortness of breath on exertion. The only peripheral edema had been in his left foot present since December 1946.

Physical examination disclosed a well developed man, mildly undernourished, lying in bed with his left knee extended to 155° with a pillow beneath it. The peripheral vessels were firm but both dorsalis pedis pulses were obtainable as were the posterior tibials. The radial pulse was of good quality. The reflexes were normal except the ankle reflex on the left, which was somewhat diminished probably because of local edema. Examination of the right foot revealed some hypertrophy of the nails but no evidence of onychomycosis. The left foot (Fig. 1) presented a rather bulbous and formless shape from the malleoli to the ends of the phalanges. The left great toe was black and the pulp of the toe diminished in quantity. The left foot presented a large sloughing area, which started over the fourth metatarsal bone on the anterior surface extending to the ankle joint and thence around the apex of the arch on to the plantar surface of the foot beneath the great toe terminating in the region of the third metatarsal head. The skin of the anterior surface was pockmarked with crypts and sinuses. Some eroded areas were evident in which a probe could be inserted into necrotic tissue.

The blood pressure was 140/80.

Urine analysis was negative. Examination of the blood showed a red-cell count of 4,200,000 and a white-cell count of 12,000, with 80 per cent neutrophils and 20 per cent lymphocytes. The nonprotein nitrogen was 25 mg per 100 cc. The fasting blood sugar was 70 mg per 100 cc. A 5-hour glucose tolerance test revealed a normal curve. The blood calcium was 9 mg per 100 cc. A Congo-red test showed no evidence of amyloid disease. The total protein was 5.6 gm per 100 cc. The serologic test for syphilis was negative. The icteric index was 4 units.

The spinal fluid was normal.

X-ray examination demonstrated sclerotic changes in the femoral arteries above the knees. Examination of both legs showed a moderate degree of osteoporosis involving practically the entire left tibia with some involvement of the bones of the right foot. Irregular bone absorption was noted in the cortex at the medial aspect at the left tibia. Films of the left foot showed a marked degree of osteolysis of the first metatarsal bone and the phalanges of the great toe. Osteolytic changes were present to a lesser degree in the other toes.

On admission to the hospital a course of penicillin, 50,000 units every 5 hours was begun. This treatment was continued for a period of 2 months supplemented by administration of sulfadiazine, 1 gm every 4 hours, and Lugol's solution, 15 drops three times a day. The patient was also given a course of Euadin. He was given a therapeutic trial of streptomycin, 0.5 gm every 12 hours for 5 weeks. This was discontinued because of mild deafness and tinnitus and after 7 days a second course was instituted. In 6 weeks symptoms of toxicity reappeared, and the drug was stopped. Neither

symptomatic nor clinical relief of the condition was evident at the time of cessation of treatment.

The patient required codeine and aspirin for relief of the pain in the foot. He was given a high-protein, high-vitamin diet supplemented by intravenous injection of proteins, and was also given a transfusion of 500 cc of whole blood on two occasions.

The treatment consisted of immersion in potassium permanganate soaks for a period of 3 weeks. This was followed by streptomycin and gramicidin by continuous drip. These applications had no apparent effect on the course of the disease.

Cultures were taken from the sinuses and from the necrotic areas on the dorsum and plantar surface of the foot. These were repeatedly grown *Aspergillus niger*. A biopsy was taken. This tissue was examined microscopically and cultured. Culture of the biopsy material again grew *A. niger*. A biopsy specimen was inoculated into a guinea pig and the animal was killed at the end of 4 months. No disease was found on post-mortem examination of the animal. The typical diagnosis of the biopsy specimen was *Madura* probably of the actinomycotic variety. At no time was

FIGURE 1 Left Foot Prior to Amputation

Actinomycetes cultured although repeated attempts were made.

The patient and two controls were tested with a vaccine prepared from *A. niger* cultured from the patient's foot. Controls were negative in 12 and 48 hours. A macule 2 cm in diameter at 12 hours developed and widened to 4 cm in 24 hours. A papule formed in the center and went on to pustule formation 15 cm in diameter. The reaction continued to necrosis and healing. A skin test with purified protein derivative No. 1 was read as 1-cm wheal and 2-cm erythema. Coccidioidin, histoplasmin and blastomycin skin tests were negative, as were agglutinations for typhoid and brucellosis.

On August 27, after no clinical improvement, a decision was made to amputate the left foot, giving the patient a below-the-knee stump. The amputation was satisfactory for a period of about 3 weeks. The patient had a flexion contracture of the left knee at 155°, which was corrected by Kirschner-wire traction to 170°. At the end of 3 weeks an intractable breakdown of the skin at the end of the stump occurred. The erosion continued into the remainder of the gastrocnemius and soleus muscles. A culture showed *A. niger* and *Staphylococcus aureus* coagulase negative. Decision was made to reamputate in the region of the thigh. This was accomplished on October 30. The patient's recovery from that date was uneventful. The stump was normal, and a prosthesis was ordered and provided.

Since the time of the second amputation the patient has continued to gain weight and to improve generally in clinical appearance.

At the first operation the left foot and leg were amputated at the junction of the upper and middle thirds. The foot had a bulbous form. The great toe was black and soft. On the anterior aspect of the foot there was a large ulcerated area, which started over the fourth metatarsal bone and extended

anteriorly upward to the level of the ankle and around the arch to the plantar surface of the foot beneath the great toe, extending as far laterally as the region of the third metatarsal. The skin and ulcer base of the dorsum were marked with sinus openings. The edge of the ulcer was firm, white and undermined. On cut section the process of tissue destruction was seen to have extended to involve the bones of

FIGURE 2 Photomicrograph of the Actinomycotic Abscess (x100)

the foot. The bones distal to and including the metatarsals were softened and eroded. The sinus tracts were seen to be processes of abscess pockets filled with a yellow-green purulent exudate. There was a tendency for the abscesses to extend along the tendon sheath. The muscles in the region of tissue destruction were scarcely recognizable and even

FIGURE 3 Photomicrograph of the Actinomycotic Abscess (x440)

above this point were pale and flabby. The arteries were patent.

The microscopical sections were prepared from the region of the ulcer edge as well as from the site of deeper tissue destruction. Sections of the former showed Negroid skin terminating abruptly at the edge of an ulcer. There a fibrino-purulent exudate covered a granulation-tissue base.

Sections through the deeper tissues showed edematous, degenerating, striated muscle and much granulation tissue.

Numerous small abscesses were present (Fig. 2). These contained a polymorphonuclear exudate. Some of these abscesses were seen to contain granules made up of a thin, delicate mycelium (Fig. 3).

Dr. Norman Conant, of Duke University School of Medicine, was kind enough to review the slides. It was his opinion that they contained actinomycotic granules.

At the second operation the upper third of the left leg and the lower quarter of the left thigh were amputated. An ulcer, 4.0 by 1.0 cm, was situated posterior to the line of the old surgical incision. There was another ulcer, which measured 5.2 by 2.3 cm, over the tibia anteriorly. The ulcer edges were composed of hyaline material and were well demarcated, averaging about 2 mm in thickness. The base of the ulcer was composed of a thin layer of green, purulent material overlying fresh granulation tissue. The ulcer over the tibia was separated from it by a thin layer of periosteum. The muscles were of a tan color and flabby consistence. The arteries were patent. The knee joint when opened presented no abnormality. The distal ends of the remainder of the tibia and fibula were softened and eroded. They were in contact with the purulent exudate from the ulcer near the old incision.

The microscopical sections showed degenerative changes identical with those described for the previous specimen except that no granules were noted.

DISCUSSION

The case of mycetoma reported above followed a rather usual clinical pattern, the response to therapy being similar to that reported in previous cases. Iodides, Fuadin, sulfadiazine, penicillin and streptomycin were tried, with no apparent benefit. Local applications, including potassium permanganate, tyrothricin and gramicidin, did not appreciably alter the course of the infection. Finally, after an adequate surgical operation, the patient made an uneventful recovery.

Of interest is the patient's sensitivity to an extract of *A. niger*. The organism was repeatedly grown on culture from the infected area but was never seen in tissue sections. It is believed that this organism may have been growing in the superficial layers, perhaps as a secondary invader, and that the patient thus became sensitized to the fungus. Unfortunately, we were unable to culture an Actinomycete to check the patient's sensitivity to that organism.

SUMMARY

A case of mycetoma, probably of the actinomycotic variety, is presented.

Of interest is the fact that sensitivity to an extract of *Aspergillus niger* was demonstrated.

Various therapeutic agents, including iodides, Fuadin, sulfadiazine, penicillin and streptomycin, were used, without benefit to the patient. Local applications of potassium permanganate, tyrothricin and gramicidin likewise were of no appreciable aid.

An uneventful recovery followed adequate surgical amputation.

CLINICAL NOTE

HERPES GESTATIONIS*

Fetal-Anomaly Syndrome Treated
Successfully with Sulfapyridine

JOHN GODWIN DOWNING, M D,† AND
OTIS F JILLSON M D ‡

BOSTON

THE following case is presented to demonstrate the dramatic response of herpes gestationis to small doses of sulfapyridine

ED, a 41-year-old woman, developed herpes gestationis at 4½ months of her second pregnancy. Her first child had died a few days after birth of what was thought to be congenital heart disease. Local applications and antihistamines were of no value. She was given sulfapyridine, 1 gm every 4 hours, and within 4 hours experienced extreme itching, nausea and vertigo. The medication was discontinued, but reinstituted 24 hours later in a dosage of 0.5 gm three times a day. At the end of 3 weeks the skin was entirely clear. Twice the sulfapyridine was stopped and the dermatitis reappeared (Fig 1). On reinstitution of 0.5 gm three times a day the eruption again completely cleared, and the patient was delivered of a normal 8-pound boy.

Lewis¹ reported a similar response to small amounts of sulfathiazole. Intensification of the dermatitis was noted by Mueller and Lapp,² who employed full medical dosage of sulfapyridine. It is suggested that with lower dosage this disease can be controlled with fewer untoward reactions.

In a statistical review of 20 cases of herpes gestationis appearing in 13 women, the average time of onset was five and three-tenths months of pregnancy. Eight of these women had histories of fetal anomalies. It was observed that if the fetal anomaly was a spontaneous abortion there was no associated herpes gestationis, because the uterus was emptied before the stage of pregnancy in which this disease had its onset. It might be postulated

that some cases of spontaneous abortion of unknown etiology are due to this syndrome of fetal anomalies and herpes gestationis. Only if these patients had future pregnancies extending beyond the period

FIGURE 1 Photograph Showing the Generalized Eruption, Consisting Mostly of Patches of Grouped Vesicles and Bullous Lesions, Which Dried Rapidly and Formed Crusts

of gestation in which herpes gestationis has its onset could the diagnosis of the disease be made

MEDICAL PROGRESS

RH AND OTHER BLOOD GROUPS (Concluded)*

LOUIS K. DIAMOND, M.D.,† AND FRED H. ALLEN, JR., M.D.‡

BOSTON

LABORATORY PROCEDURES IN BLOOD GROUPING

It must be emphasized at the outset that blood-grouping procedures are at present in an *imperfect state of development*. The tests are still dependent in all routine work on the phenomenon of red-cell agglutination. Although this is an extremely sensitive method, as many biologic tests are, it is somewhat unpredictable, being dependent on certain physicochemical and biologic factors. Red cells must be well preserved in serum or in the clot and relatively fresh (one to three days old is best although adequate preservation for several weeks is possible with respect to some of the antigens). The temperature, pH and concentrations of salt and protein must be controlled. Since the antibodies used for typing reagents may vary considerably in their activity (as pointed out in the discussion of anti-D) the conditions must be correct for the activity of the particular antibody. There is no one universally applicable technic.

In performance of blood-grouping tests it is imperative to follow in detail the directions furnished with the typing serum by the manufacturer. The importance of this statement cannot be over-emphasized. The following procedures are applicable in general but must be modified to conform to the directions furnished with a typing serum.⁵⁻⁸

Reagents Required for Blood Grouping and Compatibility Tests

Suspensions of red cells The following suspensions of red cells are required

Red cells, 2 per cent by volume suspended in physiologic saline solution, are used in the tube method for determination of the ABO group and the *tube method* for the compatibility test but should not be used in the slide test.

Red cells, 40 to 50 per cent by volume suspended in plasma or serum, are required in the slide method for determination of the Rh group and the slide method for the compatibility test.

The 2 per cent suspension of red cells can be made by the addition of 1 drop or more of blood for each 1 cc of fresh, uncontaminated, physiologic saline solution. If the patient is anemic, several drops of blood are required to obtain a 2 per cent suspension. Red cells may be obtained from the following sources: capillary whole blood⁹, blood containing an anticoagulant, and clotted blood, by removal of serum containing red cells, or by separation of a fragment of the clot with a wooden applicator stick and agitation in a tube containing physiologic saline solution.

Fluid blood with a hematocrit of 40 to 60 per cent may be obtained from a sample that is clotted or one containing an anticoagulant. If there is anemia, the sample is concentrated by removal of plasma or serum to adjust the hematocrit approximately to 40 or 50 per cent.

Precautions Red cells suspended in saline solution may lose their specific agglutinability during storage in the ice box and should not be relied upon after about twenty-four hours. In clotted blood, stored in the ice box, the red cells retain their agglutinability for many days.

Serums for grouping of blood and for compatibility tests The following serums are required: anti-A and anti-B grouping serums, anti-D grouping serum for the *slide method*¹⁰, serum from recipient and donor for the compatibility tests.

Anti-A and anti-B grouping serums are usually obtained from human donors of blood Groups B and A, respectively. Donors are selected that are known to have high concentrations of the isoagglutinin required. These serums are routinely used in the fluid state. Anti-A and anti-B grouping serums may also be prepared by immunization of rabbits; the serums are dried and used in powdered form¹¹. Anti-D grouping serum is obtained from immune human donors, since serums obtained by immunization of animals do not give consistent or reliable results. Serums

⁹Occasionally a small fibrin clot forms in the suspension. The suspended cells can be washed by centrifugation and resuspended in physiologic saline solution. The fibrin may be removed with a wooden applicator stick.

¹⁰The determination of Rh type can be done by the Landsteiner tube test, if proper saline-agglutinating serum (anti D) is available. It is particularly important, when such a serum is used to follow exactly the directions of the manufacturer.

¹¹Details of this technic are not discussed here.

CLINICAL NOTE

HERPES GESTATIONIS*

Fetal-Anomaly Syndrome Treated
Successfully with Sulfapyridine

JOHN GODWIN DOWNING, M D,† AND
OTIS F JILLSON M D ‡

BOSTON

THE following case is presented to demonstrate the dramatic response of herpes gestationis to small doses of sulfapyridine

E D, a 41-year-old woman, developed herpes gestationis at $4\frac{1}{2}$ months of her second pregnancy. Her first child had died a few days after birth of what was thought to be congenital heart disease. Local applications and antihistamines were of no value. She was given sulfapyridine, 1 gm every 4 hours, and within 4 hours experienced extreme itching, nausea and vertigo. The medication was discontinued, but reinstituted 24 hours later in a dosage of 0.5 gm three times a day. At the end of 3 weeks the skin was entirely clear. Twice the sulfapyridine was stopped and the dermatitis reappeared (Fig 1). On reinstitution of 0.5 gm three times a day the eruption again completely cleared, and the patient was delivered of a normal 8-pound boy.

Lewis¹ reported a similar response to small amounts of sulfathiazole. Intensification of the dermatitis was noted by Mueller and Lapp,² who employed full medical dosage of sulfapyridine. It is suggested that with lower dosage this disease can be controlled with fewer untoward reactions.

In a statistical review of 20 cases of herpes gestationis appearing in 13 women, the average time of onset was five and three-tenths months of pregnancy. Eight of these women had histories of fetal anomalies. It was observed that if the fetal anomaly was a spontaneous abortion there was no associated herpes gestationis, because the uterus was emptied before the stage of pregnancy in which this disease had its onset. It might be postulated

that some cases of spontaneous abortion of unknown etiology are due to this syndrome of fetal anomalies and herpes gestationis. Only if these patients had future pregnancies extending beyond the period

FIGURE 1 Photograph Showing the Generalized Eruption, Consisting Mostly of Patches of Grouped Vesicles and Bullous Lesions, Which Dried Rapidly and Formed Crusts

of gestation in which herpes gestationis has its onset could the diagnosis of the disease be made

LABORATORY PROCEDURES IN BLOOD GROUPING

It must be emphasized at the outset that blood-grouping procedures are at present in an *imperfect state of development*. The tests are still dependent in all routine work on the phenomenon of red-cell agglutination. Although this is an extremely sensitive method, as many biologic tests are, it is somewhat unpredictable, being dependent on certain physicochemical and biologic factors. Red cells must be well preserved in serum or in the clot and relatively fresh (one to three days old is best although adequate preservation for several weeks is possible with respect to some of the antigens). The temperature, pH and concentrations of salt and protein must be controlled. Since the antibodies used for typing reagents may vary considerably in their activity (as pointed out in the discussion of anti-D) the conditions must be correct for the activity of the particular antibody. There is no one universally applicable technic.

In performance of blood-grouping tests it is imperative to follow in detail the directions furnished with the typing serum by the manufacturer. The importance of this statement cannot be over-emphasized. The following procedures are applicable in general but must be modified to conform to the directions furnished with a typing serum.⁵⁻⁸

Reagents Required for Blood Grouping and Compatibility Tests

Suspensions of red cells The following suspensions of red cells are required

Red cells, 2 per cent by volume suspended in physiologic saline solution, are used in the tube method for determination of the ABO group and the *tube method* for the compatibility test but should not be used in the slide test.

Red cells, 40 to 50 per cent by volume suspended in plasma or serum, are required in the slide method for determination of the Rh group and the slide method for the compatibility test.

The 2 per cent suspension of red cells can be made by the addition of 1 drop or more of blood for each 1 cc. of fresh, uncontaminated, physiologic saline solution. If the patient is anemic, several drops of blood are required to obtain a 2 per cent suspension. Red cells may be obtained from the following sources: capillary whole blood⁹, blood containing an anticoagulant, and clotted blood, by removal of serum containing red cells, or by separation of a fragment of the clot with a wooden applicator stick and agitation in a tube containing physiologic saline solution.

Fluid blood with a hematocrit of 40 to 60 per cent may be obtained from a sample that is clotted or one containing an anticoagulant. If there is anemia, the sample is concentrated by removal of plasma or serum to adjust the hematocrit approximately to 40 or 50 per cent.

Precautions Red cells suspended in saline solution may lose their specific agglutinability during storage in the ice box and should not be relied upon after about twenty-four hours. In clotted blood, stored in the ice box, the red cells retain their agglutinability for many days.

Serums for grouping of blood and for compatibility tests The following serums are required: anti-A and anti-B grouping serums, anti-D grouping serum for the *slide method*¹⁰, serum from recipient and donor for the compatibility tests.

Anti-A and anti-B grouping serums are usually obtained from human donors of blood Groups B and A, respectively. Donors are selected that are known to have high concentrations of the isoagglutinin required. These serums are routinely used in the fluid state. Anti-A and anti-B grouping serums may also be prepared by immunization of rabbits; the serums are dried and used in powdered form.¹¹ Anti-D grouping serum is obtained from immune human donors, since serums obtained by immunization of animals do not give consistent or reliable results. Serums

⁹Occasionally a small fibrin clot forms in the suspension. The suspended cells can be washed by centrifugation and resuspended in physiologic saline solution. The fibrin may be removed with a wooden applicator stick.

¹⁰The determination of Rh type can be done by the Landsteiner tube test, if proper saline-agglutinating serum (anti-D) is available. It is particularly important when such a serum is used to follow exactly the directions of the manufacturer.

¹¹Details of this technic are not discussed here.

for the compatibility tests are obtained from clotted blood from the recipient and donor Plasma is usually unsatisfactory as a substitute for serum

Precautions Grouping (typing) serums should never be used unless they are proved* to be potent at the time they are used Anti-A and anti-B grouping serums should have a known high agglutination titer, showing strong agglutination of sensitive red cells when diluted to 1 64 or more with physiologic saline solution Serums for the slide test should show a high avidity, as evidenced in producing macroscopic agglutination in one minute, when 1 drop of serum is mixed with 1 drop of cell suspension on a glass slide Liquid grouping serums may be preserved indefinitely in the frozen state and will maintain potency for many months when stored at ice-box temperature provided there is no bacterial contamination Plasma should not be used in the compatibility tests since it contains fibrinogen and produces rouleaux formation as observed microscopically

Determination of ABO Blood Groups

Principle The first step in the preparation for blood transfusion is to determine the ABO blood group of the recipient and of the donors, at least the first step of the following three procedures being used anti-A and anti-B grouping serums of known potency are always used to determine the blood group of unknown red cells, the blood group, especially of Group O, may be confirmed by a test of the unknown serum from the recipient or donor with red cells of known Group A and Group B, the potency of anti-A and anti-B grouping serums may be checked qualitatively and quantitatively by a test with red cells of known Group A₁ and Group B, respectively

For these tests, the *tube method of Landsterner* is recommended as the standard procedure since it is rapid, reliable and simple, has a macroscopic end point of obvious agglutination and permits a large number of tests to be run simultaneously It is superior to the *slide method*, which is not described here The test tube should have an internal diameter of approximately 7 mm Reagents are measured in drops, *separate* capillary pipettes for each of the *grouping serums being used* One pipette, thoroughly rinsed in physiologic saline solution, may be used for the several suspensions of red cells One drop of serum is added to the tube, and then 2 drops of a 2 per cent suspension of red cells The tubes are agitated to mix the reagents, centrifuged† at 500 r p m for one minute, and remixed gently to loosen the cells from the bottom of the tube, and the agglutination is read macroscopically

*The potency of serum is readily checked as described below

†The tubes are not incubated and can be centrifuged immediately

Tubes showing no macroscopic agglutination are read microscopically for agglutination by transfer of a small drop to a glass slide

Method for determination of the ABO blood groups The tests listed in Table 10, by the tube method

TABLE 10 ABO Grouping with the Use of Known Antiserums (Standard Method)

GROUPING SERUM OF KNOWN POTENCY	2 PER CENT SUSPENSION OF RED CELLS TO BE GROUPED
1 drop Anti-A	2 drops
Anti B	2 drops

Interpretation. The interpretation is as follows:
 No agglutination (macroscopic or microscopic) indicates blood Group O
 Agglutination only with anti A serum indicates blood Group A
 Agglutination only with anti B serum indicates blood Group B
 Agglutination with both anti A and anti B serums indicates blood Group AB

of Landsterner, are always required for every blood grouping

Method for confirmation of blood group with the use of unknown serum It is desirable to confirm the blood group by a test of the serum from the recipient or donor as listed in Table 11, red cells of known‡ Groups A₁ and B, preferably from D-negative persons, being used

These particular tests should not replace the standard method of blood grouping described above,

TABLE 11 Typing of Unknown Serum with the Use of Known A₁ and B Cells

UNKNOWN SERUM TO BE TESTED	2 PER CENT SUSPENSION OF RED CELLS OF KNOWN BLOOD GROUP
1 drop 1 drop	2 drops Group A ₁ Group B

Interpretation. The interpretation is as follows for the blood group of the unknown serum:
 Agglutination* of both Group A₁ and Group B cells indicates blood Group O
 Agglutination* of Group A₁ cells only indicates blood Group B
 Agglutination* of Group B cells only indicates blood Group A
 No agglutination (macroscopic or microscopic) and no hemolysis indicates blood Group AB

*Occasionally, hemolysis occurs. When specific hemolysis is equivalent to agglutination but may be caused, nonspecifically by bacterial or chemical contamination or by improperly cleaned test tubes

since the agglutinins in serums from unknown patients are often low in potency, and occasionally absent

Method for checking the potency of grouping serums The grouping serums to be tested can be examined qualitatively as described above in the description of the method for the confirmation of blood group, 2 per cent suspensions of known Group A₁B or Group A₂ and Group B cells, respectively, being

‡Physicians and laboratory personnel are advised to determine and record their blood groups for ABO and Rh to make available at all times red cells of known groups for laboratory tests. The donors of these A and B test cells should be Rh negative (cde/cde) if possible and the donor of A cells should be of the subgroup A₁

used. The potency of grouping serums can be tested *quantitatively* by a preparation of serial dilutions of 1 10 to 1 160 or higher and the addition of equal quantities of a 2 per cent suspension of agglutinable red cells from Group A₂ or Group B. The maximum dilution of the serum that produces macroscopic agglutination of an equal quantity of cell suspension is taken as the end point to express the potency or titer of the serum.

False-negative agglutination. A dangerous error in blood grouping results from the failure to obtain agglutination when it should have occurred. The major cause of false-negative agglutination is weakness of the grouping serum.⁶ Another cause is the use of old cells that are not agglutinable because of long standing.⁸ Fluid grouping serum may deteriorate from standing in the room or from bacterial contamination. The most frequent error occurs from the use of anti-A grouping serum of inadequate potency. In this instance, no agglutination may occur with blood of Group A₁, and the blood group may be reported erroneously as Group O or B. This has occurred.²⁴ Such blood, when given to a Group O recipient has resulted in a fatal hemolytic transfusion reaction. Bloods of Group A₂ and Group A₂B are particularly subject to false-negative reactions since the antigen A₂ is significantly less agglutinable than the antigen A₁. A potent anti-A grouping serum will agglutinate red cells of Group A₁ and A₂ as well as A₁B and A₂B. A weak anti-A typing serum may fail to agglutinate A₂ cells. It is not necessary in the clinical use of transfusions to determine the subgroups of Group A, but it is obligatory that the anti-A typing serum be potent enough to agglutinate the subgroups of Group A. In addition, the compatibility test cannot be relied upon to detect errors arising from weak grouping serums for the following reasons: the agglutinin titer of the serum obtained from most persons tested is lower than that of a proper typing serum, and a false negative compatibility test has resulted²¹ when weak typing serum also failed to produce agglutination.

False-positive agglutination, rouleaux formation and cold agglutinins. False-positive agglutination should be suspected immediately if the major compatibility test by the tube method shows unexpected agglutination and the blood grouping has been checked. If this occurs, the recipient's red-cell suspension should be tested with the recipient's own serum, by means of the same technic as for the major compatibility test. If agglutination occurs in this test, it may be due to rouleaux formation or auto-agglutination and should be analyzed, since this serum may agglutinate all cells tested. Rouleaux formation of varying degree is always seen microscopically when cells are suspended in plasma.²⁵

Plasma should never be used for a compatibility test requiring interpretation by microscopical examination. In serum, rouleaux formation occurs

as the result of hyperglobulinemia. The formation of *rouleaux* is characteristic in its appearance, non-specific in affecting all red cells, nonabsorbable and readily decreased or eliminated by dilution of the serum 1 2 or 1 4 with physiologic saline solution. *Rouleaux formation is not a contraindication to transfusion with the cells tested.*

Cold agglutinins may cause autoagglutination and panagglutination of all cells even at room temperature.²⁶ Red cells from a patient with cold agglutinins may show agglutination with anti-A and anti-B grouping serums owing to adsorbed cold agglutinins and may thus appear to be Group AB. The red cells may be freed of cold agglutinins by washing three or more times in a large volume of warm physiologic saline solution. The cold agglutinins are nonspecific and adsorbable at low temperatures and may cause agglutination at room temperature that is reversed at 37°C. Cold agglutinins are not a contraindication to transfusion. Rarely, auto-agglutinins, other than cold agglutinins, are observed that produce agglutination at temperatures between 4 and 37°C. Occasionally, suspensions of blood infected with bacteria develop a panagglutination.⁸ This complication can be avoided by the use of fresh suspensions of red cells made from uncontaminated blood samples preserved in the icebox. Cold agglutinins found in a person's serum may be specific isoantibodies (anti-M, anti-P, anti-Lewis and so forth) — if so they will fail to agglutinate his own red cells.

Determination of the Rh Blood Group

Principle. For routine transfusion therapy it is essential to determine whether the blood is D-positive (85 per cent of the population) or D-negative (15 per cent of the population). The slide method is recommended since it is rapid and gives a strong macroscopic agglutination that provides a definitive and reliable end point.

Anti-D grouping serum for the slide method cannot be used for cells suspended in saline solution since no agglutination may occur, the cells must be suspended in a protein* medium. This grouping serum is usually labeled anti-Rh (anti-D) grouping serum "for slide test (hyperimmune)." It is a hyperimmune human serum, inactive in saline solution, that contains incomplete antibodies and may contain blocking† antibodies. It produces vigorous agglutination of red cells, in 40 to 50 per cent concentration, that are suspended in protein solutions, such as plasma, serum and albumin.

The anti-D grouping serum is obtained from immunized human donors. The naturally occurring anti-A or anti-B agglutinins in these serums are

*Two per cent by volume of red cells suspended in the patient's own serum or in albumin solution (human or bovine) can be used with this anti Rh serum in the tube method. The important factor is the presence of a sufficient concentration of protein.

†Blocking antibodies will inhibit the agglutination in the test tube of red cells that are mixed with serum known to agglutinate D positive cells. The blocking phenomenon has not been observed with the slide-test technic using a 50 per cent cell suspension in serum or plasma.

adsorbed or neutralized, leaving only the anti-D agglutinin.^{6, 37} Thus, the anti-D grouping serum agglutinates D-positive red cells, but does not agglutinate D-negative red cells, whether of Group O, A, B or AB.

Slide method for Rh grouping³⁸ A 0.2-cc sample of blood, with a hematocrit of 40 to 50 per cent, is transferred to a glass slide. Then 0.1 cc of anti-D grouping serum for the slide method is added. The blood and the typing serum are mixed over an area about 2.5 cm square, with a wooden applicator, the mixture being spread over the whole width of the slide and the ends of the film squared off. The resulting film should not be very heavy, but must not be so thin as to dry too quickly. The mixture is tilted back and forth on an illuminated ground-glass background that is warmed to about 40°C by the heat from an electric bulb. Agglutination is read, *only macroscopically*, after a period of 1 to 3 minutes of occasional tilting. The result should be compared to known D-positive and D-negative bloods set up in the same manner. Tests must be read *before drying* since a negative test may appear quite granular when dry. If drying occurs too rapidly for easy performance of the slide test owing to excessive dryness of the air a drop of bovine albumin solution* or of human albumin solution (20 to 25 gm of salt-poor albumin per 100 cc of physiologic saline solution) may be added after the slide has been exposed for thirty to sixty seconds. This addition of albumin usually enhances the agglutination if it is going to occur. Technically, it is advisable to add the drop of albumin to the top edge of the blood mixture while the slide is slightly tilted and to watch the drop as it goes down through the blood mixture before the slide is tilted again. Agglutination, if it is to occur, usually is instantly apparent in and around, and in the wake of, the drop of albumin.

Interpretation The result is reported, the variety of anti-D serum used being stated. If agglutination is observed, it is reported as D-positive. If no agglutination is observed, it is reported as D-negative. It is advisable to use more than one potent anti-D serum. If enough different serums were used in parallel, one would not overlook as many of the irregular, and important but uncommon, D antigens discussed previously. False-negative results may be expected with some regularity in the newborn baby (D-positive) with erythroblastosis fetalis. If the cells of the baby are completely coated with "blocking" antibody from the mother, they may fail to agglutinate in typing serum but may give a strongly positive direct Coombs test. Otherwise, there is no greater difficulty in typing of the blood of the newborn baby than that of an adult, provided the typing serums are potent and

from human sources rather than animal. Carefully obtained samples of blood from the placental end of the umbilical cord are satisfactory for typing purposes.

Compatibility Tests

Compatibility tests are essential to avoid errors in blood grouping, and especially to detect abnormal or immune agglutinins in the serum of the recipient. It is recommended that *three compatibility tests be done before each transfusion*—that is, two by the tube method and one by the slide method.

Tube method By means of the Landsteiner tube method, the compatibility tests shown in Table 12 are set up.

Slide method It has been demonstrated³⁸ that the slide method will detect the presence of hyper-

TABLE 12 *Compatibility Test, Major and Minor, by the Tube Method,* with the Use of Saline Solution*

†Two per cent suspension in saline solution.

‡Lack of agglutination indicates compatibility.

immune anti-Rh isoagglutinins. Thus the slide test serves as a simple test for the detection of dangerous incompatibilities that might cause a fatal hemolytic transfusion reaction. The compatibility test by the tube method usually will not detect the presence of anti-Rh agglutinins since it fails to detect the hyperimmune antibodies. The method is as follows.

A sample of 0.2 cc of the donor's oxalated whole blood, with a hematocrit of 40 to 50 per cent, is transferred to a glass slide and 0.1 cc of serum from the recipient is added as described above. The slide is read only macroscopically. If agglutination occurs, the blood is judged incompatible. Such incompatibility in this test may be due to anti-A or anti-B agglutinins, anti-Rh agglutinins or agglutinins other than anti-Rh. The test is designed primarily to detect hyperimmune anti-Rh agglutinins. A control for comparison is *always necessary*, by the use of 0.1 cc of the donor's serum or plasma, mixed with 0.2 cc of the donor's blood.

Interpretation of compatibility tests The compatibility tests in saline solution serve as a crude check on the accuracy of the determination of the blood group of donor and recipient. Agglutination is reliable evidence of the presence of an agglutinating agent that may be effective in vivo^{39, 40} and

*Supplied by Armour Laboratories, Chicago, Illinois.

may contraindicate the transfusion. A negative result does not necessarily exclude an agglutinin that may produce a hemolytic transfusion reaction^{34, 39}, no agglutination may occur with weak anti-A antibody or hyperimmune Rh antibodies.

The *compatibility test* in a saline-free protein medium (slide test) will usually detect the presence of a hyperimmune antibody that gives no agglutination in a saline medium. This screening test serves (when agglutination occurs) as a major warning that incompatibility exists and that transfusion is contraindicated until the isoantibody is identified.

Even when all cross-match tests described above show no agglutination it is still not certain in all instances that no abnormal antibodies exist in the patient's (or donor's) serum that could cause a transfusion reaction. A list of the isoantibodies that may be encountered in serum is shown in Table 13. The Coombs tests, described below, serve

patients contain isoantibodies that will not produce agglutination of red cells suspended in saline solution, although the antibody will transfer to red cells, coating them. For example, at least three different isoantibodies can be so transferred to normal red cells — namely, the hyperimmune anti-D antibody, the antibody in serums from patients with acquired hemolytic jaundice and the hemolysin from patients with paroxysmal (cold) hemoglobinuria.⁴⁵

Two different methods are available for the detection of antibody on sensitized but unagglutinated red cells: the use of an antihuman globulin serum (the Coombs test⁴⁶) and the addition to saline-free red cells of a solution of albumin or other plasma proteins.^{22, 47} In both tests the production of agglutination in the unagglutinated suspension indicates the presence of antibody on the red cell. The Coombs test is remarkably *sensitive* in the detection of small degrees of sensitization, and it is nonspecific since agglutination occurs with a variety of antibodies. The test with albumin solution is also nonspecific but is less sensitive and may be negative when the Coombs test is strongly positive.

The *value of the Coombs test in blood grouping* is immediately apparent from its sensitivity and nonspecificity in the detection of antibodies already present on red cells or the detection of antibodies that are transferred from serum to normal red cells. Although antibodies may *not* produce agglutination in saline suspensions of red cells they may cause agglutination and a severe hemolytic transfusion reaction *in vivo*, in the transfusion of D-positive red cells into a patient with hyperimmune anti-D isoantibody in the serum. Thus, the Coombs test has an important place in the testing for compatibility in certain instances of isoimmunization.

The Coombs test. Coombs, Mourant and Race,⁴⁶ in 1946, produced an immune antiglobulin serum in rabbits by the repeated injection of human serum or gamma globulin of human serum (not red cells). When this serum was adsorbed by washed normal human cells, it produced no agglutination of normal washed red cells in saline solution but did agglutinate previously unagglutinated suspensions of red cells coated with human isoantibodies. The procedure known as the *direct Coombs test* is performed by the incubation of equal parts of Coombs's serum and of a suspension of red cells washed in saline solution (unknown cells). In the procedure known as the *indirect Coombs test*, a serum is tested for the presence of antibody by incubation, in the serum, of selected normal red cells, the red cells are then washed in saline solution and tested for adsorbed antibody using antiglobulin serum as in the direct Coombs test.

†This is comparable to the slide test methods for detection of D positive cells or of anti D isoantibody, since both procedures avoid the use of saline solution and employ protein rich mediums of plasma or serum.

†Not in saline solution

as further methods for testing of compatibility by the detection of antibodies on red cells and in serum.

Coombs Tests and Test with Serum Albumin for Isoantibodies on Red Cells

It has been amply demonstrated that *red cells* may be coated with antibody globulin in certain instances but fail to agglutinate when suspended in saline solution.^{6, 20, 23, 28, 40, 41} This occurs, for example, for D-positive red cells coated with hyperimmune anti-D isoantibody,* as in the erythroblastotic infant. Coating of red cells without agglutination in saline solution or serum has been demonstrated in certain patients with acquired hemolytic jaundice⁴²⁻⁴⁵, in this instance the isoantibody is of unknown origin and is not related to any blood group. Conversely, the *serums* of certain

*The D antigen and antibody are most commonly involved in isoimmunization but other antigens of the CDE system are occasionally the cause of immunization.

Method for direct Coombs test Two drops of a 2 to 4 per cent saline suspension of red cells from the patient to be tested are placed in a small, clean test tube (8 by 70 mm). The tube is filled with uncontaminated saline solution by means of a clean pipette, the saline solution being introduced forcibly to disperse the red cells in the fluid. The tube is centrifuged rapidly for one or two minutes, and the supernatant saline solution is poured off. The cell button is then examined. If gross agglutination of the red cells is present, washing must be continued until spontaneous agglutination has been eliminated. If the cell button resuspends easily without gross clumping, the following steps are performed.

The *washing* is repeated at least twice more, the cell button being shaken up by tapping before the fresh saline solution is added. Extreme precautions about cleanness of glassware and saline solution are necessary to avoid unintentional introduction into the test tube of even minute amounts of human serum, which would be sufficient to neutralize the antiglobulin reagent when added. For the same reason, the tubes should not be inverted for mixing, since such a procedure involves the use of a potentially serum-contaminated finger or cork.

After three or four washings the cells are checked for agglutination and finally resuspended in saline solution to make approximately a 5 per cent suspension. An unagglutinated suspension of red cells is required for the Coombs test since the end point of the test is the presence or absence of agglutination. One or two drops (depending on potency) of Coombs's antiglobulin reagent are added, and mixed by gentle shaking. The tube is allowed to incubate* for thirty to sixty minutes at 37°C, it is then centrifuged at 500 r p m for 1 minute and the cells are examined for agglutination. A "positive test" is evidenced by agglutination of the red cells, which may be a solid agglutinated cell button, lesser degrees of macroscopic agglutination, or only microscopical agglutination. As a control, a tube containing the washed suspension of cells (but no Coombs's reagent) is incubated and should show no agglutination. Agglutination with Coombs's reagent indicates that globulins had been absorbed onto

the red cells and were firmly enough fixed to withstand washing.

Method for indirect Coombs test Two drops of a 2 to 4 per cent suspension of the donor cells in saline solution are mixed with two drops of the recipient's serum in a chemically clean test tube (8 by 70 mm). The mixture is incubated at 37°C for at least thirty minutes, centrifuged at 500 r p m for one minute and examined for agglutination of the red cells. (It should be noted that so far the technic is that of the "major" cross match.) Agglutination at this point concludes the test, since nothing further is to be gained by the Coombs method. If no agglutination is present, the test is completed by performance of the steps described for the direct Coombs test, by the addition of the anti-globulin serum to the donor's washed cells.

Albumin test Red cells suspected of having adsorbed hyperimmune antibodies, which failed to agglutinate them, in saline solution, after incubation at 37°C for thirty to sixty minutes are freed of saline solution after centrifugation and are resuspended in a solution of albumin (human or bovine, 20 gm per 100 cc of physiologic saline solution). Compatible plasma, serum or mixtures of albumin with serum or plasma may also be used. After standing for fifteen minutes, the tubes are centrifuged for one minute at 500 r p m, and the cell button is examined for agglutination. Doubtful or negative reactions are checked microscopically.

Limitations and interpretations A failure of sensitized cells to agglutinate in the Coombs test (false-negative reactions†) may result from weak anti-globulin serum or contamination of the test mixture with serum that may neutralize the Coombs serum. A false-positive agglutination may result from cold autohemagglutinins that were not removed by washing or from poor preparation (incomplete adsorption of nonspecific agglutinins for human red cells) of the Coombs serum. It is imperative that in the performance of the Coombs test, the suspensions be mixed by agitation of the tubes rather than by mixing against the finger, which may be contaminated with protein. Also,

*Some antiglobulin serums are potent enough for centrifugation to be done immediately.

†A control observation should be made to prove the effectiveness of the procedure and of the Coombs serum. This is done by the indirect Coombs test using known D positive red cells and known hyperimmune anti D isogantibody for sensitization. These cells should give no agglutination after washing but should show marked agglutination when treated with Coombs's serum.

glassware and solutions must be chemically and bacteriologically clean.

A *positive direct or indirect Coombs test* (agglutination occurring only after addition of anti globulin serum) or a positive *albumin test* indicates the presence of an antibody on the red cell, but does not indicate the kind or source of the antibody except when anti-D isocombody is suspected or known to be present. In the presence of the anti-D isocombody, transfusion with D-positive cells is contra-indicated. In the presence of a serum antibody in acquired hemolytic jaundice, transfusion is not contra-indicated but the transfused cells may be rapidly sensitized and destroyed *in vivo*.⁴⁷ Positive direct or indirect Coombs tests have generally not been obtained in cases in which immune anti-A or anti-B isocombodies are involved.

Gardner⁴⁸ has confirmed the fact that certain cases with *acquired hemolytic jaundice* show agglutination of the red cells in the direct Coombs test; in these cases the serum contains an antibody that may cause agglutination of normal red cells and a positive indirect Coombs test only when the pH of the serum is adjusted to 6.8.

Identification of Isocombodies

The detection of isocombodies has been discussed. The identification of the isocombodies that may be found in transfusion reactions and in erythroblastosis fetalis cannot be described adequately here, except for the identification of anti-D antibodies (see Tables 4 and 15). In general, an unknown serum is tested for agglutination with red cells from at least 2 D-positive and 2 D-negative Group O subjects. The isocombodies may be 'complete' (giving agglutination in saline solution) or 'incomplete' (hyperimmune) (giving agglutination only in saline-free protein medium), or may be a mixture of both 'complete' and 'incomplete' antibodies. Accordingly, suspensions of red cells are set up both in saline solution and (after removal of the solution) in albumin solution.

The detection of hyperimmune anti-A or anti-B requires special care. Use can be made of Witelsky's⁴⁹ observation that these antibodies are difficult to neutralize with the corresponding specific soluble antigen. A sufficient amount of the dilute solution of A and B substances (0.1 per cent, Sharp and Donahue) usually 1 to 2 parts, is added to the native serum to neutralize, completely or nearly, the saline-

active antibody, as determined by titration in a saline system. This "neutralized" serum can then be tested in a serum system (using for example, serum and cells from a Group A person for the dilution of, and testing of the serum suspected of containing hyperimmune anti-A), by successive dilutions with compatible human serum and the use of a 2 to 4 per cent suspension of known cells in serum. The hyperimmune A and B antibodies are inactive in saline solution and usually also in bovine as well as human albumin. Wiener⁵⁰ has found a buffered solution of acacia useful as a suspension medium. Group A, red cells should be used in the titration of a suspected hyperimmune anti-A, since the titer may be much lower against Group A₂ cells, or even absent, after the addition of the soluble antigen.

Trypsin and Other Agglutinating Enzymes

The use of trypsin in blood-grouping techniques has been reported by Morton and Polesky⁵¹ and studied extensively by others.⁵²⁻⁵⁴ Exposure of normal red cells to a dilute solution of trypsin alters them so that they are immediately agglutinated by hyperimmune (or blocking) antibodies when suspended in saline solution. The use of trypsin or other appropriate enzymes to treat red cells promises to a blood-grouping procedures by great simplification. The exact techniques have not had wide enough trial to be recommended for routine use.

SUMMARY

Seven blood-group systems are described comprising at least 20 separate and specific blood-group antigens. All are of very great importance in the fields of genetics, anthropology and legal medicine. At least 10 have been found responsible for cases of erythroblastosis fetalis. These same 10 have been found responsible for hemolytic transfusion reactions.

Although there is much confusion regarding the blood groups, they are simple enough to understand when considered one by one, which is usually possible in clinical practice. The chief difficulty consists of considerable variability in the types of circulating antibodies, which may occur naturally or may be produced by active immunization against any one of the blood-group antigens. This variability makes necessary, in the present imperfect

Method for direct Coombs test Two drops of a 2 to 4 per cent saline suspension of red cells from the patient to be tested are placed in a small, clean test tube (8 by 70 mm). The tube is filled with uncontaminated saline solution by means of a clean pipette, the saline solution being introduced forcibly to disperse the red cells in the fluid. The tube is centrifuged rapidly for one or two minutes, and the supernatant saline solution is poured off. The cell button is then examined. If gross agglutination of the red cells is present, washing must be continued until spontaneous agglutination has been eliminated. If the cell button resuspends easily without gross clumping, the following steps are performed.

The *washing* is repeated at least twice more, the cell button being shaken up by tapping before the fresh saline solution is added. Extreme precautions about cleanness of glassware and saline solution are necessary to avoid unintentional introduction into the test tube of even minute amounts of human serum, which would be sufficient to neutralize the antiglobulin reagent when added. For the same reason, the tubes should not be inverted for mixing, since such a procedure involves the use of a potentially serum-contaminated finger or cork.

After three or four washings the cells are checked for agglutination and finally resuspended in saline solution to make approximately a 5 per cent suspension. An unagglutinated suspension of red cells is required for the Coombs test since the end point of the test is the presence or absence of agglutination. One or two drops (depending on potency) of Coombs's antiglobulin reagent are added, and mixed by gentle shaking. The tube is allowed to incubate* for thirty to sixty minutes at 37°C, it is then centrifuged at 500 r p m for 1 minute and the cells are examined for agglutination. A "positive test" is evidenced by agglutination of the red cells, which may be a solid agglutinated cell button, lesser degrees of macroscopic agglutination, or only microscopical agglutination. As a control, a tube containing the washed suspension of cells (but no Coombs's reagent) is incubated and should show no agglutination. Agglutination with Coombs's reagent indicates that globulins had been absorbed onto

the red cells and were firmly enough fixed to withstand washing.

Method for indirect Coombs test Two drops of a 2 to 4 per cent suspension of the donor cells in saline solution are mixed with two drops of the recipient's serum in a chemically clean test tube (8 by 70 mm). The mixture is incubated at 37°C for at least thirty minutes, centrifuged at 500 r p m for one minute and examined for agglutination of the red cells. (It should be noted that so far the technic is that of the "major" cross match.) Agglutination at this point concludes the test, since nothing further is to be gained by the Coombs method. If no agglutination is present, the test is completed by performance of the steps described for the direct Coombs test, by the addition of the anti-globulin serum to the donor's washed cells.

Albumin test Red cells suspected of having adsorbed hyperimmune antibodies, which failed to agglutinate them, in saline solution, after incubation at 37°C for thirty to sixty minutes are freed of saline solution after centrifugation and are resuspended in a solution of albumin (human or bovine, 20 gm per 100 cc of physiologic saline solution). Compatible plasma, serum or mixtures of albumin with serum or plasma may also be used. After standing for fifteen minutes, the tubes are centrifuged for one minute at 500 r p m, and the cell button is examined for agglutination. Doubtful or negative reactions are checked microscopically.

Limitations and interpretations A failure of sensitized cells to agglutinate in the Coombs test (false-negative reactions[†]) may result from weak antiglobulin serum or contamination of the test mixture with serum that may neutralize the Coombs serum. A false-positive agglutination may result from cold autohemagglutinins that were not removed by washing or from poor preparation (incomplete adsorption of nonspecific agglutinins for human red cells) of the Coombs serum. It is imperative that in the performance of the Coombs test, the suspensions be mixed by agitation of the tubes rather than by mixing against the finger, which may be contaminated with protein. Also,

*Some antiglobulin serums are potent enough for centrifugation to be done immediately.

[†]A control observation should be made to prove the effectiveness of the procedure and of the Coombs serum. This is done by the indirect Coombs test using known D positive red cells and known hyperimmune anti-D antibody for sensitization. These cells should give no agglutination after washing but should show marked agglutination when treated with Coombs's serum.

glassware and solutions must be chemically and bacteriologically clean

A *positive direct or indirect Coombs test* (agglutination occurring only after addition of antiglobulin serum) or a *positive albumin test* indicates the presence of an antibody on the red cell but does not indicate the kind or source of the antibody except when anti-D isoantibody is suspected or known to be present. In the presence of the anti-D isoantibody transfusion with D-positive cells is contraindicated. In the presence of a serum antibody in acquired hemolytic jaundice, transfusion is *not* contraindicated but the transfused cells may be rapidly sensitized and destroyed *in vivo*.⁴³ Positive direct or indirect Coombs tests have generally not been obtained in cases in which immune anti-A or anti-B isoantibodies are involved.

Gardner⁴⁴ has confirmed the fact that certain cases with *acquired hemolytic jaundice* show agglutination of the red cells in the direct Coombs test, in these cases the serum contains an antibody that may cause agglutination of normal red cells and a positive indirect Coombs test only when the pH of the serum is adjusted to 6.8.

Identification of Isoantibodies

The detection of isoantibodies has been discussed. The identification of the isoantibodies that may be found in transfusion reactions and in erythroblastosis fetalis cannot be described adequately here, except for the identification of anti-D antibodies (see Tables 4 and 13). In general, an unknown serum is tested for agglutination with red cells from at least 2 D-positive and 2 D-negative Group O subjects. The isoantibodies may be "complete" (giving agglutination in saline solution) or "incomplete" (hyperimmune) (giving agglutination only in saline-free protein medium) or may be a mixture of both "complete" and "incomplete" antibodies. Accordingly suspensions of red cells are set up both in saline solution and (after removal of the solution) in albumin solution.

The detection of hyperimmune anti-A or anti-B requires special care. Use can be made of Witelsky's⁴⁵ observation that these antibodies are difficult to neutralize with the corresponding specific soluble antigen. A sufficient amount of the dilute solution of A and B substances (0.1 per cent, Sharp and Dohme), usually 1 to 2 parts, is added to the native serum to neutralize, completely or nearly, the saline-

active antibody as determined by titration in a saline system. This "neutralized" serum can then be tested in a serum system (using, for example, serum and cells from a Group A person for the dilution of, and testing of, the serum suspected of containing hyperimmune anti-A), by successive dilutions with compatible human serum and the use of a 2 to 4 per cent suspension of known cells in serum. The hyperimmune A and B antibodies are inactive in saline solution and usually also in bovine as well as human albumin. Wiener⁴⁶ has found a buffered solution of acacia useful as a suspension medium. Group A₁ red cells should be used in the titration of a suspected hyperimmune anti-A, since the titer may be much lower against Group A₂ cells, or even absent, after the addition of the soluble antigen.

Trypsin as an Aid in Agglutination Techniques

The use of trypsin in blood-grouping techniques has been reported by Morton and Pickles⁴⁷ and studied extensively by others.^{48, 49} Exposure of normal red cells to a dilute solution of trypsin alters them so that they are immediately agglutinated by hyperimmune (or blocking) antibodies when suspended in saline solution. The use of trypsin or other appropriate enzymes to treat red cells promises to aid blood-grouping procedures by great simplification. The exact techniques have not had wide enough trial to be recommended for routine use.

SUMMARY

Seven blood-group systems are described comprising at least 20 separate and specific blood-group antigens. All are of very great importance in the fields of genetics, anthropology and legal medicine. At least 10 have been found responsible for cases of erythroblastosis fetalis. These same 10 have been found responsible for hemolytic transfusion reactions.

Although there is much confusion regarding the blood groups they are simple enough to understand when considered one by one, which is usually possible in clinical practice. The chief difficulty consists of considerable variability in the types of circulating antibodies, which may occur naturally or may be produced by active immunization against any one of the blood-group antigens. This variability makes necessary, in the present imperfect

state of technical procedures, a considerable battery of different testing methods. The principles, and essential technical details, of the important methods now in use are discussed.

Information essential to the understanding of what is presently known about the blood groups and their isoantibodies is included. The problems of erythroblastosis fetalis and hemolytic transfusion reactions are relatively clear cut so far as the A, B and D (Rh₀) antigens are concerned. Clinical problems caused by other antigens and antibodies are usually easily solved by any one of a number of laboratories specializing in this work.

Even though they seem complicated, the blood groups are of such practical importance that every practicing physician who is responsible for transfusions, who deals with obstetric problems or who cares for newborn babies should have a fair knowledge of the basic concepts of blood-group incompatibility, in order that he may avoid serious risks to his patients, and be prepared to treat promptly the results of antigen-antibody reactions involving the blood-group factors.

In the process of preparation of this material for the *Syllabus of Laboratory Examinations in Clinical Diagnosis*, the manuscript was edited, criticized, changed and otherwise manipulated by a large number of persons, in particular, Dr T Hale Ham, who is largely responsible for its having been undertaken at all. Dr R R Race, of London, kindly reviewed the manuscript in its final stages.

Correction. In Table 1 of the Medical Progress report "Laboratory Data in Clinical Medicine: Units of Measure, Costs, and Quantitative Significance of Results" by Dr Thomas Hale Ham, which appeared in the September 29 issue of the *Journal*, the line reading "1 cubic millimeter (mm³) = 1,000 cubic microns" should be corrected to read "1 cubic millimeter (mm³) = 1,000,000,000 cubic microns"

MASSACHUSETTS MEDICAL SOCIETY

PROCEEDINGS OF THE COUNCIL

Stated Meeting, October 5, 1949

A STATED meeting of the Council was called to order by the President, Dr Arthur W Allen, on Wednesday, October 5, 1949, at 10 30 a m in John Ware Hall, Boston Medical Library, 8 Fenway, Boston

Two hundred and forty-one councilors were present (Appendix No 1)

The Secretary, Dr H Quimby Gallupe, presented the minutes of the Council meeting of May 23, 1949, as printed in the *New England Journal of Medicine*, issue of July 21, 1949 and moved their acceptance The motion was seconded, and it was so voted

The President then read the following obituaries

HAROLD GERARD GIDDINGS — Dr Harold Gerard Giddings died at his home on May 28, 1949 He was born in Gardiner, Maine, on March 23, 1880 He graduated from Harvard College in 1901 and from Harvard Medical School in 1907 After a surgical internship at the Massachusetts General Hospital, he took up general surgical practice in and around Boston Dr Giddings was chief of surgery at the Whidden Memorial Hospital in Everett from 1936 to 1947 and chief of the surgical outpatient department at the Massachusetts General Hospital from 1943 to 1946 During summer months he practiced surgery in Falmouth, Massachusetts In World War I, he served as a lieutenant colonel in the National Guard and commanded a Massachusetts Relief Expedition at the time of the Halifax explosion In World War II, he was a selective-service-board physician He was always actively interested in the affairs of the Society, serving on the procurement and assignment committee of Middlesex South District Medical Society and as president from 1943 to 1945 At the time of his death he had just finished his term as chairman of the Committee on Arrangements It was fortunate that he was able to attend the annual meeting of the Society in Worcester and to observe the appreciation of the fine program for which he devoted so much time and effort

He was a fellow of the American College of Surgeons

Dr Giddings loved his native state, he was an ardent fisherman and enjoyed his visits to Maine as a delegate to the Maine State Medical Society

HENRY ASHTON ROBINSON — Dr Henry Ashton Robinson died suddenly at his home in Hingham on August 21, 1949, in his sixty-third year

He was born in Hingham in 1887, attended the Hingham public schools and graduated from Harvard College in 1908 and Harvard Medical School in 1911

After practicing for several years in Marlboro, he was commissioned a first lieutenant in the United States Army in World War I and served in France with the 303rd Sanitary train of the 78th Division and was discharged as captain at the close of the war

In 1919 he settled in Hingham for the practice of medicine and was there until his death He was school physician for twenty-seven years and held other positions in social and business affairs of his town

He became a member of the Massachusetts Medical Society in 1914 and of the Norfolk South District Medical Society in 1919 He was a member of the Council from his district from 1938 to 1941 and from 1946 to 1949 He was vice-president of the Norfolk South District Medical Society in 1943 and president in 1944 and 1945 He was a member of the Committee on Public Relations from 1946 to 1949

In 1946 he was appointed to the Norfolk South District Committee to co-operate with the boards of public welfare and in 1947 was appointed chairman of the Norfolk South District Committee on School Medical Services

In January, 1948, he was appointed chairman of the Norfolk South District Committee of Professional Service Committee (Blue Shield) He was chairman of the Committee to organize a woman's auxiliary in this district

In 1949 he was appointed by Dr Belding a member of the Norfolk South District Legislative Committee He was a delegate two years ago to the meeting of the American Physicians Committee, after which he was active in planning a program for the Massachusetts Medical Society

His death leaves a vacancy in our ranks and we all realize that we have lost a tireless worker for the best interests of the Society

At the request of the President, the Council stood in silent tribute to the departed fellows

The President then announced the following interim appointments, which were approved by the Council

Committee on Code for Physicians

Donald Munro, *Chairman*
Charles C Lund
John F Conlin
Leroy A Schall
Ralph R Stratton

Committee on Pilot Clinics

John J Poutas, *Chairman*
Brooks Ryder
Sidney Cobb
George Dunlop
Alfred L Frechette

In addition to the following representatives from the districts

Julius G Kelley
George S Reynolds
William M Stobbs
Aubrey J Pothier
Elmer S Bagnall
Albert E Parkhurst
Spencer Flo
Allen S Johnson
Edward J Manwell
Robert E Archibald
Samuel A Dibbins
John J Poutas
Alfred L Frechette
Henry F Howe
Donald Martin
Brooks Ryder
George Dunlop
Sidney Cobb

President Allen then made the following remarks

The Committee to study the problem of professional service fees in the State was ordered by the Council at its last meeting to consist of 18 members — that is, one theoretically from each district In going over this problem, it seemed that it might serve a better interest for the Society if, in addition to these 18 men representing the various districts, we had a central executive committee representing the various specialties in medicine I will

state of technical procedures, a considerable battery of different testing methods. The principles, and essential technical details, of the important methods now in use are discussed.

Information essential to the understanding of what is presently known about the blood groups and their isoantibodies is included. Correction. In Table 1 of the Medical Progress report "Laboratory Data in Clinical Medicine: Units of Measure, Costs, and Quantitative Significance of Results" by Dr. Thomas Hale Ham, which appeared in the September 29 issue of the *Journal*, the line reading "1 cubic millimeter (mm³) = 1,000 cubic microns" should be corrected to read "1 cubic millimeter (mm³) = 1,000,000,000 cubic microns."

This recommendation was discussed in the Executive Committee, and apparently approved in principle, but not voted upon. It was suggested by the Executive Committee that the following recommendation replace that of the Committee on Public Relations:

That the Council shall establish a Massachusetts Medical Society citation to be awarded to a layman or a group of laymen for outstanding contributions to medical progress. Not more than three awards shall be made in any one year. The recipients shall be selected by a Committee to be designated by the President.

Also, the Executive Committee recommended that that citation should bear a name, and that the name should be the Lemuel Shattuck Award. I move you the adoption of the recommendation as presented by the Executive Committee.

The motion was seconded

Dr. Barton, Norfolk, spoke as follows:

The following remarks concern the naming of the award only. The presentation of the award as planned is an effort to improve relations between the Massachusetts Medical Society and the public, and in that respect it differs from some functions within the Society that bear the name of individuals, like the Cotting Luncheon.

If this citation is called by the name of an individual, it will gradually be referred to in the newspapers and elsewhere only by that name, and the Society's interest in it will be forgotten. Norfolk District Medical Society feels that when from time to time this award is made, it will emphasize the Massachusetts Medical Society's part in seeking out the recipient if the award is made in the Society's name.

We therefore recommend that the layman's award or citation bear the name "The Massachusetts Medical Society Citation for Outstanding Contributions to Medical Progress." I move the adoption of this recommendation.

This amendment was seconded.

Dr. John Fallon, Worcester, said that the Executive Committee believed that more publicity would be obtained by placing the name of Lemuel Shattuck on the citation. Mr. Shattuck was a layman who had produced one of the most important public-health documents.

The President called for a show of hands on Dr. Barton's amendment and declared that it was so voted. He then called for a voice vote on the main motion as amended and declared it so voted.

Dr. Kurth then moved the approval of the whole report as amended. The motion was seconded, and it was so voted.

Committee on Tax-Supported Medical Care — Dr. Albert A. Hornor, Suffolk, *Chairman*

Dr. Hornor submitted the report (Appendix No. 4) as informational and moved its acceptance. The motion was seconded, and it was so voted.

Committee on Legislation — Dr. David L. Belding, Norfolk South, *Co-Chairman*

Dr. Solomon L. Skvirsky, Norfolk, presented the report (Appendix No. 5) as informational and moved its acceptance. The motion was seconded, and it was so voted.

Subcommittee on National Legislation — Dr. Charles G. Hayden, Middlesex South, *Chairman*

Dr. Hayden presented the report as printed (Appendix No. 6) and mentioned the typographical error that had been corrected by the Executive Committee. He moved the acceptance of the informational report as corrected. The motion was seconded and it was so voted. Dr. Hayden said Reorganization Plan No. 1 mentioned in the report, had been defeated in the Senate.

STANDING COMMITTEES

Committee on Arrangements — Dr. Franklin G. Balch, Jr., Suffolk, *Chairman*

The Secretary presented the report for Dr. Balch (Appendix No. 7) and moved its acceptance with the recommendation concerning the time and place for the 1950 annual meeting. The motion was seconded, and it was so voted.

Committee on Public Health — Dr. Roy J. Ward, Worcester, *Chairman*

Dr. Ward presented the report (Appendix No. 8) as printed with two additions: telephone approval from his committee of the survey of multiple sclerosis by the Harvard School of Public Health and of the chest x-ray program in Boston. Dr. Ward made a motion that the Council also approve these two projects. The motion was seconded, and it was so voted. Dr. Ward then made a motion that certain very simple "standing orders" for nursing homes issued by the Department of Health approved by his committee be approved by the Council. The motion was seconded, and it was so voted.

Dr. Ward made a motion that the arthritic survey be approved and that it be accomplished with and through the office of the Commissioner of Health. The motion was seconded and so voted.

Dr. Ward made a motion that a sub-committee of his committee be appointed to study the problem of arthritis. The motion was seconded, and it was so voted.

He then moved for approval of the report as a whole. The motion was seconded, and it was so voted.

Committee on Membership — Dr. Lewis S. Pilcher, Middlesex South, *Chairman*

Dr. Pilcher presented his report as printed (Appendix No. 9) and spoke as follows:

The reason for discussing this report in some detail and giving special consideration to it is that the principal recommendation of the Committee on Membership concerns a problem that has been discussed before by the Council on several occasions, under differing conditions, and has been turned down. So we feel very strongly that this recommendation should be approved.

The recommendation concerns changing the by-laws as relates to application for membership of graduates of unapproved and foreign medical schools. Now, when

have to ask the Council to approve of this action on the part of the President, to make this change in the ruling, and the executive committee that we recommend is as follows

Richard H. Sweet, *Chairman*
George Prather
Leroy Schall
William Beetham
Christopher Duncan
Theodore Badger
Samuel Robins
Leo V. Hand
Richard I. Smith
Donald Munro
William T. Green

As representing the various districts, it seemed that the already appointed chairmen of Blue Shield district professional service committees would be best able to represent the Society as a whole. I will not read their names, unless you choose, but they have been previously appointed as such.

The two vacancies on the Council were filled as follows

Dr. Daniel B. Reardon — to replace Dr. Henry A. Robinson as public-relations councilor from Norfolk South

Dr. Joseph A. Holmes — to replace Dr. Harold G. Giddings on the Council from Middlesex South

REPORTS OF COMMITTEES

Executive Committee — Dr. H. Quimby Gallupe, Middlesex South, *Secretary*

The Secretary submitted the report of the Committee (Appendix No. 2), which met on September 7, 1949, at the Hotel Kenmore.

Under new business of the committee, the Secretary moved that the Council recommend to the Committee on By-laws and Council Rules that the by-laws be so changed that there shall be no fewer than six councilors elected from each district. The motion was seconded, and it was so voted without discussion.

The Secretary then moved that the President be asked to appoint a committee of 18 representing the district societies to study the problem of re-districting and councilor representation and, further, that an executive committee of not more than 7 members of the committee be appointed with power to act for the committee. The motion was seconded.

Dr. Basil E. Barton, Norfolk, moved that the motion be amended by changing the words "have power to act for the committee" to "for this purpose."

The motion to amend was seconded, and it was so voted. The President then called for a voice vote on the main motion, and it was carried unanimously.

Dr. Allen then spoke as follows:

May I now present to the Councilors a committee that we suggest to do this study concerning re-districting, and the number of councilors? It seemed to Dr. Gallupe and to me and to some others with whom we discussed this problem, that perhaps the secretaries of the various district societies would be the logical people to serve as a committee of 18 to study this problem. So we recommend the appointment of the secretaries of the various district societies.

I shall not read them all unless you request it, but I will read the committee of 7 who were selected as the executive committee, being those we considered centrally enough located to handle the problem from the standpoint of the metropolitan area, and they are as follows:

Dr. Charles G. Shedd, *Chairman*
Dr. Alexander A. Levi
Dr. Basil E. Barton
Dr. Donald Hight
Dr. Milton M. Sisson
Dr. Harold R. Kurth
Dr. Roy W. Layton

Dr. Ralph Stratton, Middlesex East, stated that Dr. Roy Layton had resigned as secretary of Middlesex East District Medical Society and that his successor had not yet come to function. Dr. Allen said that correction would be made.

A motion was made to approve the appointments, and it was seconded and so voted.

The Secretary then moved that the American Medical Association be invited to hold its Interim Clinical Session in Boston after 1950. The motion was seconded, and it was so voted.

The Secretary proposed that the choice of the Executive Committee for the American Medical Association's General Practitioner Award for 1949 had been made and that President Allen might well tell the Council about their candidate. Dr. Allen spoke as follows:

I feel that we are particularly fortunate in this state in having so many men who could qualify in this capacity. I believe that the Executive Committee gave very careful consideration to the three suggestions that were brought forth by three separate districts and it was felt that any one of these men would certainly have done credit to Massachusetts.

The vote, however, fell to one who is so well known to every man and woman who is a member of the Massachusetts Medical Society that I believe we should feel greatly honored to have him represent us. It is my hope that the entire Society in every conceivable way will back this candidate to the fullest of our abilities. We want him to win. We want him to bring this honor back to Massachusetts.

I will ask this candidate to rise, so that you will know personally he is still here and alive, and it looks as though we might win — Dr. Elmer S. Bagnall.

Committee on Public Relations — Dr. Harold R. Kurth, Essex North, *Secretary*

Dr. Kurth submitted the report as printed (Appendix No. 3). He then moved the approval of the first recommendation, that there be held a medical-press-radio conference some time in the latter part of October, 1949. The motion was seconded, and it was so voted.

Dr. Kurth then moved that the proposed health exhibit, which was to have been held in the fall of this year, be indefinitely postponed. The motion was seconded, and it was so voted. Dr. Kurth then spoke as follows:

The third recommendation was that the Council empower the Committee on Public Relations to award to some layman or group of laymen a citation for outstanding service to the medical profession, and that secondly, the Committee on Public Relations shall not make more than three such citations annually.

This recommendation was discussed in the Executive Committee, and apparently approved in principle, but not voted upon. It was suggested by the Executive Committee that the following recommendation replace that of the Committee on Public Relations:

That the Council shall establish a Massachusetts Medical Society citation to be awarded to a layman or a group of laymen for outstanding contributions to medical progress. Not more than three awards shall be made in any one year. The recipients shall be selected by a Committee to be designated by the President.

Also, the Executive Committee recommended that that citation should bear a name, and that the name should be the Lemuel Shattuck Award. I move you the adoption of the recommendation as presented by the Executive Committee.

The motion was seconded.

Dr Barton, Norfolk, spoke as follows:

The following remarks concern the naming of the award only. The presentation of the award as planned is an effort to improve relations between the Massachusetts Medical Society and the public, and in that respect it differs from some functions within the Society that bear the name of individuals, like the Cotting Lunchon.

If this citation is called by the name of an individual, it will gradually be referred to in the newspapers and elsewhere only by that name, and the Society's interest in it will be forgotten. Norfolk District Medical Society feels that when from time to time this award is made, it will emphasize the Massachusetts Medical Society's part in seeking out the recipient if the award is made in the Society's name.

We therefore recommend that the layman's award or citation bear the name "The Massachusetts Medical Society Citation for Outstanding Contributions to Medical Progress." I move the adoption of this recommendation.

This amendment was seconded.

Dr John Fallon, Worcester, said that the Executive Committee believed that more publicity would be obtained by placing the name of Lemuel Shattuck on the citation. Mr Shattuck was a layman who had produced one of the most important public-health documents.

The President called for a show of hands on Dr Barton's amendment and declared that it was so voted. He then called for a voice vote on the main motion as amended and declared it so voted.

Dr Kurth then moved the approval of the whole report as amended. The motion was seconded, and it was so voted.

Committee on Tax-Supported Medical Care — Dr Albert A. Hornor, Suffolk, *Chairman*

Dr Hornor submitted the report (Appendix No 4) as informational and moved its acceptance. The motion was seconded, and it was so voted.

Committee on Legislation — Dr David L. Belding, Norfolk South, *Co-Chairman*

Dr Solomon L. Skvirsky, Norfolk, presented the report (Appendix No 5) as informational and moved its acceptance. The motion was seconded, and it was so voted.

Subcommittee on National Legislation — Dr Charles G. Hayden, Middlesex South, *Chairman*

Dr Hayden presented the report as printed (Appendix No 6) and mentioned the typographical error that had been corrected by the Executive Committee. He moved the acceptance of the informational report as corrected. The motion was seconded and it was so voted. Dr Hayden said Reorganization Plan No 1, mentioned in the report, had been defeated in the Senate.

STANDING COMMITTEES

Committee on Arrangements — Dr Franklin G. Balch Jr, Suffolk, *Chairman*

The Secretary presented the report for Dr Balch (Appendix No 7) and moved its acceptance with the recommendation concerning the time and place for the 1950 annual meeting. The motion was seconded, and it was so voted.

Committee on Public Health — Dr Roy J. Ward, Worcester, *Chairman*

Dr Ward presented the report (Appendix No 8) as printed with two additions: telephone approval from his committee of the survey of multiple sclerosis by the Harvard School of Public Health and of the chest x-ray program in Boston. Dr Ward made a motion that the Council also approve these two projects. The motion was seconded, and it was so voted. Dr Ward then made a motion that certain very simple "standing orders" for nursing homes issued by the Department of Health approved by his committee be approved by the Council. The motion was seconded, and it was so voted.

Dr Ward made a motion that the arthritic survey be approved and that it be accomplished with and through the office of the Commissioner of Health. The motion was seconded and so voted.

Dr Ward made a motion that a sub-committee of his committee be appointed to study the problem of arthritis. The motion was seconded, and it was so voted.

He then moved for approval of the report as a whole. The motion was seconded, and it was so voted.

Committee on Membership — Dr Lewis S. Pilcher, Middlesex South, *Chairman*

Dr Pilcher presented his report as printed (Appendix No 9) and spoke as follows:

The reason for discussing this report in some detail and giving special consideration to it is that the principal recommendation of the Committee on Membership concerns a problem that has been discussed before by the Council on several occasions, under differing conditions, and has been turned down. So we feel very strongly that this recommendation should be approved.

The recommendation concerns changing the by-laws as relates to application for membership of graduates of unapproved and foreign medical schools. Now, when

this by-law was originally written, there was an influx of refugee physicians to the United States, particularly to Massachusetts. There were several unapproved medical schools within Massachusetts that were turning out large numbers of graduates each year, and it was felt that the Society had to protect itself by passing this by-law, which refused these graduates the right to apply for membership until they had been licensed for five years.

I want to call attention to the fact, however, that this by-law did not say that they had to be licensed in Massachusetts, or that they had to be residents of Massachusetts. They could come to Massachusetts after having been licensed anywhere in the United States, and as far as the by-laws are concerned, they could be in Massachusetts just one day before applying for membership in the Massachusetts Medical Society. The members of our Committee felt that that by-law, as far as the five-year provision was concerned, was no longer necessary, for the chief reason that refugee physicians are no longer a problem in this state, and secondly, that as of this year, all the unapproved medical schools in the country have been closed.

The objections to changing the by-laws are that if we do not have such a long waiting period, the physicians in the community will not have as long an opportunity to become acquainted with these applicants, and, of course, it is upon the other physicians in the community that we consider admitting these applicants to the Society.

However, under the old by-laws they did not have to be residents of the community. There was no residence requirement, and I should like to point out that under the by-laws of the Society it is the job of the Committee on Membership to satisfy itself that an applicant to membership is suited for membership, and any applicant who applies for membership in the Society who comes from an unapproved school, or who has any questionable background, is very thoroughly investigated by the Committee. We do not accept the letters that come with the application, which, everybody recognizes, may be written under pressure or may be just a formality. We call up in the community. We call up the members of the district committee and ask them to come in and discuss these men, and if there is still any question in our minds, we postpone the application for six months for further investigation. Thus, there are adequate safeguards within the Committee on Membership to assure that anybody who applies for membership in the Society will not be admitted if he should not be. And it does not require protection in the by-laws.

I should therefore like to move approval of the recommendation of the Committee on Membership to change the by-laws, Chapter V, Section 2 (b), second paragraph, to read as follows: "The applicant has possessed a license to practice medicine in the Commonwealth and has conducted that practice in the district in which he makes application for at least one year."

The motion was seconded.

Dr Frank R. Ober, Suffolk, spoke against the motion. Dr Philip G. Berman, Middlesex North, made a motion to amend, substituting two years for one year. The motion was seconded and defeated on a voice vote.

Dr Charles C. Lund, Suffolk, Dr H. Quimby Gallupe, Middlesex South, Dr Carl Bearse, Norfolk, and Dr Peirce H. Leavitt, Plymouth, spoke in favor of the main motion.

The President put the motion, and it was carried. Dr Pilcher moved that the report as a whole be approved. The motion was seconded, and it was so voted.

Committee on Society Headquarters — Dr Frank Ober, Suffolk, Chairman

Dr Ober presented his report as printed (Appendix No. 10) and spoke as follows:

We all recognize that in the last eight or nine years since Dr Phippen was president, the things that he instituted have outgrown the Society's headquarters. And the question is whether we should go into the matter of headquarters, doing something to revamp this building, or whether we should combine with some other institution or go out and select a piece of land of our own. We have had an opportunity to combine with the Museum of Natural History on the site of land down near the Charles River Dam. There are only 6 acres there.

The School of Public Health at Harvard University is going to move away from its present headquarters, if they can build a building. They are anxious to have the Department of Health in the same location, because their functions are more or less interwoven, and many men do teaching from the Department of Public Health and many in the School of Public Health give advice to the Department.

Then, too, we must consider the Library and the *Journal*, and the Society, which would be under the same roof, or under closely neighboring roofs.

There are great advantages in being connected with the Department of Public Health and the School of Public Health at Harvard, if we could have a site of land, which I am quite sure we could obtain for a small sum, not far away, where there is sufficient parking space (about 14 acres). It would hinge on selling this.

Now, if we add to the present building by constructing a piece across the corridor in the area at the back, we have something that will last temporarily, but we should decide whether we shall be satisfied with something temporary, or do we want something that will last indefinitely? As we discussed this matter, one of the members of the Committee suggested that instead of having the doctors study this situation, it would be much better if we could get a man who was competent in the field to study all the plans, and make recommendations to the committee, which we can present to the Council.

Dr Ober moved that the study be made. The motion was seconded, and it was so voted. Dr Ober then moved that a sum not exceeding \$5000 be appropriated to cover the cost of such a study. The motion was seconded, and it was so voted. Dr Ober then made a motion to approve the report as a whole. The motion was seconded, and it was so voted without discussion.

Committee on Industrial Health — Dr Henry C. Marble, Suffolk, Chairman

The Secretary presented the report as printed (Appendix No. 11) for the chairman. He noted that the date for the Industrial Health Conference had been changed to December 14, 1949. The Secretary moved the approval of the report as a whole with its recommendation. The motion was seconded and it was so voted.

SPECIAL COMMITTEES

Committee to Meet with the Massachusetts Hospital Association — Dr Albert E. Parkhurst, Essex South, Chairman

Dr Harvey Morrison presented the report (Appendix No. 12) as informational and moved its acceptance. The motion was seconded, and it was so voted.

Dr Albert Hornor made a motion that the Council extend its thanks to the Committee and request it to report further progress at the next meeting of

the Council The motion was seconded Dr McKittrick made the following remarks

I hope this isn't entirely out of order, but I should like to put my nickel's worth in Now, this committee cannot do this job I am not a member of the committee but I have put a lot of time and effort on this problem and any committee appointed isn't going to be able to do this job This job is going to be done at a local level, and that local level represents the individual hospitals We have been going through this at the Massachusetts General Hospital We have been bogged down not by the problem that is under discussion but by certain other matters that complicate it And we have eventually agreed almost in total with this report It has been done in certain other hospitals in the State and it has been done in hospitals outside this state

I should like to suggest that the Committee not be burdened with too much responsibility but that every one start working at the local level, and get the ball rolling for conferences between administration and between staffs

The so-called McKittrick report can be taken as the basis from which discussion starts and if individual hospitals will do that, continuous pressure will not be put on this committee, which can only go so far and no farther

The Secretary made the following statement

I want to second what Dr McKittrick has said, and to refer you all to the proceedings of the House of Delegates of the Annual Meeting of the American Medical Association held in Atlantic City last June, because there you will find the Hess Committee report, which every one of you should read, because it probably will mean the solution of your troubles, if you have any with your local hospital And that committee report includes in it the McKittrick report, the Report on Special Services, which, I wish to tell you, is a monument to the efforts of that committee and the Society in this whole problem

The President put the main motion, and it was so voted

Committee on Postgraduate Medical Education — Dr W Richard Ohler, Norfolk, Chairman

The Secretary presented the report as printed (Appendix No 13) for Dr Ohler as informational and moved its acceptance The motion was seconded, and it was so voted

Committee on Medical Economics — Dr Elmer S Bagnall, Essex North, Chairman

Dr Bagnall submitted the report as printed (Appendix No 14) and moved the approval of the new wording of Principle No 13 The motion was seconded

Dr Hornor opposed the motion for reasons that he mentioned as follows

I don't think it is going to do us any good to put such a thing in It is none of our business whether the schools go out for assistance or not.

Before the Congress at present is a bill embodying this idea, in which it has been insisted that funds must be furnished for schools for the education of osteopaths

I believe that schools that are now unworthy, which just hold charters and are not really operating, can use this to go to the federal Government and get money and we shall see an increase in unworthy schools

Dr Vlado A Getting, Middlesex South, spoke as follows

Being the administrator of a department that is now receiving between \$2,000,000 and \$3,000,000 in federal

funds today, I should perhaps tell you the experience we have had regarding any attempted control from the federal Government over a state program There isn't any If the Great White Father in Washington puts out regulations and rules that seem to be stringent, all we have to do is make a complaint, and the rules are changed immediately

I will say frankly that throughout the country, as a whole, the quality of public-health practice is greatly increased as a result of federal grants-in-aid for research and that every dean that the American Academy of Pediatrics representatives have communicated with has indicated not only that he is willing to accept the money but also that his experience has been good

As a member of the Approving Authority for Medical Schools it was our responsibility, and Dr Gallupe can well vouch for this, to look into the finances of training medical students The costs have gone up tremendously The income of the schools has not kept pace with the expenses

I believe that it is in the interests of the training of physicians to make it possible for them to receive money from the Government, if the Government wants to give it to them

In the Committee on Medical Economics and in the Committee on National Legislation of which committees I happen to be a member, it was decided that we in our letters to Congress would indicate that the Society is not in favor of any legislation that would support schools of osteopathy, so that complaint would be taken care of I think on the whole that this point No 13 as now written will be of benefit to all three medical schools in Massachusetts I think that if even the president of Princeton, who said he would not accept federal funds, carefully analyzed his budget, he would find that a great deal of funds now used for research in Princeton are from a federal source

Dr Charles G Hayden made the following statement

As a matter of information, I should like to point out that the bill now before Congress, which would provide for the subsidization of medical schools, was drawn in cooperation with the American Medical Association For that reason, I feel that it rightly comes within the province of this group to take action one way or another on this matter

Secondly, along the line of Dr Getting's remarks, as chairman of the Subcommittee on National Legislation, I have already sent a protest regarding the provision for subsidies for schools of osteopathy

The President put the question, and Dr Bagnall's motion was passed Dr Bagnall then made a motion to approve the report as a whole The motion was seconded, and it was so voted

Committee on New England Postgraduate Assembly — Dr Richard P Stetson, Suffolk, Chairman

The Secretary presented the informational report as printed (Appendix No 15) for the chairman and moved its acceptance The motion was seconded, and it was so voted

Committee on Diabetes — Dr Howard F Root, Suffolk, Chairman

Dr James H Townsend, Middlesex South, presented the report as informational (Appendix No 16) and moved its acceptance The motion was seconded, and it was so voted

The Co-ordinating Committee — Dr Frank H Lahey, Suffolk, *Chairman*

The Secretary presented the informational report (Appendix No 17) and moved its acceptance. The motion was seconded, and it was so voted.

Committee on Publicity Code — Dr Donald Munro, Suffolk, *Chairman*

Dr Munro presented the report as printed (Appendix No 18) and moved acceptance of the code as written in the report. The motion was seconded.

Dr Barton and Dr Norman A Welch, Norfolk, objected to Section 6 of the code because the words "head of a major department or research organization" might refer to the head of a commercial organization who might not be a physician. Dr Barton moved to amend the report by further study of Section 6. The motion was seconded.

Dr Munro said the code applied only to fellows of the Society and stated that Section 2 was the governing paragraph as to who would come under the code.

Dr McKittrick suggested that a comma placed after "hospitals" in line 1 of paragraph 6 would be helpful. On a show of hands Dr Barton's amendment was defeated. On a voice vote, Dr Munro's motion passed.

Dr Munro then moved the adoption of the second recommendation to continue the committee. The motion was seconded, and it was so voted.

Dr Munro moved the adoption of the third recommendation to publish the code in the new pamphlet on by-laws. The motion was seconded, and it was so voted. Dr Munro made a motion to accept the report as a whole. The motion was seconded, and it was so voted.

Report of Meeting of House of Delegates of the American Medical Association

Dr Leland S McKittrick, Suffolk, presented the report as printed (Appendix No 19) and moved its acceptance. The motion was seconded, and it was so voted.

Dr John Fallon, Worcester, spoke as follows:

At the last meeting of the House of Delegates, they asked that district and state societies institute committees to deal with hospital relations. Our committee under the name of the Committee to Meet with the Massachusetts Hospital Association has been doing that for a long time, and simply to get the thing in line with the American Medical Association terminology, I move that the name of this committee — and the Executive Committee approved the change — be changed to the Committee on Hospital and Professional Relations.

The motion was seconded, and it was so voted.

Advisory Committee on Red Cross Blood Bank — Dr Lamar Soutter, Suffolk, *Chairman*

Dr Carl Bearse, Norfolk, said that since neither the chairman nor any other member of the com-

mittee was present, he moved that the report be deferred. The motion was seconded.

Drs McKittrick, Gallupe, Lund and Parkins spoke against this motion because of the importance of the report. Dr Getting spoke as follows:

The Department of Public Health appropriates about \$150,000 as joint sponsor of this program. The Red Cross is spending in round figures about half a million dollars for the blood program, for the collection of the blood and for processing. In addition to that, they have in Massachusetts a pilot plant in our laboratory, where new procedures and techniques are developed after they are first tested in Dr McCoombs's laboratory at Harvard Medical School.

I believe that the purpose of this report is to improve the public relations between the hospitals, the profession at large and the American Red Cross and it is particularly important right now for the simple reason that this fall the American Red Cross will be opening a permanent blood center here in Boston, and while I can well understand the reluctance of the Council to act upon this matter, in the absence of a member of the committee, I believe that it is an oversight and I believe that the merits of the report speak for themselves.

The Secretary moved the adoption of the whole report as printed (Appendix No 20). The motion was seconded, and it was so voted.

Subcommittee of the Executive Committee on Blue Cross-Blue Shield Problems — Dr Charles J E Kickham, Norfolk, *Chairman*

Dr Kickham presented the report as amended by the Executive Committee (Appendix No 21). Concerning the only recommendation of the committee, Dr Kickham spoke as follows:

As we know, some physicians on an office basis have become members of Blue Shield, but up to the present time we understand that the association of groups of doctors or groups of physicians getting on the hospital basis, as in the Blue Cross, has not been carried out, and it was the opinion of the Committee that this discussion should be referred to an appropriate committee and brought back at a coming meeting of the Council. The Executive Committee voted that this present committee be empowered to investigate this subject more fully and to report to the Council. I, therefore, move the acceptance of the report in addition to the recommendation of the Executive Committee.

Dr Charles Hayden made the following remarks:

Again as a matter of information I should like to call attention to the fact that we receive upwards of half a dozen requests each week from physicians who want to join Blue Shield. Prior to September 1 of this year, we had no nongroup program and because physicians by and large are not associated with eligible groups, we were able to turn down those requests, giving them the information that the matter had been discussed by the Committee on Public Relations previously and that it was the policy of the Society not to make any arrangements for Blue Shield enrollments as have been made for Blue Cross enrollment. Now, under our present nongroup contract, I see no legal way in which we can turn down any physician who applies, provided he meets the qualifications that have been established for nongroup enrollment.

Dr James C McCann, Worcester, then spoke as follows:

In New York State the prepayment group had given little consideration to disruption of teaching services, since they are formally organized with the arrangement of limited staff members to teach the students associated

with the schools and colleges coming to those hospitals. We knew from the New York groups that private patients and beds in the teaching corridors could be interspersed with the teaching beds and that the effort of the teaching group was seriously disrupted.

The Blue Shield group called a meeting requesting the men in the teaching hospitals to advise us how we might maintain the objectives of prepayment and still not disrupt the teaching efforts in the schools and teaching hospitals. The suggestion was that we adopt the policy that we have previously used in payment of men associated with private groups—that is, checks were sent to a designated member of the group and the disposition of funds was then determined by the practitioners in that group.

There are several private groups in the State and the policy of those groups is to assure that all their members are participating physicians, so that then one saves the immense inconvenience of determining who in a group operates on a private patient—the Blue Shield compensates that group as such for all work done under the auspices of that group.

The suggestion of the teaching group was that we simply send out patients to them as formally organized groups, with the assurance that they would so organize. I think that the question of what is the ultimate fate of those funds, once the monies are placed in the hands of those physicians, probably is their concern. Just what the ultimate decision of these several groups will be—whether they distribute the money among themselves or whether they will of their own volition use it for research purposes—they will determine, and offhand I do not feel that Blue Shield should further supervise the fate of those funds other than seeing that they are placed in the hands of the men who are responsible for the care of the patient.

Dr. Allen put the question and it was so voted.

Advisory Committee to the Woman's Auxiliary—Dr. John F. Conlin, Suffolk, *Chairman*.

The Secretary presented the report as printed (Appendix No. 22) and moved its acceptance. The motion was seconded, and it was so voted.

NEW BUSINESS

Dr. Lund, speaking for a committee appointed by the councilors of Suffolk District Medical Society, presented the following resolution:

Whereas a statement dealing with the treatment of diabetes quoting Dr. Michael Samokian, a biochemist, and released by the American Chemical Society has been printed prominently in the public press, and

Whereas this statement referring to the chronic insulin poisoning and stating that virtually all adult victims of diabetes can be restored to normal health and life comfortably, without insulin injections, leads to the interruption of established treatment, and consequently endangers the health and life of diabetics,

Be it resolved that the Council of the Massachusetts Medical Society recommends that any information pertaining to the diagnosis and treatment of disease be released to the public only with the approval of a responsible committee or authorized officer of the organization from which the release emanates, and

Be it further resolved that the delegates of the Massachusetts Medical Society to the American Medical Association be instructed to present this resolution to the House of Delegates of the American Medical Association and the request that the trustees recommend that this action be taken by all scientific organizations, and in addition, to offer the advisory services of the American Medical Association and its constituent societies to all such organizations.

Dr. Lund made a motion to suspend the council rules for the resolution to be discussed. The motion was seconded, and it was so voted unanimously.

Dr. Munro said he approved of the resolution but believed it should be rewritten to comply with the code adopted at this meeting. He made the following motion: "to amend this resolution by adding a further paragraph to it, to the effect that this resolution be referred for final form and structure to a committee of this society, which shall be designated by the President before publication in public print and other mediums." The motion was seconded.

Dr. Fallon said he believed the resolution should be clarified before presentation to the House of Delegates. He made the motion to table. The motion was seconded and it was so voted.

A motion to adjourn was made and seconded, and it was so voted at 1:05 p.m.

H. QUIMBY GALLUPE, M.D., *Secretary*

APPENDIX NO 2

REPORT OF THE EXECUTIVE COMMITTEE

After lunch at the Hotel Kenmore on September 7, 1949, the meeting of the Committee was called to order at 1:00 p. m. by Dr Arthur W Allen with all the officers of the Society, Dr John F Conlin, Dr Joseph Garland and sixteen of the eighteen councilors present.

Under new business before the committee, the Secretary presented the following:

Under the existing by-laws (Chapter III, Section 5) the ratio of councilors is 1 for every 20 fellows, and in the same section the by-laws demand the election in each district of at least 6 councilors to designated offices.

As a result, four of the district societies are not permitted to have the required number of councilors, and, therefore, some fellows have to fill two positions.

The Secretary pointed out that the present council is too large (365) for the present seating and luncheon facilities, that one first-class mail to councilors cost over \$100 and that in districts such as Middlesex South it is often difficult to find 59 fellows as councilors.

The Secretary suggested that the present difficulties might be solved by a change in the ratio to 1 councilor to 40 fellows and that no district shall have fewer than 6 councilors. If this were done, twelve districts would each have the necessary 6 councilors, two districts between 6 and 10, two districts between 10 and 20, and the remaining two between 30 and 40. Instead of 365, the council would number nearer 270.

Dr John Fallon, Worcester, stated that when the present by-laws were written this matter had been considered, but he thought that the matter should be placed in the hands of a committee to study redistricting. He agreed that the present council is too large, but believed that it increased the interest of a larger number of fellows in the affairs of the Society.

The Secretary said that the matter of redistricting was the second to be considered under new business, since it was apparent that a district such as Middlesex South was spread over too large an area and that fellows in Charlestown and Somerville found it difficult to be interested in Framingham's problems.

Dr Dame, Franklin, stated that he thought the matter of a minimum number of councilors was the most pressing at this time and moved that the Executive Committee recommend to the Committee on By-laws and Council Rules that there shall be no fewer than 6 councilors per district. The motion was seconded, and it was so voted.

Dr Fallon suggested that a committee be appointed to study redistricting and the ratio of councilors. Dr Hornor, Suffolk, suggested that the committee might be a small one appointed by the President, a representative from each district or a representative from the hospitals over the State as members, along the lines suggested by Dr Fitz several years ago.

Dr Hurlburt, Plymouth, said he thought that redistricting was mostly a metropolitan problem. Dr Mernam, Middlesex South, suggested that the new Advisory Board might study the problem. Dr Curley, Worcester North, said he thought the committee might best consist of 3 fellows from the Boston area and 4 others spread over the State.

Dr Fallon moved that it be recommended to the Council that the President appoint a committee of 18 representing each district to study the problem of redistricting and councilor representation, and further, that an executive committee of not more than 7 of the committee have power to act. The motion was seconded, and it was so voted.

The Secretary then gave the status of the American Medical Association assessment collection as follows:

At the end of July only 49 per cent of our membership had paid. A letter was written to those who had not paid and now the percentage is near 66. The Secretary paid and now the percentage is near 66. The Secretary has now turned over further collection to the districts, hoping that by close contact the percentage paying might rise to 80 or 85.

The Secretary said that the Boston Chamber of Commerce wishes the Society to invite the American Medical Association to hold the interim clinical session in Boston.

*The motion recommending the appointment of an executive committee "with power to act" in the matter of redistricting was amended by the Council to read "for this purpose."

after 1950 and assures the Society that exhibit and hotel space is available in sufficient quantity.

Dr Kickham Norfolkt moved that the Committee recommend that the Society invite the American Medical Association to hold the interim session in Boston at a future date. The motion was seconded and it was so voted.

The Secretary stated that the next item for consideration was the selection of the Massachusetts Medical Society candidate for the American Medical Association's General Practitioner's Award as directed by the Council. He said he knew of three candidates from Essex North Dr Elmer S Bagnall from Norfolk Dr Dean S Luce and from Worcester Dr William E. Balmer. These fellows had been officially chosen by their respective district societies.

At the request of the President Dr Arnold P. George Haverhill presented the name of Dr Elmer S Bagnall as the candidate from the Essex North District Medical Society and submitted a volume of material concerning Dr Bagnall. By a vote of the committee the material was passed around for inspection.

Dr Charles J. E. Kickham Norfolkt presented the name of Dr Dean S. Luce as the candidate of his district and submitted material concerning Dr Luce which was passed around.

Dr John Fallon Worcester presented the name of Dr William E. Balmer as the candidate of his district and submitted material concerning Dr Balmer.

Dr Allen asked Dr Conlin to say something about the public-relations aspect of the award. Dr Conlin spoke as follows:

I was just trying to go back to the original purpose in making this award. The requirements were never too clearly stipulated. It was to be a person who had been engaged in general practice exclusively, who was honored and respected within his community, and who had contributed to the well-being and respect for medicine in his community. At such time as a practitioner is selected for the award, by the vote of this Executive Committee it becomes a function of the public-relations branch of the Society to make something of it. That is the purpose of the award on a national basis and I think it should guide the choice of this committee. That is what can benefit medicine in Massachusetts from the choice of such a person.

Obviously, it is a public-relations gesture, purely and simply. That is why it was designed to get the people of American thinking about the function of the kindly, old family doctor, who had borne the burden through the years and was the backbone of the medical profession and all those other things that we have heard so much about. It means that the selection emerging from this group should be one that has some chance of emerging nationally.

The President then called for a vote by ballot and named Drs Welch and Garland as tellers. While the tellers collected the ballots and returned to count them, Dr Allen spoke as follows:

Whichever candidate should be selected by the Executive Committee, I think that we should support that candidate to the very best of our ability. Now there are three excellent men whose names have been submitted, and any one of them would do credit to the State. Now, of course, two of these men will have to be defeated unfortunately, but whichever man does get the most votes, or is selected, I hope that we will spread throughout the State in every district the word that this has been done as legally as we know how that this candidate has been selected and that we hope there will be a complete accord in the State and that everybody will support this candidate to the best of his ability because it would be quite an honor to bring this award to Massachusetts if it can possibly be done.

Dr Garland then announced that Dr Elmer S. Bagnall had been selected. Dr Kickham moved that the vote be made unanimous. This motion was seconded, and it was so voted.

At this point, Dr John Curley asked for support of the World Health Organization.

COMMITTEE REPORTS

Committee on Public Relations

Dr Allen presented the recommendation that a medical press-radio conference recommended by Dr Conlin be held during the latter part of October 1949. A motion was made to approve this recommendation. The motion was seconded and it was so voted without discussion.

Dr Allen presented the second recommendation that the Health Exhibit proposed for the fall of 1949 be indefinitely postponed because plans could not be completed in time. It was moved and seconded that the Council approve this recommendation. The motion was seconded and it was so voted without discussion.

Dr Allen then presented the third recommendation concerning lay awards. The Secretary moved that the Committee recommend that the Society make awards to laymen as described in the report. The motion was seconded. The Secretary reported that after communicating with all the other states on this matter, he found that a few had made lay awards and they all thought it a fine idea. Dr Dame said he believed the Society should produce a citation of merit which would be given to one who deserved it, rather than just pick out a person to honor. Dr Conlin spoke at length on the public-relations value of the award.

The original motion was withdrawn and the President asked Dr Dame to draw up a substitute motion embracing the points brought out in discussion—namely, the citation, the number of awards, the choice by the public-relations group, the need for careful publicity and the value of naming the citation.

While Dr Dame and Dr Conlin were conferring on the wording of a motion the President voted that the remainder of the report was informational. The Secretary moved the acceptance of the report as a whole, and it was so voted.

Dr Dame then made the following motion: "That the Council establish a Massachusetts Medical Society citation to be awarded to a layman or a group of laymen for outstanding contributions to medical progress. Not more than three awards shall be made in any one year. The recipients shall be selected by a committee to be designated by the President."

Dr Fallon suggested that the citation should bear a name, and Dr Garland said that probably Lemuel Shattuck had made the greatest contribution to Massachusetts. Dr McKittick said he thought the committee and the Council should be briefed on Lemuel Shattuck. (The discussion ended here without a second to Dr Dame's motion; however, the Committee was not antagonistic and were in favor of naming the citation.)

Information obtained by the Secretary revealed that under a resolve of the Legislature on Mar. 2, 1849, Mr Shattuck was named the chairman of a commission to produce a sanitary survey of the State. The report was published in 1850. Its proposal was the creation of state and local boards of health then nonexistent. The report was perhaps the most significant single document in the history of public health.

STANDING COMMITTEES

Committee on Tax-Supported Medical Care

This report was submitted by the President as informational. It was moved, seconded and voted to approve the report.

Committee on Legislation

The report was approved as informational.

Committee on National Legislation

This report was approved as informational. At the request of the President, Dr Haven said that the letters were printed because of their interest and for the information of the Councilors, that Senator Lodge could not be convinced to vote our way and that Senator Smith of Maine could not be won over. Dr Allen commented on the excellent job done by the committee during the hot summer. Dr Hornor called attention to the fact that the year "1938" should be changed to "1948". The amended report was then approved by vote of the committee.

APPENDIX NO 2

REPORT OF THE EXECUTIVE COMMITTEE

After lunch at the Hotel Kenmore on September 7, 1949, the meeting of the Committee was called to order at 1:00 p.m. by Dr. Arthur W. Allen with all the officers of the Society, Dr. John F. Conlin, Dr. Joseph Garland and sixteen of the eighteen councilors present.

Under new business before the committee, the Secretary presented the following:

Under the existing by-laws (Chapter III, Section 5) the ratio of councilors is 1 for every 20 fellows, and in the same section the by-laws demand the election in each district of at least 6 councilors to designated offices.

As a result, four of the district societies are not permitted to have the required number of councilors, and, therefore, some fellows have to fill two positions.

The Secretary pointed out that the present council is too large (365) for the present seating and luncheon facilities, that one first-class mail to councilors cost over \$100 and that in districts such as Middlesex South it is often difficult to find 59 fellows as councilors.

The Secretary suggested that the present difficulties might be solved by a change in the ratio to 1 councilor to 40 fellows and that no district shall have fewer than 6 councilors. If this were done, twelve districts would each have the necessary 6 councilors, two districts between 6 and 10, two districts between 10 and 20, and the remaining two between 30 and 40. Instead of 365, the council would number nearer 270.

Dr. John Fallon, Worcester, stated that when the present by-laws were written this matter had been considered, but he thought that the matter should be placed in the hands of a committee to study redistricting. He agreed that the present council is too large, but believed that it increased the interest of a larger number of fellows in the affairs of the Society.

The Secretary said that the matter of redistricting was the second to be considered under new business, since it was apparent that a district such as Middlesex South was spread over too large an area and that fellows in Charlestown and Somerville found it difficult to be interested in Framingham's problems.

Dr. Dame, Franklin, stated that he thought the matter of a minimum number of councilors was the most pressing at this time and moved that the Executive Committee recommend to the Committee on By-laws and Council Rules that there shall be no fewer than 6 councilors per district. The motion was seconded, and it was so voted.

Dr. Fallon suggested that a committee be appointed to study redistricting and the ratio of councilors. Dr. Horner, Suffolk, suggested that the committee might be a small one appointed by the President, a representative from each district or a representative from the hospitals over the State as members, along the lines suggested by Dr. Fitz several years ago.

Dr. Hurlburt, Plymouth, said he thought that redistricting was mostly a metropolitan problem. Dr. Merriam, Middlesex South, suggested that the new Advisory Board might study the problem. Dr. Curley, Worcester North, said he thought the committee might best consist of 3 fellows from the Boston area and 4 others spread over the State.

Dr. Fallon moved that it be recommended to the Council that the President appoint a committee of 18 representing each district to study the problem of redistricting and councilor representation, and further, that an executive committee of not more than 7 of the committee have power to act. The motion was seconded, and it was so voted.

The Secretary then gave the status of the American Medical Association assessment collection as follows:

At the end of July only 49 per cent of our membership had paid. A letter was written to those who had not paid and now the percentage is near 66. The Secretary has now turned over further collection to the districts, hoping that by close contact the percentage paying might rise to 80 or 85.

The Secretary said that the Boston Chamber of Commerce wishes the Society to invite the American Medical Association to hold the interim clinical session in Boston.

*The motion recommending the appointment of an executive committee "with power to act" in the matter of redistricting was amended by the Council to read "for this purpose."

after 1950 and assures the Society that exhibit and hotel space is available in sufficient quantity

Dr. Kichham, Norfolk, moved that the Committee recommend that the Society invite the American Medical Association to hold the interim session in Boston at a future date. The motion was seconded, and it was so voted.

The Secretary stated that the next item for consideration was the selection of the Massachusetts Medical Society candidate for the American Medical Association's General Practitioner's Award as directed by the Council. He said he knew of three candidates from Essex North, Dr. Elmer S. Bagnall, from Norfolk, Dr. Dean S. Luce, and from Worcester, Dr. William E. Balmer. These fellows had been officially chosen by their respective district societies.

At the request of the President, Dr. Arnold P. George, Haverhill, presented the name of Dr. Elmer S. Bagnall as the candidate from the Essex North District Medical Society and submitted a volume of material concerning Dr. Bagnall. By a vote of the committee, the material was passed around for inspection.

Dr. Charles J. E. Kichham, Norfolk, presented the name of Dr. Dean S. Luce as the candidate of his district and submitted material concerning Dr. Luce, which was passed around.

Dr. John Fallon, Worcester, presented the name of Dr. William E. Balmer as the candidate of his district and submitted material concerning Dr. Balmer.

Dr. Allen asked Dr. Conlin to say something about the public-relations aspect of the award. Dr. Conlin spoke as follows:

I was just trying to go back to the original purpose in making this award. The requirements were never too clearly stipulated. It was to be a person who had been engaged in general practice exclusively, who was honored and respected within his community, and who had contributed to the well-being and respect for medicine in his community. At such time as a practitioner is selected for the award, by the vote of this Executive Committee, it becomes a function of the public-relations branch of the Society to make something of it. That is the purpose of the award on a national basis, and I think it should guide the choice of this committee. That is, what can benefit medicine in Massachusetts from the choice of such a person?

Obviously, it is a public-relations gesture, purely and simply. That is why it was designed, to get the people of American thinking about the function of the kind of old family doctor, who had borne the burden through the years and was the backbone of the medical profession, and all those other things that we have heard so much about. It means that the selection emerging from this group should be one that has some chance of emerging nationally.

The President then called for a vote by ballot and named Drs. Welch and Garland as tellers. While the tellers collected the ballots and retired to count them, Dr. Allen spoke as follows:

Whichever candidate should be selected by the Executive Committee, I think that we should support that candidate to the very best of our ability. Now, there are three excellent men whose names have been submitted, and any one of them would do credit to the State. Now, of course, two of these men will have to be defeated, unfortunately, but whichever man does get the most votes, or is selected, I hope that we will spread throughout the State in every district the word that this has been done as legally as we know how, that this candidate has been selected and that we hope there will be a complete accord in the State and that everybody will support this candidate to the best of his ability, because it would be quite an honor to bring this award to Massachusetts, if it can possibly be done.

Dr. Garland then announced that Dr. Elmer S. Bagnall had been selected. Dr. Kichham moved that the vote be made unanimous. This motion was seconded, and it was so voted.

At this point, Dr. John Curley asked for support of the World Health Organization.

COMMITTEE REPORTS

Committee on Public Relations

Dr. Allen presented the recommendation that a medical-press-radio conference recommended by Dr. Conlin be held during the latter part of October, 1949. A motion was made to approve this recommendation. The motion was seconded, and it was so voted without discussion.

Dr. Allen presented the second recommendation that the Health Exhibit proposed for the fall of 1949 be indefinitely postponed because plans could not be completed in time. It was moved and seconded that the Council approve this recommendation. The motion was seconded, and it was so voted without discussion.

Dr. Allen then presented the third recommendation concerning lay awards. The Secretary moved that the Committee recommend that the Society make awards to laymen as described in the report. The motion was seconded. The Secretary reported that after communicating with all the other states on this matter, he found that a few had made lay awards and they all thought it a fine idea. Dr. Dame said he believed the Society should produce a citation of merit, which would be given to one who deserved it, rather than just pick out a person to honor. Dr. Conlin spoke at length on the public-relations value of the award.

The original motion was withdrawn, and the President asked Dr. Dame to draw up a substitute motion embodying the points brought out in discussion—namely, the citation, the number of awards, the choice by the public-relations group, the need for careful publicity and the value of naming the citation.

While Dr. Dame and Dr. Conlin were conferring on the wording of a motion, the President voted that the remainder of the report was informational. The Secretary moved the acceptance of the report as a whole, and it was so voted.

Dr. Dame then made the following motion: "That the Council establish a Massachusetts Medical Society citation to be awarded to a layman or a group of laymen for outstanding contributions to medical progress. Not more than three awards shall be made in any one year. The recipients shall be selected by a committee to be designated by the President."

Dr. Fallon suggested that the citation should bear a name, and Dr. Garland said that probably Lemuel Shattuck had made the greatest contribution to Massachusetts. Dr. McKittrick said he thought the committee and the Council should be briefed on Lemuel Shattuck. (The discussion ended here without a second to Dr. Dame's motion, however, the Committee was not antagonistic and were in favor of naming the citation.)

Information obtained by the Secretary revealed that under a resolve of the Legislature on May 2, 1849, Mr. Shattuck was named the chairman of a commission to produce a sanitary survey of the State. The report was published in 1850. Its proposal was the creation of state and local boards of health then nonexistent. The report was perhaps the most significant single document in the history of public health.

STANDING COMMITTEES

Committee on Tax-Supported Medical Care

This report was submitted by the President as informational. It was moved, seconded and voted to approve the report.

Committee on Legislation

The report was approved as informational.

Committee on National Legislation

This report was approved as informational. At the request of the President, Dr. Hayden said that the letters were printed because of their interest and for the information of the Councilors, that Senator Lodge could not be convinced to vote our way and that Senator Smith of Maine could not be won over. Dr. Allen commented on the excellent job done by the committee during the hot summer. Dr. Hornor called attention to the fact that the year "1938" should be changed to "1948." The amended report was then approved by vote of the committee.

Committee on Arrangements

The Secretary moved that dates and place suggested for the 1950 annual meeting be approved. The motion was seconded and so voted.

Committee on Membership

Dr Pilcher presented the report of the Committee and stated that the recommendation was approved by four of his committee, and that one absentee wished to be recorded as not favoring it. The Secretary moved that the recommendation of the committee be approved. This motion was seconded. The Secretary then reviewed the problem and stated the reasons for the recommendation as printed in the Circular of Advance Information. Dr Fallon said the Committee on Membership would still have as much power as ever. Dr Hornor said the present by-law was written as it is at the request of the Committee on Membership at the time.

Dr Parkhurst questioned the value of only a year and wondered if fellows would sponsor a man after such a short acquaintance. Dr Allen said that by next year most graduates of unapproved schools would have been registered five years. Dr Cook said he thought this a step forward. Dr Allen put the question, and it was so voted.

The Secretary then moved that the report of the Committee on Membership concerning retirements and resignations and deprivations be approved. The motion was seconded. Dr Hubbard said the name of Dr Charlotte A. Stewart should be removed from the list of deprivations because she had paid her dues. With this amendment, the motion was passed.

Committee on Public Health

The report was presented by Dr Ward and was approved, including the recommendation concerning the survey, without discussion, as was the matter of the subcommittee.

Committee on Society Headquarters

In the absence of the chairman, Dr Joseph S. Barr presented the report of the committee and said that with the permission of the President, he would like to present some thoughts of his own as follows:

The problem of planning changes in the physical layout of the Massachusetts Medical Society Headquarters cannot be satisfactorily solved without defining rather carefully the scope of the Society's activities. This not only should embrace the present situation but also should include a careful look into the future. If we assume that the federal Government will, in the near future, be the dominant factor in American medicine, our plans should be modest and tempered by expediency. If, on the other hand, we foresee continuation of our present voluntary system, we are faced with a challenging opportunity. The Massachusetts Medical Society is the logical, in fact the only organization, that can assume a position of active leadership in all phases of the never-ceasing struggle to improve the health of the people of the Commonwealth and of this geographic region.

The postgraduate training program for general practitioners, not only of Massachusetts but also of New England, will need to be expanded far beyond our present efforts in that direction. Television will probably be the new courier to carry the best of modern medical progress directly to the staff of every community hospital, not just once a year but perhaps every month. The community hospitals, the community health center and the general practitioners are key figures, and we must give them every assistance in the fulfillment of their needs. Regional rather than state co-ordination of postgraduate medical programs is obviously of value.

Our relation to Government agencies, federal and state, needs to be realistically reappraised. We must work with these agencies, for Government is now in medicine and will be in it increasingly in the foreseeable future. The Massachusetts Medical Society must actively study public-health problems and assist in solving them. Our relation with the public itself leaves much to be desired. The lay public needs education not only in personal hygiene and home nursing and in the understanding of disease processes, but also in the broader fields of pub-

lic health and medical economics. The Society must assume leadership in the field of lay education and in the dissemination of medical news of interest to the public.

The Headquarters Committee has wrestled for years with the problem of how to house the expanding activities of the Massachusetts Medical Society. There appear to be two possible alternative solutions to the problem. One is to enlarge and alter our present headquarters. The other is to build a new headquarters in a new location. Several surveys have been made and two sets of plans have been independently prepared that would improve what we now have. No adequate study of a new building program has been made. Such a study should be undertaken and completed before a sound basis for decision between these two plans can be reached.

A new building program is an ambitious venture and will require a great deal of careful study. For such a venture to succeed, the co-operation of many existing organizations will be necessary. It is unrealistic to expect that a committee can without assistance prosecute and complete such a study. It is believed that the study can best be undertaken by selecting one person, who, under the direction of the Committee, would devote his full-time efforts to the project. At the end of a limited time, perhaps three months, he should be prepared to submit a preliminary report. If the report indicates beyond reasonable doubt that the project would receive support from other interested organizations and that it is possible to finance a new building program satisfactorily, he should then be authorized to proceed with the preparation of more detailed plans.

Careful study may reveal that a new building program for the Massachusetts Medical Society is completely visionary and impractical. It may, on the other hand, reveal that this program is not only possible but also the only sound solution to our present pressing problems. There are many details and problems that will arise in connection with the proposed study. If someone with the essential initiative and ability is selected and is given proper authorization and assistance, he should be able to submit a concrete report with specific recommendations, something that has not been done previously.

Dr Hornor then made the following statement:

The question is whether the Massachusetts Medical Society should continue to grow steadily by confining its activities to meeting immediate problems to the best of its ability or should look forward to great expansion either alone or in combination. The Committee decided against combining with a nonmedical group, but did not feel capable of making the decision about combining with such organizations as Harvard School of Public Health and Massachusetts Department of Public Health without a more thorough investigation than we felt capable of performing. If the Executive Committee thinks it can answer the question, the Committee on Society Headquarters will be grateful and proceed accordingly; otherwise, we would like paid help who can devote many hours to the problem.

Dr Hornor then made a motion that the recommendation of the committee be approved. The motion was seconded. Thirty-five pages of discussion followed, during which the following points were emphasized: the committee had not accomplished very much for ten years, the committee might do a great deal of the groundwork itself, all parties concerned in the future building plans should be invited to sit in with the committee, the plans of the Library trustees for the enlargement of 8 Fenway should be carefully considered, the plans of the future development of the Society in postgraduate-education programs should be decided, the possibility of interesting a foundation interested in an enlarged program should be considered, the man selected to draw plans should also evaluate the problem as a whole, the treasurer believed that any money expended for the purpose should come out of the general expenses and not the Building Fund.

The President then put the question, and the motion was defeated. Dr Conlin pointed out the difficulties of operating in the cramped quarters at 8 Fenway. Dr Allen said he thought it would be too bad to spend a large sum on 8 Fenway if there was hope that we might have a truly dignified Academy of Medicine. Dr John Curley moved re-

consideration of the motion. This was seconded, and it was so voted.

It was then pointed out in discussion that the Committee was sure that it could not solve the problem without expert advice and help, someone to do the leg work. Dr. Dame asked if the plan to join the Boston Museum of Science had been turned down. Dr. Barr said it had not. Dr. Barr said a policy for the future could not be developed without consultation of a great many people. Dr. Conlin stated that he did not know of any medical society satisfied with present quarters—they were all outgrowing them. Dr. Barr said that any plans developed by an employed person or group would have to be acceptable to the Committee. The President put the original motion again, which was seconded, and it was so voted.

Committee on Industrial Health

In the absence of the chairman, Dr. Henry Marble, the Secretary moved that the recommendation to hold an industrial health conference in Boston on November 16, 1949, be approved. The motion was seconded, and it was so voted without debate.

SPECIAL COMMITTEES

Committee to Meet with the Massachusetts Hospital Association

This report was approved as informational without discussion. Dr. Hornor moved that the Committee be thanked for its fine efforts and be asked to make another report at the February meeting of the Council. The motion was seconded, and it was so voted.

Committee on Postgraduate Medical Education

This report was approved as informational.

Committee on Medical Economics

The report was presented by Dr. Bagnall, who moved the approval of the report. The motion was seconded. Dr. Hornor said he would like to see No. 13 left out of the principles, because he felt the problem was one between a certain school needing help and wishing to get it from the Government. Dr. Bagnall said it was not a state or individual problem because medical schools were educating students for the whole country. Private sources of aid are drying up. Dr. Curley objected to federal control after federal aid. Dr. Bagnall answered that the paragraph stipulates no interference by the Government.

Dr. Allen put the question, and it was carried by a majority of two.

Committee on New England Postgraduate Assembly

This report was approved as informational.

Committee on Diabetes

Dr. Root presented the report and said that now there are 148 units in 40 states taking part in the program. It was hoped to have an exhibit at the Eastern States Exposition. He said industry is very much interested. The most important thing was to get the interest of the doctors and that it would cost some extra money to send them a letter. Dr. Hubbard said Dr. Root should apply to the Committee on Finance. On motion made and seconded, the report was approved without discussion.

Co-ordinating Committee

This report was approved without discussion.

Committee on Publicity Code

In the absence of Dr. Munro, Dr. Hornor presented the report and moved that the code be approved. The motion was seconded. Dr. Conlin outlined the history of the code, how it originally came from the Eye and Ear Infirmary as a hospital code to guide their staff, how it had been reviewed by the Committee on Ethics and Discipline and found not affecting the code of ethics of the Society. It was then referred back to a special committee to write a code applying to all fellows of the Society, and although a little cumbersome, it is spelled out for a purpose. It can be clarified for newspapers and radio at the proposed conference with press and radio.

The President stated the motion, and it was so voted. Dr. Hornor moved approval of the second recommendation to continue the committee. The motion was seconded, and it was so voted.

Dr. Hornor moved approval of the third recommendation, to publish the code in the new booklet on by-laws. The motion was seconded, and it was so voted.

Report of the Meeting of House of Delegates of the American Medical Association

This report was accepted as informational. The Secretary stated that the report of the Committee on Hospitals and the Practice of Medicine (The Hess Committee) had included the report of the Committee on Special Services of the Society and had praised the Massachusetts Medical Society for its valuable contribution. He also said he hoped everyone would read this report in the proceedings of the House of Delegates. Dr. Conlin moved that these remarks be given to the Council in the report of the Executive Committee. The motion was seconded, and it was so voted.

Dr. Fallon moved that the name of the Committee to meet with the Massachusetts Hospital Association be changed to the Committee on Hospitals and Professional Relations. The motion was seconded, and it was so voted.

Advisory Committee for Red Cross Blood Bank

Dr. Lamar Soutter presented the report and said that the Red Cross had to meet the approval and continue under that approval in everything that is done. The program depends greatly on publicity and on the support of the professions for success. The recommendations of the committee fall into three groups: publicity in the *Journal*, telling the doctors how they can help and the training of hospital personnel. It was moved and seconded that the first recommendation be approved. It was so voted.

It was moved that the second recommendation be approved if changed to "that the help of the *Journal* should be enlisted with the following ends in view." The motion was seconded, and it was so voted with the approval of Dr. Soutter.

Dr. Allen ruled that the permission asked for to write to hospitals and district societies for information on how the program is working was not necessary since the committee had that power. Dr. Soutter moved that the Society give its support to the program of training technicians. This motion was seconded and so voted. Dr. Hornor requested that the word "district" be substituted for "county." Dr. Soutter agreed.

Committee on Blue Cross-Blue Shield Problems

Dr. Kichham presented the report and asked permission to change the wording of the report by substituting for lines 17 to 24 on page 32 of the Circular of Advance Information beginning with the word "the" in line 17 and ending with the word "it" on line 24, the following:

It was pointed out that until about a year ago Blue Shield made no payments for medical services rendered to ward service cases, because it was the confirmed policy of the hospitals involved that staff physicians should not bill for such services. During 1948 this policy on the part of several teaching hospitals was altered to the extent that staff groups, but not individual physicians, were permitted to receive payments for third parties, such as Blue Shield and commercial insurance companies, for medical services rendered to service-ward patients. Formal group arrangements were made at two hospitals, and informal group arrangements were made at several other hospitals, after which Blue Shield began making payment to these groups.

Such permission was granted by vote of the committee. Dr. Kichham said that his committee had considered the recommendation at the end of the report, and that the matter of physician enrollment had subsequently been discussed several times without results. He hoped the President would be allowed to refer the subject to an appropriate committee. Dr. Hornor stated that the Committee on Public Relations had previously voted against group enrollment of physicians in Blue Shield.

Dr. Tripp moved that the subject be studied further by this committee which will report to the Council at a later date. The motion was seconded, and it was so voted.

Committee on Arrangements

The Secretary moved that dates and place suggested for the 1950 annual meeting be approved. The motion was seconded and so voted.

Committee on Membership

Dr Pilcher presented the report of the Committee and stated that the recommendation was approved by four of his committee, and that one absentee wished to be recorded as not favoring it. The Secretary moved that the recommendation of the committee be approved. This motion was seconded. The Secretary then reviewed the problem and stated the reasons for the recommendation as printed in the Circular of Advance Information. Dr Fallon said the Committee on Membership would still have as much power as ever. Dr Hornor said the present by-law was written as it is at the request of the Committee on Membership at the time.

Dr Parkhurst questioned the value of only a year and wondered if fellows would sponsor a man after such a short acquaintance. Dr Allen said that by next year most graduates of unapproved schools would have been registered five years. Dr Cook said he thought this a step forward. Dr Allen put the question, and it was so voted.

The Secretary then moved that the report of the Committee on Membership concerning retirements and resignations and deprivations be approved. The motion was seconded. Dr Hubbard said the name of Dr Charlotte A Stewart should be removed from the list of deprivations because she had paid her dues. With this amendment, the motion was passed.

Committee on Public Health

The report was presented by Dr Ward and was approved, including the recommendation concerning the survey, without discussion, as was the matter of the subcommittee.

Committee on Society Headquarters

In the absence of the chairman, Dr Joseph S Barr presented the report of the committee and said that with the permission of the President, he would like to present some thoughts of his own as follows:

The problem of planning changes in the physical layout of the Massachusetts Medical Society Headquarters cannot be satisfactorily solved without defining rather carefully the scope of the Society's activities. This not only should embrace the present situation but also should include a careful look into the future. If we assume that the federal Government will, in the near future, be the dominant factor in American medicine, our plans should be modest and tempered by expediency. If, on the other hand, we foresee continuation of our present voluntary system, we are faced with a challenging opportunity. The Massachusetts Medical Society is the logical, in fact the only organization, that can assume a position of active leadership in all phases of the never-ceasing struggle to improve the health of the people of the Commonwealth and of this geographic region.

The postgraduate training program for general practitioners, not only of Massachusetts but also of New England, will need to be expanded far beyond our present efforts in that direction. Television will probably be the new courier to carry the best of modern medical progress directly to the staff of every community hospital, not just once a year but perhaps every month. The community hospitals, the community health center and the general practitioners are key figures, and we must give them every assistance in the fulfillment of their needs. Regional rather than state co-ordination of postgraduate medical programs is obviously of value.

Our relation to Government agencies, federal and state, needs to be realistically reappraised. We must work with these agencies, for Government is now in medicine and will be in it increasingly in the foreseeable future. The Massachusetts Medical Society must actively study public-health problems and assist in solving them. Our relation with the public itself leaves much to be desired. The lay public needs education not only in personal hygiene and home nursing and in the understanding of disease processes, but also in the broader fields of pub-

lic health and medical economics. The Society must assume leadership in the field of lay education and in the dissemination of medical news of interest to the public.

The Headquarters Committee has wrestled for years with the problem of how to house the expanding activities of the Massachusetts Medical Society. There appear to be two possible alternative solutions to the problem. One is to enlarge and alter our present headquarters. The other is to build a new headquarters in a new location. Several surveys have been made and two sets of plans have been independently prepared that would improve what we now have. No adequate study of a new building program has been made. Such a study should be undertaken and completed before a sound basis for decision between these two plans can be reached.

A new building program is an ambitious venture and will require a great deal of careful study. For such a venture to succeed, the co-operation of many existing organizations will be necessary. It is unrealistic to expect that a committee can without assistance prosecute and complete such a study. It is believed that the study can best be undertaken by selecting one person, who, under the direction of the Committee, would devote his full time efforts to the project. At the end of a limited time, perhaps three months, he should be prepared to submit a preliminary report. If the report indicates beyond reasonable doubt that the project would receive support from other interested organizations and that it is possible to finance a new building program satisfactorily, he should then be authorized to proceed with the preparation of more detailed plans.

Careful study may reveal that a new building program for the Massachusetts Medical Society is completely visionary and impractical. It may, on the other hand, reveal that this program is not only possible but also the only sound solution to our present pressing problems. There are many details and problems that will arise in connection with the proposed study. If someone with the essential initiative and ability is selected and is given proper authorization and assistance, he should be able to submit a concrete report with specific recommendations, something that has not been done previously.

Dr Hornor then made the following statement:

The question is whether the Massachusetts Medical Society should continue to grow steadily by confining its activities to meeting immediate problems to the best of its ability or should look forward to great expansion either alone or in combination. The Committee decided against combining with a nonmedical group, but did not feel capable of making the decision about combining with such organizations as Harvard School of Public Health and Massachusetts Department of Public Health without a more thorough investigation than we felt capable of performing. If the Executive Committee thinks it can answer the question, the Committee on Society Headquarters will be grateful and proceed accordingly; otherwise, we would like paid help who can devote many hours to the problem.

Dr Hornor then made a motion that the recommendation of the committee be approved. The motion was seconded. Thirty-five pages of discussion followed, during which the following points were emphasized: the committee had not accomplished very much for ten years, the committee might do a great deal of the groundwork itself, all parties concerned in the future building plans should be invited to sit in with the committee, the plans of the Library trustees for the enlargement of 8 Fenway should be carefully considered, the plans of the future development of the Society in postgraduate-education programs should be decided, the possibility of interesting a foundation interested in an enlarged program should be considered, the man selected to draw plans should also evaluate the problem as a whole, the treasurer believed that any money expended for the purpose should come out of the general expenses and not the Building Fund.

The President then put the question, and the motion was defeated. Dr Conlin pointed out the difficulties of operating in the cramped quarters at 8 Fenway. Dr Allen said he thought it would be too had to spend a large sum on 8 Fenway if there was hope that we might have a truly dignified Academy of Medicine. Dr John Curley moved re-

consideration of the motion. This was seconded, and it was so voted.

It was then pointed out in discussion that the Committee was sure that it could not solve the problem without expert advice and help, someone to do the leg work. Dr Dame asked if the plan to join the Boston Museum of Science had been turned down. Dr Barr said it had not. Dr Barr said a policy for the future could not be developed without consultation of a great many people. Dr Conlin stated that he did not know of any medical society satisfied with present quarters—they were all outgrowing them. Dr Barr said that any plans developed by an employed person or group would have to be acceptable to the Committee. The President put the original motion again, which was seconded, and it was so voted.

Committee on Industrial Health

In the absence of the chairman, Dr Henry Marble, the Secretary moved that the recommendation to hold an industrial health conference in Boston on November 16, 1949, be approved. The motion was seconded, and, it was so voted without debate.

SPECIAL COMMITTEES

Committee to Meet with the Massachusetts Hospital Association

This report was approved as informational without discussion. Dr Hornor moved that the Committee be thanked for its fine efforts and be asked to make another report at the February meeting of the Council. The motion was seconded, and it was so voted.

Committee on Postgraduate Medical Education

This report was approved as informational.

Committee on Medical Economics

The report was presented by Dr Bagnall, who moved the approval of the report. The motion was seconded. Dr Hornor said he would like to see No. 13 left out of the principles, because he felt the problem was one between a certain school needing help and wishing to get it from the Government. Dr Bagnall said it was not a state or individual problem because medical schools were educating students for the whole country. Private sources of aid are drying up. Dr Curley objected to federal control after federal aid. Dr Bagnall answered that the paragraph stipulates no interference by the Government.

Dr Allen put the question, and it was carried by a majority of two.

Committee on New England Postgraduate Assembly

This report was approved as informational.

Committee on Diabetes

Dr Root presented the report and said that now there are 148 units in 40 states taking part in the program. It was hoped to have an exhibit at the Eastern States Exposition. He said industry is very much interested. The most important thing was to get the interest of the doctors and that it would cost some extra money to send them a letter. Dr Hubbard said Dr Root should apply to the Committee on Finance. On motion made and seconded, the report was approved without discussion.

Co-Ordinating Committee

This report was approved without discussion.

Committee on Publicity Code

In the absence of Dr Munro, Dr Hornor presented the report and moved that the code be approved. The motion was seconded. Dr Conlin outlined the history of the code, how it originally came from the Eve and Ear Infirmary as a hospital code to guide their staff, how it had been reviewed by the Committee on Ethics and Discipline and found not affecting the code of ethics of the Society. It was then referred back to a special committee to write a code applying to all fellows of the Society, and although a little cumbersome, it is spelled out for a purpose. It can be clarified for newspapers and radio at the proposed conference with press and radio.

The President stated the motion, and it was so voted. Dr Hornor moved approval of the second recommendation to continue the committee. The motion was seconded, and it was so voted.

Dr Hornor moved approval of the third recommendation, to publish the code in the new booklet on by-laws. The motion was seconded, and it was so voted.

Report of the Meeting of House of Delegates of the American Medical Association

This report was accepted as informational. The Secretary stated that the report of the Committee on Hospitals and the Practice of Medicine (The Hess Committee) had included the report of the Committee on Special Services of the Society and had praised the Massachusetts Medical Society for its valuable contribution. He also said he hoped everyone would read this report in the proceedings of the House of Delegates. Dr Conlin moved that these remarks be given to the Council in the report of the Executive Committee. The motion was seconded, and it was so voted.

Dr Fallon moved that the name of the Committee to meet with the Massachusetts Hospital Association be changed to the Committee on Hospitals and Professional Relations. The motion was seconded, and it was so voted.

Advisory Committee for Red Cross Blood Bank

Dr Lamar Soutter presented the report and said that the Red Cross had to meet the approval and continue under that approval in everything that is done. The program depends greatly on publicity and on the support of the professions for success. The recommendations of the committee fall into three groups: publicity in the *Journal*, telling the doctors how they can help and the training of hospital personnel. It was moved and seconded that the first recommendation be approved. It was so voted.

It was moved that the second recommendation be approved if changed to "that the help of the *Journal* should be enlisted with the following ends in view." The motion was seconded, and it was so voted with the approval of Dr Soutter.

Dr Allen ruled that the permission asked for to write to hospitals and district societies for information on how the program is working was not necessary since the committee had that power. Dr Soutter moved that the Society give its support to the program of training technicians. This motion was seconded and so voted. Dr Hornor requested that the word "district" be substituted for "county." Dr Soutter agreed.

Committee on Blue Cross-Blue Shield Problems

Dr Kickham presented the report and asked permission to change the wording of the report by substituting for lines 17 to 24 on page 32 of the Circular of Advance Information beginning with the word "the" in line 17 and ending with the word "fit" on line 24, the following:

It was pointed out that until about a year ago Blue Shield made no payments for medical services rendered to ward service cases, because it was the confirmed policy of the hospitals involved that staff physicians should not bill for such services. During 1948 this policy on the part of several teaching hospitals was altered to the extent that staff groups, but not individual physicians, were permitted to receive payments for third parties, such as Blue Shield and commercial insurance companies, for medical services rendered to service-ward patients. Formal group arrangements were made at two hospitals, and informal group arrangements were made at several other hospitals, after which Blue Shield began making payment to these groups.

Such permission was granted by vote of the committee. Dr Kickham said that his committee had considered the recommendation at the end of the report, and that the matter of physician enrollment had subsequently been discussed several times without results. He hoped the President would be allowed to refer the subject to an appropriate committee. Dr Hornor stated that the Committee on Public Relations had previously voted against group enrollment of physicians in Blue Shield.

Dr Tripp moved that the subject be studied further by this committee which will report to the Council at a later date. The motion was seconded, and it was so voted.

Dr Fallon asked for clarification of the meaning of the words "judicious application by the medical profession" on page 33, line 9. Dr Conlin said that for the doctor to charge an extra fee for these patients might be warranted in some cases, but that to do so would demand good judgment if severe criticism were not to be brought against the doctor and Blue Shield. On a motion duly made and seconded, the report as amended was approved.

Advisory Committee to Woman's Auxiliary

Dr Conlin presented the report as informational and it was approved by the committee as such.

Dr Conlin said that the Harvard School of Public Health is to conduct a survey of multiple sclerosis in the State with funds supplied by the National Society for Multiple Sclerosis and that approval of this survey had been obtained by a telephone vote of the Committee on Public Health. It should have been included in the report of that committee. Dr Conlin made a motion that a recommendation to approve the survey be added as an amendment to the report of the Committee on Public Health. The motion was seconded, and it was so voted.

Dr Conlin made a motion that a recommendation endorsing the Boston Chest X-ray Program be appended to the Report of the Committee on Public Health. This motion was seconded, and it was so voted.

On motion duly made and seconded, the meeting adjourned at 6:50 p.m.

H QUIMBY GALLUPE, *Secretary*

APPENDIX NO 3

REPORT OF THE COMMITTEE ON PUBLIC RELATIONS

The meeting of the Public Relations Committee of the Massachusetts Medical Society was held at the Harvard Club at 6:00 p.m. on July 27, 1949. President Arthur W. Allen was in the chair, there were present 15 out of the 18 representatives of the district societies. Dr H. Quimby Gallupe, secretary of the Massachusetts Medical Society, and Dr John F. Conlin, director of medical education and information, were also present.

Dr John F. Conlin presented to the Committee the desirability of a medical-press-radio conference to be held in the latter part of October, 1949. To this meeting would be invited, in addition to the medical profession, representatives of various hospitals and members of the press and radio. He felt that by and large the press is favorable to organized medicine. There is, however, some doubt in the minds of the press about possible sources of authentic information regarding medical subjects and medical information, such as the value of new drugs and recent medical advances. It was his opinion that newspapermen are just as ethical as members of the medical profession, and that members of the press are anxious to disseminate accurate information provided sources for the obtaining of such accurate information are available to them. It was Dr Conlin's contention that the first such conference should be held in Boston and later be decentralized to the various district societies in order that there might be such sources of authentic information as the local press might desire. It was unanimously voted by the members of the Committee that such a conference be held.

It was suggested by the Committee at its meeting on August 4, 1948, and later approved by the Council, that a health exhibit should be organized in the fall of 1949. Inasmuch as plans could not be completed for such a program, the Committee unanimously voted to postpone action indefinitely.

Dr John F. Conlin called to the Committee's attention that some states were recognizing laymen for meritorious or distinguished service in the support of public health and good medicine. It was felt that such a program wherever initiated stimulated good public relations. Many laymen or groups of laymen have rendered invaluable service to the progress of medicine by their energetic efforts in its behalf. Therefore, the Committee unanimously endorsed the following resolutions:

That the Council empower the Committee on Public Relations to award some layman or group of laymen a citation for outstanding service to medical progress.

That the Committee shall make not more than three such citations annually.*

Dr Conlin reviewed the work that has been completed with reference to the national education campaign against compulsory health insurance. He emphasized that although there seems to be no immediate danger that the Administration's compulsory health bill will be passed, it was apparent that complacency and inactivity on the part of the medical profession might be disastrous. Efforts to perfect the machinery of the present organization must continue during the coming months. Emphasis was placed upon the necessary work to be carried on by the district co-ordinating committees with reference to the "Tell it to Twenty" portion of the Massachusetts campaign. A strong speakers' bureau should be developed in each district in which not only does the medical profession take part, but also competent and willing lay speakers are encouraged to present organized medicine's point of view regarding the Administration's health bill.

HAROLD R. KURTH, M.D., *Secretary*

*The recommendation to name the lay award "The Lemuel Shattuck Award" was amended by the Council to read "The Massachusetts Medical Society Citation for Outstanding Contributions to Medical Progress."

APPENDIX NO 4

REPORT OF THE COMMITTEE ON TAX-SUPPORTED MEDICAL CARE

The committee on Tax-Supported Medical Care has not met. The chairman of the committee has tried to get help on the questions referred to the committee at the last meeting of the Council from the Commissioner of Public Welfare of the Commonwealth of Massachusetts. Mr. Patrick Tompkins, the commissioner, has postponed any meeting with the members of the committee until after the legislature has prorogued. The committee will continue to work on this problem.

WILLIAM W. BABSON, M.D.

DONALD HIGHT, M.D.

FRANCIS P. MCCARTHY, M.D.

ALBERT A. HORNOR, M.D., *Chairman*

APPENDIX NO 5

REPORT OF THE COMMITTEE ON LEGISLATION

A meeting of the Committee on Legislation was held at the Harvard Club on June 24, 1949. The meeting was called to order by President Arthur W. Allen, who nominated the following men as members of the Executive Committee: Dr Alfred M. Glickman, Dr William E. Browne, Dr Solomon L. Skvirsky, and Dr John Butts.

Dr Allen's nominations were approved by the Committee. Dr Skvirsky stated that he would be unable to serve as secretary of the Committee. By vote of the Committee his resignation was accepted, and Dr Daniel F. Gallery, of Bristol South, was elected.

After some discussion it was voted that the Executive Committee be granted power to act on legislative matters in any case of emergency.

The main business of the meeting was a discussion of the cash sickness bill No. 2591, the passage of which had been urged by the Governor in his inaugural address. Mr. Charles Dunn stated that the Society should prepare a brief explaining its stand on this bill. On the completion of the discussion, the Committee voted unanimously in opposition to the bill, and Mr. Dunn was authorized to state in the brief that the legislative councilors of the Massachusetts Medical Society regret that they cannot approve the bill in its present form.

At the suggestion of the chairman, Dr David L. Belding, Dr Charles G. Hayden and Dr John F. Conlin were asked to assist Mr. Dunn in the writing of the brief. The meeting adjourned at 10:00 p.m.

DAVID L. BELDING, M.D., *Chairman*

The brief as presented to the Committee on Ways and Means of the Legislature meeting in Executive Session was as follows:

Statement of the Massachusetts Medical Society on House No. 2591, the Cash Sickness Compensation Bill,

for the Committee on Ways and Means of the Massachusetts General Court.

The Massachusetts Medical Society finds itself not in complete agreement with House No 2591, the Cash Sickness Compensation Bill, as it now stands.

This bill has been carefully studied by the Society since printed copies became available. It is not our purpose to single out points we would praise or condemn as private citizens and voters interested in the broad problems of the public health.

Our principle function as a medical society is to view this, as all other legislation pertaining to health, as working for or against the best possible standards of medical progress and the mental and physical health of the public.

Under this bill as drawn the physician is held responsible for the medical operation of the sickness compensation plan. The claimant for benefits must have filed a physician's certificate (*Sec 7 (a) (f)*) and, "if directed to do so by the director, (shall) have submitted to a medical examination for the purpose of determining his sickness" (*idem*).

In practice this requirement would charge practicing physicians not only with administrative responsibilities but with under-writing responsibility as well. E. H. O'Connor, managing director, Insurance Economics System of America, has stated, "As these state plans begin to expand, as is evident from legislative bills introduced in Rhode Island, California and New Jersey, more benefits will be paid and the cash sickness benefits of a state fund must be protected. It will naturally follow that the state will be forced to set up rules and regulations for the certification of claimants."

Solvency of a state fund might be protected if it were possible to determine ability to work in all instances through promulgation of rules, and regulations and the application of existing medical knowledge. Every physician knows there are many instances where it is absolutely impossible to determine medically whether a person is or is not able to work.

This is particularly true in cases of mental illness. The definition of "sickness" (*Sec 3 (m)*) contains the words

"because of his physical or mental condition, he is unable to perform his regular or customary work." It was stated in Federal Security Administrator Oscar R. Ewing's report to the President that from 30 to 50 per cent of all persons consulting doctors have complaints due at least in part to emotional disorders. For the evaluation of these complaints it is stated 4500 psychiatrists are available in this country where some 15,000 are needed.

From the point of view of the medical profession, charged with the responsibility of certification and professional administration, it cannot be too much stressed that this program concerns itself essentially with temporary disability. Experience has emphasized the importance of adequate administrative control for the successful operation of such plans. We wish to stress that the evaluation of conditions of temporary disability depends upon factors which are at best 50 per cent subjective.

The dangers to the solvency of the cash sickness compensation fund from malingering have been recognized by the architects of this bill. "He (the director) shall also publicize the potential results of malingering" (*Section 18*). In view of what has been said above concerning the subjective factors of temporary disability it must be made clearly apparent that merely designating the physician as the policeman is not the answer. There are no magic tests for the evaluation of purely subjective symptoms.

For the 6750 physician fellows of the Massachusetts Medical Society we feel we can promise full co-operation within the code of ethics of the Society and of the American Medical Association within the limitations previously noted. We point out, however, that no criteria for diagnoses are established within the bill and there is no provision for a medical advisory board to assist in this and other important functions under the bill.

The bill defines a "physician" (*Section 3 (j)*) as "an individual licensed to practice medicine or dentistry under the laws of this or any other state." For some 2500 physicians licensed to practice in Massachusetts the added ethical controls over fellows of the Massachusetts Medical

Society are absent. For them the basic legal controls of malpractice laws are the limits to which they can be held.

Under *Section 8 Claims and Appeals (e)* provision is made for calling as an expert witness any medical adviser appointed by the director. There is no provision made for establishing the qualifications of such experts.

In view of the tremendous responsibilities placed upon the individual physician and upon the medical profession in the administration of this plan, we seriously question the absence of the physician's voice in the set-up for administrative control.

This defect is the more notable since *Section 12 Penalties* states, "Any person convicted of a violation of any provision of this chapter or of a violation of any order, rule or regulation of the director or of the division made under the authority of any provision of this chapter the punishment for which is not otherwise provided, shall be punished by a fine or not more than fifty dollars for the first offense, and for any subsequent offense within a period of two years immediately following his final conviction of a like offense by a court of the Commonwealth, shall be punished by a fine of not less than fifty dollars nor more than two hundred dollars, or by imprisonment for not more than two years, or both."

Respectfully submitted for the President and Fellows of the Massachusetts Medical Society

/s/ JOHN F. COLLIN, M.D.

JOHN F. COLLIN, M.D.

Director of Medical Information and Education

APPENDIX NO 6

REPORT OF THE SUBCOMMITTEE ON NATIONAL LEGISLATION

The Subcommittee on National Legislation met during the annual meeting of the Society at Worcester on two occasions to consider the provisions of a mimeographed bill sent by Representative Herter to the Society for criticism prior to introduction into the Congress. The Subcommittee's criticism of this bill, which was subsequently introduced by Mr. Herter and others in the House (H.R. 4918) and by Senators Flanders and Dies in the Senate (S. 1970), is appended hereto.

After the annual meeting the Subcommittee met with the Committee on Medical Economics on three occasions, and it is anticipated that there will be additional joint meetings of these two groups. National legislation and medical economics are so inextricably bound together that it seems judicious for two committees independently to consider the problems involved.

Letters expressing opposition to extension of the Social Security Act to cover physicians (H.R. 2895) and opposition to the inclusion of health and medical functions in a proposed Department of Welfare (Reorganization Plan No. 1 of 1949) were sent to all the Massachusetts senators and representatives in Congress as well as to the committee hearing the proposals. Copies of these letters are appended hereto.

When Reorganization Plan No. 1 came to vote in the Senate, Senator Saltonstall voted against it and Senator Lodge voted for it. Senator Lodge explained his action on the grounds that the Hoover Commission had recommended the establishment of a Department of Welfare and that he (Lodge) was not convinced that once such a department was established, it would be virtually impossible to remove its health and medical functions.

The chairman of the Subcommittee attended two meetings of the Committee on Legislation held subsequent to the annual meeting.

AUGUSTUS THORNDIKE, M.D.

WILLIAM H. SWEET, M.D.

CHARLES G. HAYDEN, M.D., *Chairman*

May 26, 1940

Hon. Christian A. Herter

House of Representatives

Washington 25, D. C.

My dear Congressman:

The Subcommittee on National Legislation of the Massachusetts Medical Society sincerely appreciates your in-

terest in the health of the Nation and the people of Massachusetts. It also appreciates the opportunity afforded to scrutinize the proposed National Health Act of 1949.

Because it is impossible in a few days to analyze thoroughly all the implications of a bill of this type, the Subcommittee is submitting herewith a few preliminary observations for your consideration. (See attachment.)

In general, it appears that this bill endeavors to establish a comprehensive system of medical and hospital care, utilizing voluntary prepayment plans and avoiding compulsion insofar as the potential subscriber is concerned. There is no mention made of employer contribution nor is the method of financing clearly defined. Ostensibly, subscribers would pay in accordance with their ability, and pools of reserves would be established to subsidize plans overburdened with poor risks. It seems that the chief financial burden would be carried by those with greater-than-average income who would pay in much more than they would receive in the form of benefits.

The plan visualized is not an insurance program because it offers services which do not lend themselves to actuarial determinations. Just how those persons and institutions who would render the services are to be included in the program and compensated for their efforts is not clear. While the bill does not say so explicitly, there are indications that it is an attempt to synthesize prepayment and group practice and extend the result nationwide. While such an amalgamation may have transcending merit, the available evidence at this time is far from conclusive.

From an administrative standpoint, the bill is replete with conflicting interests and duties vested in several boards, authorities and councils.

It is the opinion of the Subcommittee that this bill, if passed, would ultimately result in the absorption by the Federal Government of voluntary, non-profit, prepayment medical and hospital care plans.

Although much is currently being voiced and written about the health of the nation and the availability and cost of medical care, no one has yet been able to define adequate medical care in terms that are practical and realistic. Until this is done and until there is general agreement on basic facts and concepts, it will be impossible to properly evaluate the problem, let alone suggest a reasonable answer. Therefore we propose that an impartial body patterned after the Hoover Commission be constituted on the National level to correlate the activities of similar Commissions established in the several States, that these Commissions be given ample opportunity to establish facts and evaluate concepts, and that upon completion of their tasks all interested parties sit down together and work out the kind of medical care that will adequately serve the needs of a free people.

Respectfully yours,

*By direction of the President of
Massachusetts Medical Society,
ARTHUR W. ALLEN, M.D.
CHARLES G. HAYDEN, M.D., Chairman
Subcommittee on National Legislation*

PRELIMINARY OBSERVATIONS CONCERNING THE PROPOSED "NATIONAL HEALTH ACT OF 1949"

By the Subcommittee on National Legislation of the
Massachusetts Medical Society

1 The provision that the Surgeon General, subject to approval of the Federal Security Administrator, shall make such administrative regulations and perform such other functions as he finds necessary to carry out the provisions of Title VII is in keeping with current practice. We believe, however, that the medical activities of the Federal government should be co-ordinated in an independent agency directly responsible to the President.

Furthermore, it appears that, except for certain loans, the medical care aspects of this program are to be financed by premiums obtained from subscribers in accordance with their ability to pay. If this is so, regulatory supervision by the Federal government without financial participation might well be questioned.

2 The provision that the Federal Health Council shall be composed of persons who are not professionally engaged in the provision of health services would seem to

be injudicious. It is our feeling that such a body should, in its own interest and that of the public, include persons actually engaged in the provision of health services.

3 The list of Personal Health Services to be provided contains many services which are not insurable because they are subject to serious abuse. In order to provide all the services listed it would appear to be necessary to alter fundamentally the existing pattern of medical, hospital and related practice. The bill does not state how this is to be accomplished.

4 The term, "licensed physicians" would seem to include chiropractors, osteopaths, and others, if licensed by the State. Only fully qualified physicians and surgeons should be allowed to participate.

5 The restrictions placed upon the organization and operation of Co-operating Prepayment Health Service Plans would, in our opinion, result in the abandonment of such plans by just those conscientious and able citizens who should be on the governing boards. For example:

a Benefits offered must be within limits authorized by the State's program.

b Contracts must be approved by the Health Region Authority.

c Enrollment will be limited by the Health Region Authority which will also determine the mechanism of enrollment (individual, group, etc.).

d Reserve requirements will be established by the State Health Council.

e Adjustments in subscription charges must be made in certain instances as required by the State Plan.

f Subscription charges must be fixed in terms of subscriber's family income.

g Rules and regulations will be determined by the Surgeon General, the State Agency, the State Health Council, and the Health Region Authorities.

h Selection Factor will be determined by the Surgeon General.

6 The provision that the State Plan shall be administered by a single State Agency subject to the powers of the State Health Council and Health Region Authorities (and the Surgeon General) would seem to make for divided authority and inefficient administration. The possibility that two or more contiguous states may be involved is subject to this same criticism. Also, the lack of correlation between the proposed agencies and those already in existence (State and local health departments, etc.) might well result in conflict, overlapping, inefficiency and waste of funds.

7 The provisions that the Health Region Authority shall be composed of persons who do not hold positions of administrative responsibility for any health program or other activity of the State or any political subdivision thereof, and who are not professionally engaged in the provision of health or medical services again bars just those persons whose knowledge and experience would be invaluable.

8 The requirement that each Health Service District include within its area a four-year medical college would seem to impose unrealistic geographic arrangements.

9 The requirement that the State Health Council determine and prescribe the kinds of personal health services to be provided and the reserve requirements therefor, circumvents State Insurance Departments which are already authorized to make such determinations in most States.

10 The provision that prepayment health service plans shall subsidize medical schools is unique. As the program visualized is not compulsory, the burden of subsidization would fall on subscribers alone and not on the general public, all of whom should contribute if governmental subsidy is necessary and desirable.

11 Fixing of subscription charges in terms of a percentage of the subscriber's family income would seem to introduce serious administrative difficulties. How, for instance, is family income to be determined in those instances where more than one member of the family is employed, or where there is income other than wages or salary?

12 The provision for creation of a Study and Planning Commission has merit. It is our opinion that a Commission similar to the Hoover Commission should be constituted in every State and that the activities of these

several State Commissions should be correlated by a similar Commission on the Federal level. Furthermore, we believe that until such time as these Commissions have submitted their findings and recommendations, legislation in this field should be delayed.

13 We favor in principle extension of the hospital construction program. Because of the limited time available, that portion of the bill dealing with this subject was not analyzed.

14 We favor in principle establishment of local public health units. Because of the limited time available, that portion of the bill dealing with this subject was not analyzed.

July 6, 1949

Senator Henry Cabot Lodge, Jr
Senate Office Building
Washington, D C.

Dear Senator Lodge

There are two social security bills before the House Ways and Means Committee certain provisions of which, if enacted into law, would intimately involve the medical profession. These are H R. 2892 and H R. 2893.

As originally written, H R. 2892 contained a provision which would institute medical assistance for certain categories of indigents. We shall reserve our comments on this provision until such time as we may have the opportunity of examining the revised bill.

H R. 2893, as revised, is reliably reported to contain a provision broadening the coverage of the Social Security Act to include most self-employed persons but excluding farmers. A tax of perhaps 2½ per cent on income up to \$4200 or \$4800 would be levied for the purpose of providing old-age benefits at age 65 to those self-employed who at that age retire from business as well as cash benefits for permanent disability.

Because few physicians retire at age 65 and because virtually complete retirement is necessary to qualify for an old-age pension, physicians would be compelled to contribute for years to a fund from which few if any would ever derive benefits. We are, therefore, opposed to extension of the Social Security Act to include physicians.

Respectfully submitted

By Direction of the President

CHARLES G HAYDEN, M D, *Chairman*
Subcommittee on National Legislation

July 21, 1949

Senator Joseph R. McCarthy
Senate Committee on Expenditures in the Executive Offices
Senate Office Building
Washington, D C.

Dear Senator McCarthy

On June 20, 1949, President Truman, exercising authority delegated to him in Public Law 109, submitted to the Congress Reorganization Plan No 1. Under this Plan a Department of Welfare will be created to take over and perform the functions and conduct the programs now administered by the Federal Security Agency. Reorganization Plan No 1 will automatically go into effect on August 19, 1949 if Congress is still in session on that date or unless prior to that date either House of Congress passes a simple resolution against it by the affirmative vote of a majority of the authorized membership of that House.

The Massachusetts Medical Society opposes the inclusion of federal health and medical functions in a Department of Welfare. Instead, it has for some time favored the creation of a Department of Health or, if such is not feasible at this time, the creation of an independent federal agency similar to the United Medical Administration recently recommended by the Hoover Commission. The compelling arguments for a United Medical Administration as elaborated by the Hoover Commission are well known and need not be recounted here.

When President Truman submitted Reorganization Plan No 1, he stated that the creation of a Department of Welfare, including health and medical functions, would not in any way interfere with the presentation of additional reorganization plans such as one establishing a

United Medical Administration. However, Federal Security Administrator Oscar R. Ewing is now on record as being opposed to the removal of health and medical functions from the Federal Security Agency and, inferentially, from the proposed Department of Welfare. The Massachusetts Medical Society believes that once federal health and medical functions are lodged in a Department of Welfare, it will be next to impossible to remove them.

In the interest of economy and efficiency, the Federal Security Agency (Administration) has been subjected to several reorganizations. The Reorganization Act of 1939 was designed to, "reduce expenditures, increase efficiency, consolidate agencies according to major purposes, reduce the number of agencies by consolidating those having similar functions and by abolishing such as may not be necessary, and to eliminate overlapping and duplicating of efforts." The Reorganization Act of 1946 had similar purposes. It changed the Federal Security Agency (Administration) from a holding company with a small staff and a small budget to an operating agency which has burgeoned to incredible proportions. Prior to 1946, there existed three component bureaus—one each for health, education, and social security, now there exists a single agency headed by an administrator with a group of assistants. In 1939 there were five top administrative jobs in the bureaus dealing with health, education, and social security. These jobs paid about \$10,000 each and were held by the Surgeon General of the Public Health Service, the Commissioner of Education, and the three members of the Social Security Board. At the present time (1950 budget) provision is made for a Federal Security Administrator at \$12,000, three assistant administrators at \$10,000 each, nine more officials at \$10,000 each, four at more than \$9900 each, and six at over \$9000, or a total of twenty-three positions at over \$9000 each—and these only include persons in the office of the administrator. When the three-person Social Security Board was abolished and replaced by a Commissioner of Social Security, other positions were created for the remaining two members of the Board.

In 1946, prior to reorganization, Federal Security Administration expenditures were \$743,000,000. In 1946, following reorganization, they jumped to \$928,000,000. In 1948 they were \$1,028,000,000, and in 1949, \$1,370,000,000. In 1950 they will be \$1,511,000,000 under existing legislation and \$1,897,000,000 under proposed legislation.

Whether the previous reorganizations of the Federal Security Agency (Administration) have accomplished the purposes intended by the Congress is debatable, but that they have resulted in a serious potential concentration of power and influence over the daily lives of a significant segment of the population of this Nation seems beyond question.

The attitude of Federal Security Administrator Ewing toward the medical profession is well known and need not be elaborated here. Inasmuch as Mr. Ewing would no doubt become the first Secretary of Welfare, his attitude, corresponding as it does with the attitude of the present Minister of Health in England, Aneurin Bevan, is not likely to inspire confidence or a will to co-operate on the part of the medical profession in the solution of the intimate problems of medical care.

Respectfully submitted

By direction of the President

CHARLES G HAYDEN, M D, *Chairman*
Subcommittee on National Legislation

August 10, 1949

Senator Henry Cabot Lodge, Jr
Senate Office Building
Washington, D C.

Dear Senator Lodge

In a final attempt to dispel any misunderstanding in regard to the Hoover Commission's recommendations as they relate to Reorganization Plan No 1, the following quotations from the report of the Voorhees Task Force and the Hoover Commission itself are respectfully presented.

*"Task Force Report on Federal Medical Services (Appendix 0)
Prepared for
The Commission on Organization of the Executive Branch
of the Government
January, 1949*

"According to your chairman's instructions, we have proceeded upon the assumption that the Commission will recommend a new cabinet-level department embracing health, education, and security, in which the broad field of health will be one of the three major functions, also that standard Government nomenclature below the department level will be 'bureau' and thereafter 'division'. We, therefore, describe the health organization which we propose as the National Bureau of Health in such new department

"The above instructions excluded from our consideration the question as to whether a separate Cabinet department would be established for health alone, as urged by professional groups. However, should this be done, the organization which we are proposing would be adapted to such plan with only a few changes in nomenclature" (Page xix)

*"Task Force Report on Federal Medical Services
(Supplement to Appendix 0)
Prepared for
The Commission on Organization of the Executive Branch
of the Government
March 1949*

"As our committee had been instructed to assume that any consolidated health organization would be a part of a new cabinet-level department embracing health, education and security, which the Commission would recommend, our main report contained on page 1 the following statement 'The above instructions excluded from our consideration the question as to whether a separate cabinet department would be established for health alone, as urged by professional groups. However, should this be done, the organization which we are proposing would be adapted to such plan with only a few changes in nomenclature'

"Thus, we answered in the affirmative the question as to whether the organization, which we originally designated as the National Bureau of Health, could function as an independent department or agency

"It remains to consider whether such an alternative would be preferable. This question has been fully considered by our committee, and we have reached the conclusion that such an independent organization would be preferable to placing this function in a larger department, as the Commission originally proposed" (Page 1)

*"Reorganization of Federal Medical Activities
A report to the Congress by the Commission on Organization
of the Executive Branch of the Government
March, 1949*

"Recommendation No 1 To accomplish these purposes, the Commission recommends the establishment of a United Medical Administration into which would be consolidated most of the large-scale activities of the Federal Government in the fields of medical care, medical research, and public health (in which we include preventive medicine)" (Page 2)

Although the Hoover Commission in another report advocated the establishment of a Department of Welfare, it is clearly the intent of the above recommendations that federal health and medical services should be excluded from such a Department.

The Massachusetts Medical Society has taken no stand in regard to the establishment of a Department of Welfare from which federal health and medical functions would be excluded. It is, however, opposed to the establishment of a Department of Welfare which, contrary to the well substantiated recommendations of the Hoover Commission, would include federal health and medical functions

Respectfully submitted
By direction of the President
CHARLES G HAYDEN, M D, Chairman
Subcommittee on National Legislation

August 11, 1949

Senator Henry Cabot Lodge
Senate Office Building
Washington 25, D C

Dear Senator Lodge

I have tried, without success to date, to achieve an estimate of the amount of money which might be saved were a United Medical Administration established. If I come upon this information prior to the end of next week, I shall send it to you by wire

At the moment all I can say is that it seems likely that Congress would have better control of appropriations for health and medical functions if these functions were consolidated instead of being scattered throughout some forty odd divisions and bureaus as is now the case and as they would continue to be scattered under proposed Reorganization Plan No 1

Respectfully submitted
By direction of the President
CHARLES G HAYDEN, M D, Chairman
Subcommittee on National Legislation

August 15, 1949

Senator Leverett A Saltonstall
Senate Office Building
Washington, D C

Dear Senator Saltonstall

The Massachusetts Medical Society believes that once federal health and medical functions are lodged in a Department of Welfare, it will be next to impossible to remove them for the following reasons

1 Federal Security Administrator Oscar R Ewing, who, as payment for his services during the last Presidential campaign, would no doubt be the first Secretary of Welfare, has testified that he will resist the removal of health and medical services from such a Department

2 The President in his letter transmitting Reorganization Plan No 1 and in his recent letter to Vice President Barkley studiously avoided mentioning his intentions in regard to the establishment of a United Medical Service. It would have been an easy matter for him to have stated flatly that, subsequent to the establishment of a Department of Welfare, he would introduce a plan designed to remove health and medical functions

3 It is a well-known fact that it is much easier to exclude functions from a department or agency before it is established than to remove functions later. The anomalous autonomy of the Children's Bureau is an excellent illustration of this point

4 Elevation of the Federal Security Administration as is will accomplish nothing that is not already capable of accomplishment

5 At the present time forty different federal agencies furnish some degree of medical care to 24,000,000 persons. It would seem logical that first priority be given to this wasteful and extravagant situation

6 None of the Reorganization Plans so far submitted by the President will result in economy but all will effect a concentration of political power and prestige

Respectfully submitted
By direction of the President
CHARLES G HAYDEN, M D, Chairman
Subcommittee of National Legislation

APPENDIX NO 7

REPORT OF THE COMMITTEE ON ARRANGEMENTS

The Committee on Arrangements wishes to report that the dates of May 15, 16, 17 and 18, 1950, have been selected for the 1950 annual meeting of the Society, and that the next annual meeting of the Council will be held on the evening of May 15 in Boston

It is recommended that these dates be approved by the Council

GORDON DONALDSON, M D
ALBERT EHRENFRIED, M D
JAMES A HALSTED, M D
JOHN W NORCROSS, M D
FRANKLIN G BALCH, JR, M D, Chairman

APPENDIX NO 8

REPORT OF THE COMMITTEE ON PUBLIC HEALTH

On August 10, 1949, a meeting of the Committee was held at the Hotel Kenmore, Boston, to discuss the relation of the Massachusetts Medical Society to the increased incidence of poliomyelitis. Present at this meeting were the following: Arthur W. Allen, M.D., H. Quimby Gallup, M.D., Joseph Garland, M.D., Charles Bradford, M.D., Vlado A. Getting, M.D., Roy Feemster, M.D., Roy J. Ward, M.D., Alfred L. Frechette, M.D., Warren R. Sisson, M.D., and John J. Poutas, M.D.

The first item of business was the election of a secretary for the Committee. John J. Poutas, M.D., was re-elected secretary for the fourth consecutive year.

Next on the agenda was consideration and approval of proposed minimal "Standing Orders" for use in convalescent and nursing homes. This material was submitted to the committee by Dr. Alton S. Pope, deputy commissioner of Health, and was discussed at this meeting by Dr. Getting, commissioner of health. The purpose of the standing orders is to restrict self-medication to a minimum. The proposed standing orders were read by the secretary, and it was pointed out that they are "minimals." It was moved and voted that they be approved in principle.

A letter, written by Francis C. Hall, M.D., president, New England Chapter, Arthritis and Rheumatism Foundation, to Dr. Arthur W. Allen, was read in which the assistance of the Society was requested in a survey to ascertain the number of arthritis clinics in the State and to render advice regarding encouragement and expansion of any existing clinics and the wisdom of establishing new clinics.

The Committee voted approval of this survey and recommended that it be accomplished with and through the office of the Commissioner.

A request by the same foundation that an arthritis subcommittee of the Committee on Public Health be appointed was approved and it is accordingly referred to the Council for necessary action.

The main item of business on the agenda consisted of a detailed discussion of the situation in the State and country with respect to infantile paralysis.* Drs. Getting and Feemster gave a very detailed outline of the problem and presented the following for committee action:

A proposed newspaper release to the effect that the Committee on Public Health and the Massachusetts Department of Public Health had jointly considered and approved a set of recommended practices for the control of poliomyelitis adopted by a national conference in Ann Arbor, Michigan, in June, 1949, under the auspices of the National Foundation for Infantile Paralysis. The Committee considered in detail the proposed release, and approval was duly voted.

It was also proposed and voted that these recommended practices be given the earliest possible publication in the *New England Journal of Medicine* and disseminated to all physicians.

The advisability of radio broadcasts by a panel of physicians on the general subject of infantile paralysis was discussed, moved and voted.

The Committee then formally offered its commendation to Dr. Getting for the excellence of his department and the splendid and effective co-operation it has always shown to this committee.

ALFRED L. FRECHETTE, M.D.
JOHN J. POUTAS, M.D.
WARREN R. SISSON, M.D.
CONRAD WESSELHOEFF, M.D.
ROY J. WARD, M.D. *Chairman*

*Two additions to the report were made by the Council by recommendation of the Committee—namely, approval of the survey of multiple sclerosis by the Harvard School of Public Health and approval of the Chest X-Ray Program in Boston.

APPENDIX NO 9

REPORT OF THE COMMITTEE ON MEMBERSHIP

A regular meeting of the Committee on Membership was held on August 10, 1949. The Committee discussed the question of the possibility of amending the by-laws relating to applicants for membership in the Society with particular reference to Chapter 5, Section 2b which states that "applica-

tions from a graduate of a discontinued medical school or a foreign medical school may apply only when the applicant has possessed a license to practice medicine in the United States or its territories for at least five years."

It was felt that the original reason for this by-law was largely past since the last unapproved medical school had now been closed.

It was felt further that there would be a few cases in which an unjust hardship would be placed upon some well intentioned graduate of an unapproved school if he was not allowed to have the privilege of membership in the Society during the first five years of his practice.

Therefore, it was voted that it be recommended that the following change be made in paragraph 2 of Section 2(b) of Chapter V: "The applicant has possessed a license to practice medicine in the Commonwealth and has conducted that practice in the district from which he makes application, for at least one year."

The following reasons for this change are given: knowledge of the doctor by his fellows for one year is better than registration for any length of time elsewhere, the Committee on Membership has often turned down otherwise eligible candidates because they were not known in the town or city for at least a year, the first five years of practice are the hardest, and the by-laws make them more difficult because the doctor cannot become a staff member in an approved hospital until he is a fellow of the Society and he cannot, therefore, take advantage of the Gallup Plan because most hospitals stick to the ruling mentioned above, if this by-law were changed, more hospitals would accept the Gallup Plan, the applicant would be able to give better care to his patients, this is the ultimate objective of the Society, it would be a good public-relations effort, and the number of such applicants is steadily decreasing.

The vote was four in favor of this recommendation and one opposed (by proxy).

APPENDIX NO 10

REPORT OF THE COMMITTEE ON SOCIETY HEADQUARTERS

It is the opinion of the Committee that a survey to see what is the best thing to do for the future home of the Society should be made, and that the present headquarters, the present facilities, and the possibility of obtaining more land and buildings in the near neighborhood, such as the Bostonian Hotel and the tenements on Hemingway Street across from the Library should be examined, the possibility of acquiring land at the dam site where the Boston Museum of Natural History is contemplating building should be investigated and that it should be known whether or not it might be advisable to obtain a piece of land and combine, on this land, the Medical Library, the *Journal* office, the headquarters, and a building for the Massachusetts Medical Society in co-operation with the School of Public Health of Harvard, which is moving to build a new building, and combining, at the same time, with the Department of Public Health. It is recommended that the Society employ a man to survey all the possibilities and make a final report to the Council. It is also recommended that a sum, not exceeding \$5000, be appropriated to carry out the thorough survey that is recommended.

APPENDIX NO 11

REPORT OF THE COMMITTEE ON INDUSTRIAL HEALTH

The Committee met at the Harvard Club on July 20, 1949, to outline a program for the coming year. Besides the members of the committee, Dr. William Fleming, of Boston University, Dr. Dwight O'Hara, of Tufts, Dr. Albert Seeler, of Harvard School of Public Health, the members of the Advisory Committee and the officers of the Society were present.

The following suggestions were made concerning the program a survey should be made of the industrial-health facilities in the State, the need for instruction in industrial health in medical schools, in postgraduate courses and in industrial plants, the need for a series of programs for professional and lay people concerning industrial-health problems, the need for a clearing house of industrial-health information, and the need for insurance covering the worker for industrial and nonindustrial disabilities.

The Committee recommends that an industrial-health conference be held in Boston on December 14, 1949, under the auspices of the Society. The program will consist of a morning session devoted to industrial medicine and surgery, an afternoon session for management, labor, state agencies and insurance companies, and an evening session of general interest to all.

If this recommendation is approved, the conference program will be directed by Dr George Wilkins, Dr Karl Benedict and Dr John Poutas.

The survey of industrial-health facilities will be conducted by Dr George Morris, Dr Harriet Hardy and Mr William Seymour.

APPENDIX NO 12

REPORT OF THE COMMITTEE TO MEET WITH THE MASSACHUSETTS HOSPITAL ASSOCIATION

Since the request from Norfolk District Medical Society to the Council "for a delineation of the developments which had taken place regarding the report of the Committee on Special Services" and the resolution from the joint Committee of the Anesthesiologists, Pathologists, Physical Therapists, and Roentgenologists that "the Committee from the Massachusetts Medical Society to meet with the Massachusetts Hospital Association be instructed to take steps to expedite the acceptance and practice of the principles enunciated by the Committee to study Special Services" are so similar as to be practically concomitant they will be answered together.

First we wish to quote from the report made to the Council on May 24, 1948, by this committee of the previous conference held March 3, 1948, with the Committee on Professional Services of the Massachusetts Hospital Association when we tried to get their approval of the principles enunciated by the Committee to Study Special Services. The Society was represented by Drs Bagg and Gallupe and four members of the Committee, which included Dr McKittrick. The Hospital Association was represented by Dr Norbert A Wilhelm, of the Peter Bent Brigham Hospital, and Mr Warren F Cook, of the New England Deaconess Hospital.

Arguments about why these principles should be approved by the Hospital Association were presented, chiefly by Drs Bagg and McKittrick. Dr Wilhelm stated that his committee had met the day previously and had voted that no action be taken at this time. Their decision was based chiefly upon their belief of the uncertainty whether the Blue Cross could continue to provide adequate prepaid hospital insurance. As hospital administrators they believed its successful operation was essential to the welfare of hospitals, and they refused to approve anything they thought might further embarrass it. They also said that because of poor public relations on the part of the hospitals, a more complicated system of billing hospital costs to the patient would be too confusing and undesirable to be undertaken. Incidentally, they stated they believed that very few hospitals had a system of accounting sufficiently comprehensive to be able to work out all details of cost accounting that would be necessary under this plan.

There was a great deal of discussion during which the representatives of the Society tried unsuccessfully to convert the representatives of the Association to its point

of view. They were unwilling to grant their approval of these principles even though the Society agreed to the postponement of their adoption until a later date because they believed that in these days when the Blue Cross and so many hospitals are in great financial distress, the whole question of voluntary hospital service is at stake. They insisted that now was not the time to undertake the adoption of these principles. Although the Committee believed in the fairness of these principles and urged their adoption, it was believed that the representatives of the Association were sincere in their point of view. As a result of this conference, it was believed that nothing more could be done at present.

From this quotation it is obvious that the statement contained in the preamble to the resolution presented by the Joint Committee of the Anesthesiologists, Pathologists, Physical Therapists, and Roentgenologists that "it was decided not to press for acceptance and practice of the principles enunciated by the Committee to Study Special Services at that time, etc." does not represent the intentions, the sincerity, or the efforts of the Committee at that meeting. There was plenty of explanation, persuasion, and pressure on the part of the Committee but they, particularly Dr Wilhelm, were steadfast in refusing to agree to anything for the reasons given.

Late last fall the Chairman, mindful of the Council vote that this committee continue its efforts, consulted the secretary of the New England Pathological Society (Dr Nickerson), who was a member of the original Committee to Study Special Services as to whether or not they wished us again to communicate with the Committee on Professional Services of the Massachusetts Hospital Association for more discussion of the McKittrick Report. He was told that they did not at that time, since the general situation was unchanged. He stated that with Dr McKittrick on both the Blue Shield and Blue Cross boards, he felt the interests of the special services would be safeguarded. He also said they might again bring up their problem at a later time. That request was made at the Council Meeting on the evening of May 23 in a resolution representing a Joint Committee of the Anesthesiologists, Pathologists, Physical Therapists, and Roentgenologists requesting this committee "to take steps to expedite the acceptance and practice by the Massachusetts Hospital Association of the principles enunciated by the Committee to Study Special Services."

The second and most recent meeting with the Professional Services Committee of the Massachusetts Hospital Association was held June 30, 1949. This time each side was represented by a new committee. On that for Professional Services of the Hospital Association were Dr Guy W Brugler, director of the Children's Hospital, Mr Warren F Cook, executive director of the New England Deaconess Hospital, and Mr Paul F Nallon, superintendent of the Hampden County Hospital in Greenfield.

The Committee representing the Society now has an anesthesiologist, a pathologist and a roentgenologist.

Present at this meeting were the members of the Committee and Dr Leland S McKittrick, president-elect of the Society. Dr Arthur W Allen, president of the Society, attended a conference held prior to the meeting with the Hospital Association and joined in a discussion of the problem. Dr Brugler and Mr Nallon appeared for the Hospital Association. Mr Cook sent word that he was unable to attend although we did not know it until the conference began. Also, the date for the meeting had been arranged through his office before the notices were sent out.

Beginning with Dr Donald A. Nickerson, pathologist at the Salem Hospital, where the principles in the McKittrick Report were accepted and put in practice a year ago, the Committee did the best it could by explanation, argument and persuasion to convince the two members of the Professional Services Committee that the Massachusetts Medical Society really supports these principles enunciated by the Committee to Study Special Services. Dr McKittrick spoke at length in favor of these principles and reported that the Massachusetts General Hospital is now reorganizing its departments to conform to them. Their attention was also called to the fact that the Committee on Hospitals and Practice of Medicine of the American Medical Association had included these principles in their report to the

House of Delegates, which was accepted, and gave a strong endorsement urging that they be approved and adopted generally.

Finally after about an hour and a half of discussion, during which we had done most of the talking and they had proved good listeners, we were told their committee lacked authority to act on our request and that the matter would be discussed at the meeting of their trustees in September. They were urged to try to hold a trustee's meeting before August 15 if possible, so that we might include their answer in our report for the October meeting. However, in a letter written July 11, Mr Cook stated that it would be impossible to have a meeting of the trustees before September, and therefore no action can be taken on the McKittick Plan by the Association by August 15.

We await their report anxiously and hopefully. If their answer is unfavorable, we shall request other conferences.

APPENDIX NO 15

REPORT OF THE COMMITTEE ON POSTGRADUATE MEDICAL EDUCATION

This is a brief report of progress. The Committee has had one meeting at which were present representatives from the various teaching centers throughout the State. At this meeting attempts were made to meet the wishes of the local district chairmen regarding the nature and the conduct of educational programs for the year. Plans to implement these various programs are now under way.

One other item is worth reporting at this time. For reasons of convenience and economy, it seems best to all concerned to transfer the exercises formerly held at Sanders Theater to John Ware Hall at 8 Fenway for the coming season.

W RICHARD OHLER, M D, *Chairman*

APPENDIX NO 14

REPORT OF THE COMMITTEE ON MEDICAL ECONOMICS

Several meetings of the committee were held through the summer months jointly with the Subcommittee on National Legislation on invitation of Dr Hayden, its chairman.

Several important matters are under consideration by the members of these committees, ably assisted by a few elder statesmen of the Society. Report on these discussions at present would be premature, but in general this group is endeavoring to implement previously adopted policies aiming toward better co-ordination of groups concerned in the distribution of medical care in Massachusetts. We presently expect to have some of these matters ready at the next meeting of the Council.

The Council has referred back to the Committee on Medical Economics for clarification paragraph 13 of the fourteen paragraphs adopted jointly with the Committee on Public Relations on February 9, 1949.

We discussed the wording in comparison with the American Medical Association principle No 12, which asks for "adequate support with funds free from political control" and so forth. It was suggested that the "free from political control" qualification might be debatable strategically because strictly speaking, political control in the best sense would be proper in an assumed good government. When Government provides funds it must to a proper degree, regulate the expenditures. However, the committee suggests the following new wording for paragraph No 13.

We agree that the federal Government may properly assist financially such medical schools as are found unable to meet their operative costs, upon their request for such assistance provided that such assistance shall not be construed as authorizing any federal department, agency, officer, or employee to exercise any supervision or control over the admission of students, curriculum, teaching personnel or administration of such medical schools,

except such supervision as may be necessary to insure that grants shall be expended solely for the purposes for which they are made.

We believe effective organization of state and district health councils would immeasurably improve the community concept of local health needs. The initiative of the people themselves, and especially of the medical and public-health personnel, must provide the spark.

HAROLD M FROST, M D
VLADO A GETTING, M D
HUGH LEAVELL, M D
HENRY A ROBINSON, M D
ELMER S BAGNALL, M D, *Chairman*

The fourteen proposals as finally adopted by the Council were as follows:

(1) The objective of adequate medical care in our free society is to make available to everyone—regardless of race, color, creed, financial status or place of residence—every known essential preventive, diagnostic and curative medical service of high quality. The attainment of such medical care must necessarily be an evolutionary process, which will require the co-operation of all concerned over a period of years.

(2) The principle of voluntary prepayment health insurance should be the basic method of financing medical care for the large majority of the American people, in order to remove the burden of unpredictable sickness costs and abolish the economic barrier to adequate medical services.

(3) The success of any plan for medical care is dependent on the mutual co-operation of the public, those rendering professional services and the administrative agencies. This co-operation can be obtained only if those rendering the services are convinced that they will have a continuing authoritative voice in the formulation and execution of policies and plans, thereby assuming their proper share of responsibility.

(4) Voluntary prepayment group health plans, embodying group practice and providing comprehensive service, when practicable, sometimes offer their members adequate medical care. No such plan shall be obstructed in procuring enabling legislation. No physician participating in such a plan shall be denied, by reason of participation per se, 1, membership in established medical societies, 2, hospital-staff appointments dependent upon such society memberships, 3, consultation courtesies by nonparticipating physicians on the usual plane of ethical relationship.

(5) The people have the right to establish voluntary prepayment plans on any basis guarded by legal restrictions necessary to assure proper standards and qualifications.

(6) Provision of adequate medical care for those unable to obtain it by voluntary prepayment plans or by direct payment is the responsibility of the local or state government. Part of the burden of this responsibility may be assumed by charitable agencies. Federal grant-in-aid to state programs administered by state boards of health is an acceptable method of helping to meet this responsibility.

(7) The medical care of those who are able to purchase it by voluntary prepayment plans or by direct payment is the responsibility of the individual.

(8) The federal Government, should, wherever possible, support voluntary prepayment programs for hospital and medical care.

(9) Eligibility for receiving benefits under a program aided by federal grants should be determined by the individual states or communities.

(10) The patient shall have free choice of his physician, group of physicians, clinic or hospital from among those participating in any plan, provided that the physician, group of physicians, clinic or hospital shall have the right to refuse or accept the patient.

(11) Physicians and other qualified persons rendering medical care shall receive adequate remuneration for their services.

(12) The physician shall be free to elect or reject without prejudice participation in a medical-care plan. The

The following suggestions were made concerning the program a survey should be made of the industrial-health facilities in the State, the need for instruction in industrial health in medical schools, in postgraduate courses and in industrial plants, the need for a series of programs for professional and lay people concerning industrial-health problems, the need for a clearing house of industrial-health information, and the need for insurance covering the worker for industrial and nonindustrial disabilities.

The Committee recommends that an industrial-health conference be held in Boston on December 14, 1949, under the auspices of the Society. The program will consist of a morning session devoted to industrial medicine and surgery, an afternoon session for management, labor, state agencies and insurance companies, and an evening session of general interest to all.

If this recommendation is approved, the conference program will be directed by Dr George Wilkins, Dr Karl Benedict and Dr John Poutas.

The survey of industrial-health facilities will be conducted by Dr George Morris, Dr Harriet Hardy and Mr William Seymour.

APPENDIX NO 12

REPORT OF THE COMMITTEE TO MEET WITH THE MASSACHUSETTS HOSPITAL ASSOCIATION

Since the request from Norfolk District Medical Society to the Council "for a delineation of the developments which had taken place regarding the report of the Committee on Special Services" and the resolution from the joint Committee of the Anesthesiologists, Pathologists, Physical Therapists, and Roentgenologists that "the Committee from the Massachusetts Medical Society to meet with the Massachusetts Hospital Association be instructed to take steps to expedite the acceptance and practice of the principles enunciated by the Committee to study Special Services" are so similar as to be practically concomitant they will be answered together.

First we wish to quote from the report made to the Council on May 24, 1948, by this committee of the previous conference held March 3, 1948, with the Committee on Professional Services of the Massachusetts Hospital Association when we tried to get their approval of the principles enunciated by the Committee to Study Special Services. The Society was represented by Drs Bagg and Gallupe and four members of the Committee, which included Dr McKittrick. The Hospital Association was represented by Dr Norbert A. Wilhelm, of the Peter Bent Brigham Hospital, and Mr Warren F. Cook, of the New England Deaconess Hospital.

Arguments about why these principles should be approved by the Hospital Association were presented, chiefly by Drs Bagg and McKittrick. Dr Wilhelm stated that his committee had met the day previously and had voted that no action be taken at this time. Their decision was based chiefly upon their belief of the uncertainty whether the Blue Cross could continue to provide adequate prepaid hospital insurance. As hospital administrators they believed its successful operation was essential to the welfare of hospitals, and they refused to approve anything they thought might further embarrass it. They also said that because of poor public relations on the part of the hospitals, a more complicated system of billing hospital costs to the patient would be too confusing and undesirable to be undertaken. Incidentally, they stated they believed that very few hospitals had a system of accounting sufficiently comprehensive to be able to work out all details of cost accounting that would be necessary under this plan.

There was a great deal of discussion during which the representatives of the Society tried unsuccessfully to convert the representatives of the Association to its point

of view. They were unwilling to grant their approval of these principles even though the Society agreed to the postponement of their adoption until a later date because they believed that in these days when the Blue Cross and so many hospitals are in great financial distress, the whole question of voluntary hospital service is at stake. They insisted that now was not the time to undertake the adoption of these principles. Although the Committee believed in the fairness of these principles and urged their adoption, it was believed that the representatives of the Association were sincere in their point of view. As a result of this conference, it was believed that nothing more could be done at present.

From this quotation it is obvious that the statement contained in the preamble to the resolution presented by the Joint Committee of the Anesthesiologists, Pathologists, Physical Therapists, and Roentgenologists that "it was decided not to press for acceptance and practice of the principles enunciated by the Committee to Study Special Services at that time, etc." does not represent the intentions, the sincerity, or the efforts of the Committee at that meeting. There was plenty of explanation, persuasion, and pressure on the part of the Committee but they, particularly Dr Wilhelm, were steadfast in refusing to agree to anything for the reasons given.

Late last fall the Chairman, mindful of the Council vote that this committee continue its efforts, consulted the secretary of the New England Pathological Society (Dr Nickerson), who was a member of the original Committee to Study Special Services as to whether or not they wished us again to communicate with the Committee on Professional Services of the Massachusetts Hospital Association for more discussion of the McKittrick Report. He was told that they did not at that time, since the general situation was unchanged. He stated that with Dr McKittrick on both the Blue Shield and Blue Cross boards, he felt the interests of the special services would be safeguarded. He also said they might again bring up their problem at a later time. That request was made at the Council Meeting on the evening of May 23 in a resolution representing a Joint Committee of the Anesthesiologists, Pathologists, Physical Therapists, and Roentgenologists requesting this committee "to take steps to expedite the acceptance and practice by the Massachusetts Hospital Association of the principles enunciated by the Committee to Study Special Services."

The second and most recent meeting with the Professional Services Committee of the Massachusetts Hospital Association was held June 30, 1949. This time each side was represented by a new committee. On that for Professional Services of the Hospital Association were Dr Guy W. Brugler, director of the Children's Hospital, Mr Warren F. Cook, executive director of the New England Deaconess Hospital, and Mr Paul F. Nallon, superintendent of the Hampden County Hospital in Greenfield.

The Committee representing the Society now has an anesthesiologist, a pathologist and a roentgenologist.

Present at this meeting were the members of the Committee and Dr Leland S. McKittrick, president-elect of the Society. Dr Arthur W. Allen, president of the Society, attended a conference held prior to the meeting with the Hospital Association and joined in a discussion of the problem. Dr Brugler and Mr Nallon appeared for the Hospital Association. Mr Cook sent word that he was unable to attend although we did not know it until the conference began. Also, the date for the meeting had been arranged through his office before the notices were sent out.

Beginning with Dr Donald A. Nickerson, pathologist at the Salem Hospital, where the principles in the McKittrick Report were accepted and put in practice a year ago, the Committee did the best it could by explanation, argument and persuasion to convince the two members of the Professional Services Committee that the Massachusetts Medical Society really supports these principles enunciated by the Committee to Study Special Services. Dr McKittrick spoke at length in favor of these principles and reported that the Massachusetts General Hospital is now reorganizing its departments to conform to them. Their attention was also called to the fact that the Committee on Hospitals and Practice of Medicine of the American Medical Association had included these principles in their report to the

House of Delegates, which was accepted, and gave a strong endorsement urging that they be approved and adopted generally.

Finally after about an hour and a half of discussion, during which we had done most of the talking and they had proved good listeners, we were told their committee lacked authority to act on our request and that the matter would be discussed at the meeting of their trustees in September. They were urged to try to hold a trustee's meeting before August 15 if possible, so that we might include their answer in our report for the October meeting. However, in a letter written July 11, Mr Cook stated that it would be impossible to have a meeting of the trustees before September, and therefore no action can be taken on the McKittick Plan by the Association by August 15.

We await their report anxiously and hopefully. If their answer is unfavorable, we shall request other conferences.

APPENDIX NO 13

REPORT OF THE COMMITTEE ON POSTGRADUATE MEDICAL EDUCATION

This is a brief report of progress. The Committee has had one meeting at which were present representatives from the various teaching centers throughout the State. At this meeting attempts were made to meet the wishes of the local district chairmen regarding the nature and the conduct of educational programs for the year. Plans to implement these various programs are now under way.

One other item is worth reporting at this time. For reasons of convenience and economy, it seems best to all concerned to transfer the exercises formerly held at Sanders Theater to John Ware Hall at 8 Fenway for the coming season.

W RICHARD OHLER, M D, *Chairman*

APPENDIX NO 14

REPORT OF THE COMMITTEE ON MEDICAL ECONOMICS

Several meetings of the committee were held through the summer months jointly with the Subcommittee on National Legislation on invitation of Dr Hayden, its chairman.

Several important matters are under consideration by the members of these committees, ably assisted by a few elder statesmen of the Society. Report on these discussions at present would be premature, but in general this group is endeavoring to implement previously adopted policies aiming toward better co-ordination of groups concerned in the distribution of medical care in Massachusetts. We presently expect to have some of these matters ready at the next meeting of the Council.

The Council had referred back to the Committee on Medical Economics for clarification paragraph 13 of the fourteen paragraphs adopted jointly with the Committee on Public Relations on February 9, 1949.

We discussed the wording in comparison with the American Medical Association principle No 12, which asks for "adequate support with funds free from political control" and so forth. It was suggested that the "free from political control" qualification might be debatable strategically because strictly speaking, political control in the best sense would be proper in an assumed good government. When Government provides funds it must, to a proper degree regulate the expenditures. However, the committee suggests the following new wording for paragraph No 13.

We agree that the federal Government may properly assist financially such medical schools as are found unable to meet their operative costs, upon their request for such assistance provided that such assistance shall not be construed as authorizing any federal department, agency, officer, or employee to exercise any supervision or control over the admission of students, curriculum, teaching personnel or administration of such medical schools,

except such supervision as may be necessary to insure that grants shall be expended solely for the purposes for which they are made.

We believe effective organization of state and district health councils would immeasurably improve the community concept of local health needs. The initiative of the people themselves and especially of the medical and public-health personnel, must provide the spark.

HAROLD M FROST, M D
VLANO A GETTING, M D
HUGH LEAVELL, M D
HENRY A ROBINSON, M D
ELMER S BAGNALL, M D, *Chairman*

The fourteen proposals as finally adopted by the Council were as follows:

(1) The objective of adequate medical care in our free society is to make available to everyone — regardless of race, color, creed, financial status or place of residence — every known essential preventive, diagnostic and curative medical service of high quality. The attainment of such medical care must necessarily be an evolutionary process, which will require the co-operation of all concerned over a period of years.

(2) The principle of voluntary prepayment health insurance should be the basic method of financing medical care for the large majority of the American people, in order to remove the burden of unpredictable sickness costs and abolish the economic barrier to adequate medical services.

(3) The success of any plan for medical care is dependent on the mutual co-operation of the public, those rendering professional services and the administrative agencies. This co-operation can be obtained only if those rendering the services are convinced that they will have a continuing authoritative voice in the formulation and execution of policies and plans, thereby assuming their proper share of responsibility.

(4) Voluntary prepayment group health plans, embodying group practice and providing comprehensive service, when practicable, sometimes offer their members adequate medical care. No such plan shall be obstructed in procuring enabling legislation. No physician participating in such a plan shall be denied, by reason of participation per se, 1, membership in established medical societies, 2, hospital-staff appointments dependent upon such society memberships, 3, consultation courtesies by nonparticipating physicians on the usual plane of ethical relationship.

(5) The people have the right to establish voluntary prepayment plans on any basis guarded by legal restrictions necessary to assure proper standards and qualifications.

(6) Provision of adequate medical care for those unable to obtain it by voluntary prepayment plans or by direct payment is the responsibility of the local or state government. Part of the burden of this responsibility may be assumed by charitable agencies. Federal grant-in-aid to state programs administered by state boards of health is an acceptable method of helping to meet this responsibility.

(7) The medical care of those who are able to purchase it by voluntary prepayment plans or by direct payment is the responsibility of the individual.

(8) The federal Government, should, wherever possible, support voluntary prepayment programs for hospital and medical care.

(9) Eligibility for receiving benefits under a program aided by federal grants should be determined by the individual states or communities.

(10) The patient shall have free choice of his physician, group of physicians, clinic or hospital from among those participating in any plan, provided that the physician, group of physicians, clinic or hospital shall have the right to refuse or accept the patient.

(11) Physicians and other qualified persons rendering medical care shall receive adequate remuneration for their services.

(12) The physician shall be free to elect or reject without prejudice participation in a medical-care plan. The

rights of the physician as to the choice of methods by which he is to be paid shall be fully protected.

(13) We agree that the federal Government may properly assist financially such medical schools as are found unable to meet their operative costs, upon their request for such assistance, *provided* that such assistance shall not be construed as authorizing any federal department, agency, officer or employee to exercise any supervision or control over the admission of students, curriculum, teaching personnel or administration of such medical schools, except such supervision as may be necessary to ensure that grants shall be expended solely for the purpose for which they are made.

(We believe effective organizations of state and district health councils would immeasurably improve the community concept of local health needs. The initiative of the people themselves, and especially of the medical and public health personnel, must provide the spark.)

(14) The Massachusetts Medical Society looks upon these basic principles as essential to the development of any successful medical-care plan and, as guides by which to evaluate medical-care plans that may be proposed in the future, with the understanding that changing conditions may require their later revision.

APPENDIX NO 15

REPORT OF THE COMMITTEE ON NEW ENGLAND POSTGRADUATE ASSEMBLY

The New England Postgraduate Assembly will be held in the Copley Plaza Hotel on November 9, 10 and the morning of November 11. The central committee will hold a meeting early in the fall to approve final plans.

The scheduled time of meetings is the same as before, the papers being limited to one half hour. Twenty-four papers will be presented. All the speakers are from outside Boston. The subject matter is widely varied involving the various aspects and interests of all.

Through the courtesy of E. R. Squibb and Company, facilities of television have been offered to the Assembly for the morning of November 10 and 11. Inasmuch as installation of the transmitting equipment and transmitting the program involves considerable expense, it has been necessary to confine the television program to one institution. Lots were drawn and the first to be drawn was the New England Medical Center. It is thought that they will have invited talent from other hospitals to give as broad a representation as possible.

This is an innovation for the New England Assembly, and it is hoped that with careful attention to details it will become a very valuable adjunct to the meeting. It was initiated by Mr. Boyd when in discussion it was felt that the clinics at the various hospitals provided a very uncertain attendance.

On the evening of November 9 it is planned to have a smoker or jamboree in the State Suite of the Copley Plaza Hotel. It is hoped that doctors and their wives will participate in an evening of entertainment and social activities.

The dinner will be held in the State Suite of the Copley Plaza Hotel on the following night, Thursday, November 10. It is expected that a speaker of national prominence will provide an incentive for a satisfactory attendance.

The members of the registration committee are the secretaries of the district societies throughout New England and through Dr. Conlin's office will be kept informed of the developments of plans for the Assembly.

Applications for space at the Assembly have been very satisfactory.

RICHARD P. STETSON, M.D., *Chairman*

APPENDIX NO 16

REPORT OF THE COMMITTEE ON DIABETES

The Committee has held two meetings since the annual meeting of the Society in May. At the first, representatives of the district societies were present and consideration was given to the Diabetes Detection Program with particular reference to industry. It was noted that the Diabetes Detection Program throughout the United States has made progress and actually more than 90 committees or diabetes societies

are organized in 37 states. The committees appointed for last year's drive have continued their efforts in many places and many new committees have been formed.

The Diabetes Detection Program is not a drive for funds. It represents an effort sponsored and conducted by American medicine to find and bring to treatment undiscovered diabetic cases.

The Diabetes Detection Drive was first approved by the House of Delegates of the American Medical Association on November 30, 1948, and again on motion of the New York delegate on June, 1949, at Atlantic City. It represents an effort wholly consistent with the national education campaign of the American Medical Association. This year the program of diabetes detection offers a variety of methods to the public. The time-honored method of diabetes detection is to have a urine and blood test in the family doctor's office as part of the regular, periodic health examination. In many communities, with the co-operation of doctors, public-health organizations, boards of health, tuberculosis associations and so forth, detection centers will be available for those who do not have regular physicians. A new principle of self-testing has been adopted this year by which a patient may purchase at a drug store the equipment for testing the urine and may then carry out the directions given in the equipment for making his own urine tests. The results are then to be reported to his family physician. The method now most effective has been a program managed by the county or district medical society in co-operation with public-health agencies by which free urine tests are especially offered to the relatives of known diabetic patients and often as part of a concerted campaign for chest x-rays. The Committee begs the co-operation of all members of the Society particularly in providing for free urine tests during Diabetes Week, October 16-16, 1949.

APPENDIX NO 17

REPORT OF THE CO-ORDINATING COMMITTEE

On August 1, 1949, the chairman of the committee, after a conference with the officers of the Society and the editor of the *New England Journal of Medicine*, mailed to every councilor a bulletin that gives a picture of the activities of the Society in carrying out the American Medical Association educational campaign. The bulletin gives the names of fellows on the committee, it mentions the need for a positive program of medical care, the end of the National Physicians Committee and the action of the American Medical Association concerning Dr. Fishbein, it describes the meeting at the Hotel Statler on May 1 and the "Tell it to Twenty" program. The bulletin points out the matter of timing and emphasizes the disastrous effect of complacency and inactivity. A report of the highlights of the activities are summarized 300 talks by 20 physicians to many types of groups, editorial support, the Massachusetts Health Conference on February 19 and 20, 30,000 pieces of literature distributed from 8 Fenway, and participation on the radio and other programs. The importance of the county-society activities is stressed by demonstration of the need for an active district-society committee, the "Tell it to Twenty" portion of the campaign, the need for resolutions against compulsory national health insurance, and the importance of a strong speaker's bureau and contacts with local press and radio facilities. The bulletin points out the importance of the Women's Auxiliary in the campaign, the need for personal contacts with congressmen. There is a list of the literature now available through the Society office.

The bulletin ends by urging all to use the literature effectively and to keep the Society informed at frequent intervals concerning the progress of the campaign in the eighteen districts.

FRANK H. LAHEY, M.D., *Chairman*

APPENDIX NO 18

REPORT OF THE COMMITTEE TO WRITE A PUBLICITY CODE

In accordance with the vote of the Council at their meeting on May 23, 1949, at which time it was moved and voted that "a committee of five write a Massachusetts Medical Society code to govern publicity," the following report and recommendations are submitted

A It is recommended that the following Publicity Code of the Massachusetts Medical Society be accepted

Publicity Code
of the
Massachusetts Medical Society

PREAMBLE Believing that the relationship between organized medicine as represented in this Commonwealth by the Massachusetts Medical Society and the public as represented by the press, the radio, non-medical magazines and other similar media of communication should be cordial, co-operative and more closely integrated than it has been in the past, the Council of the Massachusetts Medical Society acting for the Society in a regular meeting hereby authorizes the following Publicity Code to implement such relationship

1 This document shall be known as the Publicity Code of the Massachusetts Medical Society

2 The purpose of this code is to establish acceptable ethical limits within which Fellows of the Society who are also members of hospital staffs or of administrative departments of hospitals or other institutions devoted exclusively to the teaching, investigation or practice of medicine may contribute in writing or by interview to the non-medical press and magazines or the radio or other media of communication

3 This code shall be supplemental to the present codes of ethics that govern the Fellows of the Massachusetts Medical Society

4 The name of any Fellow of the Massachusetts Medical Society as designated in Section 2 of this code may be used for purposes of publicity only with permission of the Chief of Staff or the Chief of the appropriate service of the hospital and of the hospital director. This permission applies only provided that the Fellow is identified as a member of the staff rather than as an individual and where the emphasis is on the services rendered and not on the individual Fellow

5 If the hospital organization does not include a Chief of Staff or Chief of Service, the name of any Fellow may be used for purposes of publicity as otherwise limited in Sections 2 and 4 of this code only after permission has been obtained from the Supervising Censor of the District Society of which the Fellow in question is a member. Permission from the hospital director will not suffice in these circumstances

6 In the case of institutions other than hospitals devoted exclusively to the teaching, investigation and practice of medicine, the name of any Fellow may be used for purposes of publicity only as follows: A With permission of the head of a major department or research organization. B With permission of the Dean of a Medical School or someone specifically designated by him for this purpose. These permissions apply only if the emphasis is placed on the services rendered or work done rather than on the individual Fellow

7 The name of any Fellow may be used in connection with an individual case or project with the consent of the individual Fellow and in accordance with the requirements listed in Sections 4, 5 and 6 of this code. This permission applies only whenever the case or project illustrates the work performed at the hospital or the institution (see Sections 4, 5 and 6 of this code) and the emphasis is placed on the services rendered or work done and not on the individual Fellow

8 The name of any Fellow may be used in information given out about a patient or a project in conformity with the requirements listed above in Sections 4, 5 and 6 of this code whenever the press, magazines, radio and other media of communication have most of the facts already and are calling the hospital or institution for purposes of verification of data received from other sources

9 Fellows of the Massachusetts Medical Society as described in Section 2 of this code who are contacted directly by representatives of the press, magazines, radio or other media of communication and who are unwilling to conform to the requirements as laid down in Sections 4, 5, 6, 7 and 8 of this code must consider themselves responsible for the contents of said interviews regardless of their alleged accuracy or inaccuracy

10 Except as specified in Section 9 of this code Fellows of the Massachusetts Medical Society as described in Section 2 of this code, the use of whose name by the press, magazines, radio or other media of communication has not been specifically authorized in accordance with the provisions of Sections 4, 5, 6, 7 and 8 of this code shall after investigation by the proper authorities be held absolved of all blame for such authorized use regardless of the accuracy or inaccuracy of the article or interview in question

11 It is recommended that Fellows of the Massachusetts Medical Society who are forced to respond to inquiries from the press, magazines, radio or other media of communication without an opportunity to invoke the provisions listed in Sections 4, 5, 6, 7 and 8 of this code limit their reply to the single statement, "No Comment."

12 Violations of this Publicity Code by Fellows of the Massachusetts Medical Society shall be subject to review by the Committee on Ethics and Discipline of the Massachusetts Medical Society. The Committee on Ethics and Discipline may initiate action for this purpose or may take action in response to written complaints relative to infractions of this code provided the complaint is signed by the complainant. The decisions of the Committee on Ethics and Discipline shall be rendered in accordance with Chapter VII, Section 9 of the By-Laws of the Massachusetts Medical Society

B Your committee is strongly of the opinion that the scope of this code should be widened and its influence extended. To accomplish these ends it is desirable that governing Boards of Hospitals, hospital directors, authoritative representatives of the press, of the non-medical magazines, of the radio and of other similar media of public communication be informed of this desire as coming from the Massachusetts Medical Society as well as the Society's willingness to co-operate with these agencies to that end

Your committee therefore recommends that it be continued in existence for this purpose

C Your Committee further recommends that this code be included with the By-Laws and Code of Ethics presently in preparation for publication and distribution to the Fellows of the Massachusetts Medical Society

RALPH R. STRATTON, M.D.

JOHN F. CONLY, M.D.

CHARLES C. LUND, M.D.

LEROY A. SCHALL, M.D.

DONALD MUNRO, M.D., Chairman

APPENDIX NO 19

REPORT OF THE MEETING OF THE HOUSE OF DELEGATES OF AMERICAN MEDICAL ASSOCIATION

The attendance at the meeting of the American Medical Association in Atlantic City was the second largest of the 87 previous sessions. The technical and scientific exhibits were crowded all the time and the color television of actual operations performed by nationally known surgeons at the nearby Atlantic City Hospital evoked unusual interest.

The House of Delegates met on the morning of the 6th at the Travmore Hotel and continued in session until the 9th. There was the usual high percentage of attendance and considerable business was accomplished. Your delegates were all present and were given the following reference committee appointments

Dr. Alchittreck — chairman Emergency Medical Service
Dr. Phippen — member — Legislation and Public Relations
Dr. Rickham — member — Reports of Officers
Dr. Curley — Corps of Sergeant-at-Arms

Dr. Phippen also served on the committee to nominate candidates for the Distinguished Service Award and on the

rights of the physician as to the choice of methods by which he is to be paid shall be fully protected

(13) We agree that the federal Government may properly assist financially such medical schools as are found unable to meet their operative costs, upon their request for such assistance, *provided* that such assistance shall not be construed as authorizing any federal department, agency, officer or employee to exercise any supervision or control over the admission of students, curriculum, teaching personnel or administration of such medical schools, except such supervision as may be necessary to ensure that grants shall be expended solely for the purpose for which they are made

(We believe effective organizations of state and district health councils would immeasurably improve the community concept of local health needs. The initiative of the people themselves, and especially of the medical and public health personnel, must provide the spark.)

(14) The Massachusetts Medical Society looks upon these basic principles as essential to the development of any successful medical-care plan and, as guides by which to evaluate medical-care plans that may be proposed in the future, with the understanding that changing conditions may require their later revision

APPENDIX NO 15

The bulletin points out the importance of the Women's Auxiliary in the campaign, the need for personal contacts with congressmen. There is a list of the literature now available through the Society office

The bulletin ends by urging all to use the literature effectively and to keep the Society informed at frequent intervals concerning the progress of the campaign in the eighteen districts

FRANK H. LAHEY, M.D., *Chairman*

In further considering the method of collection, two points are important that the Red Cross method of voluntary free donation is still new and in a trial period that will probably have to go on for months or even several years before we can logically determine whether it will be a success or failure, and to be successful, it must have the full active support of the medical profession, any action short of which might cripple the program, which would be unfortunate as well as rendering us somewhat lame. We discussed a number of minor difficulties with the program, most of which we felt could be ironed out at the Red Cross advisory meetings, since any public recommendations made to correct them might contribute to shaking public confidence in the program as a whole. The essential difficulty of the Red Cross Program is an insufficient number of donors. When it can collect enough blood, most present problems will solve themselves.

The Committee recommends that the Society give both verbal and active assistance to ensure the success of the Red Cross State Blood Program, because its success will be a great boon to patients and to physicians alike.

It further recommends the following specific measures to assist the program:

That the editorial board of the *Journal* should from time to time write editorials expressing approval of the Red Cross program and explaining the purpose, its value to patients and to doctors and explaining what doctors can do locally to help—it should stress the following points: the value of blood and blood derivatives without payment for the product, the fact that hospitals and doctors will not lose money by banding this blood, since reasonable charges for laboratory work administration will continue as before, that local blood banks will be encouraged to exist and will probably flourish under this system, that the establishment of local storage depots by the Red Cross at strategic sites in the State has already begun and will probably be expanded that the supplying of blood by the Red Cross to the small hospitals where the use of blood is sporadic but vital has already been of great value and will be expanded, that all doctors should realize the value of the program to themselves and should take an active part in their local Red Cross program to ensure that collections be at a high level and distribution on the best possible basis for their needs, the whole success of the program resting on large collections (this they can do by joining the blood program committee of their local chapters, setting an example in their communities by their own, or family donation of blood to the Red Cross, serving as speakers for their Red Cross chapters, discussing with their local chapters, or the directors of the program, any problems that arise in their use of blood, informing their patients or their families when they have received blood or albumin or gamma globulin from the Red Cross and encouraging them to replace it, and setting up in co-operation with the Red Cross a program for distribution from one hospital to another in case of need).

That the Red Cross should expedite its collection of blood in the metropolitan area by establishment of a donor center in Boston.

That the Committee be authorized to write to hospitals and district medical societies to find out how the blood program is working locally and on the basis of its findings make recommendations to the Red Cross through the Red Cross Advisory Committee, several members of which serve on this committee.

That the Red Cross should extend its advertising and publicity campaigns to obtain a better response from the public.

That one of the really great problems in this state at present is the inadequate technical training of many of the persons responsible for grouping and cross matching—a problem beyond the scope of the activities of the Red Cross, but one that this committee should solve a sub-committee made up of Dr William Moloney and Dr F. H. Allen investigated the matter and on the basis of their studies this committee submits the following recommendations for the improvement of the situation that it should be brought to the attention of district medical societies and hospital directors by the Executive Committee of the Massachusetts Medical Society that the correct grouping and cross-matching of patients before

transfusion remains the legal responsibility of the doctor administering the blood and of the hospital in which the transfusion is given, that in some instances this is now being done by ill trained personnel, which can cause serious mistakes (according to a survey made by Dr McReady of the State Biological Laboratory there are a number of hospitals in which the grouping and cross-matching are done by untrained persons), that this can be remedied by training the persons conducting the grouping and cross-matching, that this training can be carried out at the State Blood Grouping Laboratory free of charge, and by the larger blood banks—the members of this committee who represent blood banks have expressed their willingness to do this—when the Red Cross blood laboratory is opened it will be able to participate in a training program and that current work on new and better techniques is so encouraging that we should wait another three to six months for their development before initiating such a training program.

APPENDIX NO 21

REPORT OF THE COMMITTEE ON BLUE CROSS-BLUE SHIELD PROBLEMS

A meeting of the Committee was held on July 29, 1949, at 8 Fenway. The Blue Shield program of payments for the care of ward cases in teaching hospitals was discussed. Representatives of the Massachusetts General Hospital, Children's Hospital and Massachusetts Eye and Ear Infirmary, Boston Floating Hospital and Blue Shield were present. The hospitals had been informed that payments had not been made to doctors caring for Blue Shield patients on the wards. The hospitals had replied that it was not the policy in their institution to consider ward patients as private patients and to place them in that category would injure the teaching program.

Blue Shield suggested that staff doctors form groups to receive Blue Shield fees and to disburse the money as they saw fit.* One hospital representative stated that the group in his hospital had employed the money collected for laboratory research, intern travel expenses, postgraduate education and so forth.

It was the opinion of the Committee that teaching facilities in these hospitals must be maintained, and that Blue Shield fees for the care of these patients when requested by a particular hospital staff be paid to doctors or a group of doctors and not to a hospital, and that when paid the monies may be used for any purposes decided by a vote of the doctors concerned.

The House of Delegates of the American Medical Association meeting at Atlantic City in June 1949, dissolved all formal relations existing between the American Medical Association and Associated Medical Care Plans, the national association of Blue Shield plans. In effect this action means that the Council on Medical Service of the American Medical Association will no longer be represented on the Blue Shield Commission, which is the governing board of A.M.C.P., and that the implied objection of the American Medical Association to the formation of a Blue Shield insurance company better to serve national accounts has been removed.

The Blue Shield Commission has already taken preliminary steps to establish a national insurance company and is only awaiting approval by a majority of plans before bringing

*The Council amended this report by deleting the lines beginning with the word "The" in the third sentence of the first paragraph and ending with the word "fit" in the second paragraph and substituting the following: "It was pointed out that until about a year ago Blue Shield made no payments for medical services rendered to ward service cases because it was the confirmed policy of the hospitals involved that staff physicians should not bill for such services. During 1948 this policy on the part of several teaching hospitals was altered to the extent that staff groups but not individual physicians were permitted to receive payments from third parties such as Blue Shield and commercial insurance companies for medical services rendered to service ward patients. Formal group arrangements were made at two hospitals and informal group arrangements were made at several other hospitals after which Blue Shield began making payment to these groups."

so-called Hess Committee on Practice of Medicine by Hospitals

The Distinguished Service Award was given to Dr Seal Harris, of Alabama, by vote of the House of Delegates

The highlight of the first morning session was the announcement by the chairman of the Board of Trustees of the curtailment of Dr Fishbein's activities. This is old news now, but as a matter of fact it did not occasion quite the stir that the newspapers would have you to believe. Nearly everyone expected something of the kind would happen. Every member of the House appreciates Dr Fishbein's ability and capacity for work and realizes what he has accomplished with the *Journal*. I think most of them felt very sorry but realized that it was a move in the best interests of all the members of the American Medical Association. He will actually retire when the reorganization of the editorial office has been accomplished and his successors trained for the jobs. (I believe there will be four)

The Committee on Emergency Medical Service reported that the status of the Surgeon General of the Army had been much improved. He now has supreme authority in the Army Medical Department reporting directly to the Chief of Staff and not through the Adjutant General's office as heretofore. It also announced the establishment of a Division of Medical Service in the office of the Secretary of Defense and that the first Director of Medical Services of the armed services had been appointed. This should bring about more co-operation between the Medical Corps of the Army, Navy and Air.

The House approved a resolution from the Section of Anesthesiology recommending the trustees to provide funds for a study of operating-room deaths.

The House adopted the recommendation of the Council on Medical Service as follows:

The formation of a national co-ordinating agency representing all qualified voluntary prepayment plans in accordance with the proposal made to the Board of Trustees by the Council on Medical Service, that there shall be no official connection between the American Medical Association and the Associated Medical Care Plans, however, the American Medical Association will continue to approve or disapprove all voluntary medical-care plans, the recognition of A M C P as a trade organization of member plans and Blue Cross as occupying a similar position for voluntary prepayment hospital care plans, the recognition of the responsibility of the American Medical Association to promote the principle of voluntary insurance by educating the people as to their need for such coverage and by obtaining full co-operation from state and county medical organizations in the local field and to inform the American people of the availability of approved plans that propose to supply on a prepayment basis security against the economic hazards of serious illness.

The House approved a report of the Council of Medical Service setting forth 20 principles as guides for approving lay-operated medical-care plans. This is a progressive step since there are already 171 lay-operated or consumer-sponsored plans in 43 states. There are now 95 sponsored by medical societies.

The House approved sponsorship of a national health conference to encourage discussion of the American Medical Association twelve-point program by farm, labor and other lay organizations.

A resolution was introduced aimed to limit the care of non-service-connected disability by the Veterans Administration, and to limit the hospital-building program of the Veterans Administration. This was reported favorably by the reference committee but was rejected by the House. It was later reconsidered and after considerable discussion was referred to the Board of Trustees for further consideration.

The House adopted a resolution creating a special committee composed of members of the Board of Trustees, House of Delegates and other fellows of the Association to arrange a conference with members of Congress with a view of developing legislation that would meet the objectives of the American Medical Association program in its effort to solve the problem of making medical care more readily accessible to the American people. This committee would work in co-operation with other existing committees and make its report from time to time to the Board of Trustees.

The Committee on Hospitals and the Practice of Medicine defined the corporate practice of medicine and gave a summary of the laws covering the practice of medicine in all states. It reiterated the fact that neither hospital nor doctor should be exploited at the expense of the other. It urged that all specialists should be regularly appointed members of the medical staff with a voice in its management. It concluded that most controversies should be settled at the local level and suggested that every component society appoint a committee on hospitals and professional relations.

The reference committee in recommending the adoption of this report further reminded the delegates that the Judicial Council had jurisdiction in such matters and might, if the evidence warranted, find either the hospital or lay group guilty of violating the Principles of Ethics and recommend that the Judicial Council withdraw the Association's approval of a hospital that did not comply.

The House approved the following resolution that the House of Delegates of the American Medical Association express its disapproval of the extension of so-called "social security" to self-employed persons, including physicians and surgeons. This resolution has now been mailed to all state secretaries, urging them to interest their members in opposing this legislation.

Much other business was transacted, and the House accomplished a good deal of work in a short time.

WALTER G. PHIPPEN, M.D.

APPENDIX NO 20

REPORT OF THE ADVISORY COMMITTEE FOR RED CROSS BLOOD BANK

On July 20, 1949, the Committee met to consider various problems in connection with blood collection and distribution. The entire committee was present except for Dr. Joseph Ross, who was unable to attend. Because we felt that the success of our work would depend on a very close relation with the Red Cross, and that no help that we might be able to give the Red Cross would be valuable unless they both understood and desired it, we invited Dr. William Freeman, of Fall River, the state medical director of the Red Cross program, to attend. He came to the meeting and gave us a considerable amount of help.

It was the feeling of the Committee that we should first decide whether we considered the Red Cross program to be valuable to both patients and the medical profession of the State. We discussed this matter at some length and came to the conclusion that it was indeed valuable. We have all served in an advisory capacity to the Red Cross—Dr. Brown in Northampton, and the rest of us in the metropolitan area. We have therefore been cognizant of the fact that the present program of blood collection and distribution was more or less forced upon the Red Cross in March, 1948, when funds were no longer forthcoming from the State for the maintenance of the blood program. This has meant, of course, that the support of the medical profession has been vital for the Red Cross to carry on with the program, which, although still in its infancy and small, was already valuable.

The fundamental purpose behind the National Red Cross Blood Program has been twofold—namely, the setting up of a program, which, in the event of local or nation-wide catastrophe, would be able to supply blood throughout the country, and, at the same time, to make blood available to all who need it in hospitals everywhere without charge for the product. Whether or not the Red Cross is the logical agency for setting up a nation-wide program we did not feel to be a matter for our consideration, since such a program has already been set up at the instigation of and with the sanction of the federal Government.

Blood for all, without the necessity for establishing credit or making repayment, is extremely worthy on an idealistic basis. All of us, however, have had considerable experience with the collection of blood in our own hospitals. Some of us are not thoroughly convinced that a sufficiently high level of public enthusiasm can be permanently maintained in the absence of a national catastrophe to ensure a steady supply of the amount of blood necessary to meet hospital needs.

In further considering the method of collection, two points are important that the Red Cross method of voluntary free donation is still new and in a trial period that will probably have to go on for months or even several years before we can logically determine whether it will be a success or failure, and to be successful, it must have the full active support of the medical profession, any action short of which might cripple the program, which would be unfortunate, as well as rendering us somewhat to blame. We discussed a number of minor difficulties with the program, most of which we felt could be ironed out at the Red Cross advisory meetings, since any public recommendations made to correct them might contribute to shaking public confidence in the program as a whole. The essential difficulty of the Red Cross Program is an insufficient number of donors. When it can collect enough blood, most present problems will solve themselves.

The Committee recommends that the Society give both verbal and active assistance to ensure the success of the Red Cross State Blood Program, because its success will be a great boon to patients and to physicians alike.

It further recommends the following specific measures to assist the program

That the editorial board of the *Journal* should from time to time write editorials expressing approval of the Red Cross program and explaining the purpose, its value to patients and to doctors, and explaining what doctors can do locally to help—it should stress the following points: the value of blood and blood derivatives without payment for the product, the fact that hospitals and doctors will not lose money by handling this blood, since reasonable charges for laboratory work administration will continue as before that local blood banks will be encouraged to exist and will probably flourish under this system that the establishment of local storage depots by the Red Cross at strategic sites in the State has already begun and will probably be expanded that the supplying of blood by the Red Cross to the small hospitals where the use of blood is sporadic but vital has already been of great value and will be expanded, that all doctors should realize the value of the program to themselves and should take an active part in their local Red Cross program to ensure that collections be at a high level and distribution on the best possible basis for their needs, the whole success of the program resting on large collections (this they can do by joining the blood program committee of their local chapters, setting an example in their communities by their own, or family donation of blood to the Red Cross, serving as speakers for their Red Cross chapters, discussing with their local chapters or the directors of the program, any problems that arise in their use of blood informing their patients or their families when they have received blood or albumin or gamma globulin from the Red Cross and encouraging them to replace it, and setting up in co-operation with the Red Cross a program for distribution from one hospital to another in case of need).

That the Red Cross should expedite its collection of blood in the metropolitan area by establishment of a donor center in Boston.

That the Committee be authorized to write to hospitals and district medical societies to find out how the blood program is working locally and on the basis of its findings make recommendations to the Red Cross through the Red Cross Advisory Committee, several members of which serve on this committee.

That the Red Cross should extend its advertising and publicity campaigns to obtain a better response from the public.

That one of the really great problems in this state at present is the inadequate technical training of many of the persons responsible for grouping and cross matching—a problem beyond the scope of the activities of the Red Cross, but one that this committee should solve a sub-committee made up of Dr William Moloney and Dr F. H. Allen investigated the matter and on the basis of their studies this committee submits the following recommendations for the improvement of the situation that it should be brought to the attention of district medical societies and hospital directors by the Executive Committee of the Massachusetts Medical Society that the correct grouping and cross-matching of patients before

transfusion remains the legal responsibility of the doctor administering the blood and of the hospital in which the transfusion is given, that in some instances this is now being done by ill trained personnel, which can cause serious mistakes (according to a survey made by Dr McReady of the State Biological Laboratory there are a number of hospitals in which the grouping and cross-matching are done by untrained persons), that this can be remedied by training the persons conducting the grouping and cross-matching, that this training can be carried out at the State Blood Grouping Laboratory free of charge, and by the larger blood banks—the members of this committee who represent blood banks have expressed their willingness to do this—when the Red Cross blood laboratory is opened it will be able to participate in a training program and that current work on new and better technics is so encouraging that we should wait another three to six months for their development before initiating such a training program.

APPENDIX NO 21

REPORT OF THE COMMITTEE ON BLUE CROSS-BLUE SHIELD PROBLEMS

A meeting of the Committee was held on July 29, 1949, at 8 Fenway. The Blue Shield program of payments for the care of ward cases in teaching hospitals was discussed. Representatives of the Massachusetts General Hospital, Childrens' Hospital and Massachusetts Eye and Ear Infirmary, Boston Floating Hospital and Blue Shield were present. The hospitals had been informed that payments had not been made to doctors caring for Blue Shield patients on the wards. The hospitals had replied that it was not the policy in their institution to consider ward patients as private patients and to place them in that category would injure the teaching program.

Blue Shield suggested that staff doctors form groups to receive Blue Shield fees and to disburse the money as they saw fit.* One hospital representative stated that the group in his hospital had employed the money collected for laboratory research, intern travel expenses, postgraduate education and so forth.

It was the opinion of the Committee that teaching facilities in these hospitals must be maintained, and that Blue Shield fees for the care of these patients when requested by a particular hospital staff be paid to doctors or a group of doctors and not to a hospital, and that when paid the monies may be used for any purposes decided by a vote of the doctors concerned.

The House of Delegates of the American Medical Association meeting at Atlantic City in June, 1949, dissolved all formal relations existing between the American Medical Association and Associated Medical Care Plans, the national association of Blue Shield plans. In effect this action means that the Council on Medical Service of the American Medical Association will no longer be represented on the Blue Shield Commission, which is the governing board of A M C P, and that the implied objection of the American Medical Association to the formation of a Blue Shield insurance company better to serve national accounts has been removed.

The Blue Shield Commission has already taken preliminary steps to establish a national insurance company and is only awaiting approval by a majority of plans before bringing

*The Council amended this report by deleting the lines beginning with the word "The" in the third sentence of the first paragraph and ending with the word "fit" in the second paragraph and substituting the following: "It was pointed out that until about a year ago Blue Shield made no payments for medical services rendered to ward service cases because it was the confirmed policy of the hospitals involved that staff physicians should not bill for such services. During 1948 this policy on the part of several teaching hospitals was altered to the extent that staff groups, but not individual physicians, were permitted to receive payments from third parties, such as Blue Shield and commercial insurance companies for medical services rendered to service ward patients. Formal group arrangements were made at two hospitals and informal group arrangements were made at several other hospitals after which Blue Shield began making payment to these groups."

the matter to a conclusion. The Board of Directors of Massachusetts Medical Service has voted its approval. The Blue Cross national insurance company is well on its way to completion. Sufficient capital funds have been raised and assurance of favorable action by the Illinois Commissioner of Insurance has been received.

The recent expansion (September 1, 1949) of the Blue Shield program to include nongroup enrollment was a significant step in the right direction. A previous effort in this regard, undertaken in June, 1947, was nullified by concurrent difficulties in which Blue Cross found itself.

Revision of the Blue Shield subscriber certificate (effective September 1, 1949) should go a long way toward clarifying administrative details. The provision that a member who uses private accommodations when such accommodations are not medically necessary is automatically classed as over-income will require judicious application by the medical profession.

Much dissatisfaction is reported by physicians with the restrictions and limitations on "existing" and congenital conditions in the Blue Cross subscriber contract. It also appears that patients are being forced to accept ward service because they are unable to pay the difference between the board and room rate at the hospital and the \$7.00 credit allowed by Blue Cross. This is also true of the differential between the \$70.00 provided by Blue Cross for maternity care and the hospitals' charges for this service. It is anticipated that the Society representatives on the Blue Cross Board of Directors will give these matters their serious attention.

Many requests that they be permitted to enroll themselves and their families in Blue Shield are being received from physicians. *It is recommended that this matter again be referred to the appropriate committee for consideration.*

PAUL M. BUTTERFIELD, M.D.
JOHN FALLON, M.D.
HARVEY A. KELLY, M.D.
JOSEPH C. MERRIAM, M.D.
CHARLES J. E. KICKHAM, M.D.

APPENDIX NO. 22

REPORT OF THE ADVISORY COMMITTEE TO THE WOMAN'S AUXILIARY

The Committee is happy to report that 12 of the 18 district auxiliaries are now organized and that over 1000 ladies are now active members.

The Auxiliary has already more than fulfilled the high hopes that were held for it. The ladies have shown excellent

interest and have participated capably and enthusiastically in furthering the efforts of the Society.

Much has been accomplished on the suggested sixteen point program for the Auxiliary outlined by the Committee in October, 1948, and presented to the Council at its February meeting.

Additional fields of activity have been reviewed and are offered to the Auxiliary for consideration and such action as may be indicated.

Continued efforts toward maximum enrollment in numbers of district auxiliaries and in individual memberships.

Co-operation with the phase of the National Education Campaign of the American Medical Association that pertains to the Auxiliary. Such activities may well include the training of speakers and arranging for their appearance before various women's groups, passage of appropriate resolutions by each of the district auxiliaries opposing the Administration's compulsory national tax sickness program, arranging for framing of colored reproduction of Sir Luke Fildes' picture "The Doctor" for display in physicians' offices, and distribution of national education campaign literature.

Sponsorship of "Career Days" in high schools throughout the state. Contact with school committees and school superintendents and principals should urge the value of presentation of the background of various trades and professions to high-school students about to seek employment or who intend to continue their education. Such programs indirectly aid the medical, nursing and other health professions by attracting the most competent and suitable candidates.

Co-operation with Medical and Surgical Relief Committee, Incorporated, in the collection of medical and surgical supplies for overseas hospitals and institutions that give free medical aid to the needy.

The Committee wishes to congratulate the officers and members of the Auxiliary for the excellent results they have accomplished. Under the presidency of Mrs. Leighton F. Johnson of Norfolk much progress was made in the first year. The annual meeting of the Auxiliary in Worcester in May was a distinct success.

To Mrs. Charles E. Ayers, of Worcester, and to her fellow officers for 1949-50 we wish every success in the continued growth and development of this valuable adjunct to the Society. The continued enthusiasm and active co-operation of the Auxiliary members are urgently needed.

BENJAMIN CASTLEMAN, M.D. *Associate Editor*

EDITH E. PARRIS, *Assistant Editor*

CASE 35491

PRESENTATION OF CASE

A fifty-nine-year-old retired insurance salesman was brought to the hospital in a state of confusion and disorientation.

He had always been well until five months before admission, when on waking one morning, he was found to be confused and unable to recognize his wife. He had a thick, slurred speech and shortly afterward, during examination by a physician, he suddenly had a convulsive seizure. This began with a turning of the eyes upward and, it was thought, to the left and a drawing up of the left corner of the mouth, followed by clonic movements of both arms and legs, lasting two or three minutes. Three similar convulsions occurred in rapid succession. There was no incontinence and no biting of the tongue. After fourteen hours of unconsciousness the patient improved and was left with some thickening of speech and weakness of the extremities. He recalled a "snapping" feeling in the left frontal region the night before the onset of symptoms. There had been no headache. A month later he seemed to be in "perfect health." One month before admission he was again confused for a few minutes. During the next week he became "weaker" and complained of a sharp constant pain across the low lumbar region, which increased on coughing or sitting down but felt better on walking or lying. Ten days before admission, there was progressive weakness of the legs and eventually inability to walk. No numbness or paresthesia had been observed. He developed increasing constipation and a feeling of urgency and difficulty in voiding. Six days before admission his speech again became thick, and at times he was irrational. He developed a "rapid clonic tremor" of both hands and twisted and pulled at the bedclothes. He occasionally complained of diplopia, of pains and headache in the

right frontal region and "tingling" in the nose. Two days before admission he changed markedly for the worse, becoming excitable, voluble and completely confused. He had lost 15 pounds in the previous four months.

The past history was irrelevant except for occasional frontal headaches and a morning cough for the past five or six years. Recently he had taken one "phenobarb" and one or two "bromides" a day. Previous to his illness, nothing abnormal had been found at bi-annual insurance examinations.

Physical examination revealed a confused, disoriented, slightly euphoric man in no acute discomfort. There was incontinence of urine. A scaling erythematous eruption was seen over the face, chest and arms. There was a purulent nasal discharge, and the tongue was red and smooth. The heart sounds were slapping and of poor quality. The lungs and abdomen were normal. The neck and spine were rigid. There was well localized tenderness and bilaterally radiating pain on pressure over about the seventh thoracic vertebra. Midthoracic pain was also brought on by coughing. The cranial nerves were normal. Speech was slurred, rapid and indistinct, with some groping for words. There was slight weakness in the arms and scarcely any strength in the legs. The weakness was more marked on the right side. Pain sensibility was diminished over the legs and lower abdomen, but a definite level could not be made out. Vibration was felt over the malleoli. The tendon reflexes were difficult to obtain or were absent, and the findings of the different examiners did not agree in all respects. There was no agreement about the comparative activity of the arm jerks. Knee jerks were thought to be more active on the left. The ankle jerks, the abdominal reflexes and the plantar reflexes were absent, and on one occasion there was an equivocal extension reflex on the left. The pupils were equal and reacted normally on admission, but later the left was somewhat larger than the right. There was slight blurring of the nasal margins of the optic disks, thought to be not definitely abnormal. Confrontation fields were normal.

The temperature was 99.6°F, the pulse 85, and the respirations 84. The blood pressure was 140 systolic, 90 diastolic.

The red-cell count was 4,300,000, and the white-cell count 1500, with 78 per cent neutrophils. The bromide was 6.6 milliequiv, and the chloride 103.0 milliequiv per liter. The acid phosphatase was 1.9 units. A blood Hinton test was negative. The urine was normal. An electroencephalogram was diffusely abnormal. The initial spinal-fluid pressure was equivalent to 98 mm of water, with normal dynamics. The fluid was xanthochromic, clotted rapidly and contained 2 lymphocytes and 140 red cells per cubic millimeter. The total protein was 282 mg, the sugar 61 mg, and the chloride 641 mg.

per 100 cc The gold-sol curve was 0145555555 The Wassermann reaction was negative

X-ray films of the skull showed slight displacement of the pineal shadow toward the right A chest film was normal, except for minor degenerative changes in the spine

Six days after the lumbar puncture, combined cistern and lumbar punctures gave the following results cistern, initial pressure 210, jugular compression 350, release 250, xanthochromia +, lymphocytes 1, and protein 192 mg, lumbar, initial pressure 210, jugular compression 350, release 250, xanthochromia ++, lymphocytes 5, and protein 402 mg

The patient's course in the hospital was steadily downhill Four days after admission the temperature rose to 101.5°F, and rales appeared in the right axilla Penicillin and sulfadiazine were of no avail Voiding became progressively more difficult, and a Foley catheter was inserted On the eighth hospital day a skull trephination was performed Three days later another chest x-ray film showed patchy areas of increased density over both lower-lung fields The patient became flushed, dyspneic and lapsed into deep coma He died on the fourteenth hospital day

DIFFERENTIAL DIAGNOSIS

DR ROBERT SCHWAB* The left-sided seizure began with twitching on the left side of the face, which was said to have been observed by a local physician It might have been an error in observation It is difficult in a case of early seizure to be sure whether it involved the left or right side The left-sided seizure does not fit in with the neurologic findings It would seem from the original examination that this convulsion would if anything be a right-sided affair with aphasia Dr Cole assures me that I have a four-to-one chance that this patient was right-handed and therefore that the lesion was in the left frontal area That is where he had the snapping sensation, and the right side was weak It is much more reasonable to suppose that the original seizure began on the right side of the face and became generalized

The spinal-fluid findings and the laboratory findings are worth consideration at this point I should like to ask Dr Kubik about this because it is an important point in the differential diagnosis Is this a red herring or a misprint that there was a white-cell count of 1500?

DR CHARLES S KUBIK The white-cell count was 15,000

DR SCHWAB We have a striking abnormality in the spinal fluid in that the protein was increased to 282 mg per 100 cc On the first examination the pressure was said to be normal, and the fluid clotted rapidly, with normal sugar and no increase in cells, except a few red cells, which may have been the re-

sult of trauma The chlorides were down slightly, and I believe that could be explained by the increase in protein The normal sugar is evidence against infection in the meninges The gold-sol curve is a meningitic one, which is found in marked increase in albumin content as opposed to globulin The blood Hinton and spinal-fluid Wassermann reactions were negative

The second factor we will discuss along with the first one is the combined puncture in the lumbar and cisternal regions The marked increase in protein in the lumbar space over the cistern indicates a slight chemical block, but there was no evidence of dynamic block Again, no evidence of infection was noted, as indicated by the absence of white cells in the fluid The neurologic findings were absent knee jerks, slight weakness of the right side and slight papilledema, which is a further check of the protein of 282 mg per 100 cc During the second puncture, he complained of diplopia, and the x-ray films showed the pineal body shifted to the right

DR REGINALD LINGLEY As far as I can see, the films show only a displacement of the pineal body toward the right side There is no evidence of chronic pressure, and the sella turcica is normal

DR SCHWAB This is a very important sign, particularly with a good anteroposterior film such as this, and it indicates a space-occupying lesion in the left side of the cranium that would be consistent with right-sided weakness, the onset of convulsions on the right side, and the complaint of headache in the left frontal region We must not forget that this patient complained for some time (five months or so) of loss of weight, increasing constipation and pain in the back Also, at entry he had tenderness in the back in the same area That is impossible to correlate with a single lesion in the left frontal region So it seems to me that we have to start out by supposing we have two lesions a lesion in the spinal canal of some sort and a lesion in the left frontal area, perhaps of the same nature The most obvious etiology of the two lesions or multiple lesions is neoplasm I was seriously led by what I thought was a leukopenia to the consideration of a blood-cell tumor such as leukemia Hodgkin's disease sometimes invades the nervous system, causing lesions, so that the patient complains of central-nervous-system symptoms rather than generalized ones, and at autopsy one may find evidence of leukemia or Hodgkin's disease infiltrating the meninges But with the leukopenia removed, I am not so certain that that consideration is tenable A white-cell count of 15,000 would be reasonable for anyone admitted with chronic cough and some loss of weight One would suppose that there was involvement of the meninges around the spinal cord, giving a loss of ankle jerks, weakness of the legs and tenderness in the spine The other lesion in the frontal area, causing the original epileptic seizure

*Associate neurologist, Massachusetts General Hospital

and the stupor, could possibly produce intracranial pressure

Again coming to the consideration of the most plausible causes for lesions in two places, the commonest are tumors of the brain that are metastatic. Lung tumors have a high incidence of brain and spinal-cord involvement. This man had both loss of weight and chronic cough preceding entry. The presence of a smooth, red tongue and chronic infection might go with any debilitating illness and fit in with a carcinomatous condition if that were causing the two lesions of the central nervous system. I do not believe it likely at his age that he had multiple hemangiomas, they could cause a high spinal-fluid protein and could occur in more than one place. My first bet would be that it was a metastatic tumor, and my second one, a primary intracranial neoplasm that had spread directly down the spinal cord, down the meninges or with its own metastases. The third possibility is a blood-forming tumor such as leukemia or Hodgkin's disease, but we have no evidence for such a lesion. The condition was rapidly growing, in a man who was in reasonably good health three months before he came to the hospital. Before death he failed to respond to trephination and other exploratory measures in the hospital. My impression is that he had metastatic cancer in the brain and spinal cord.

DR AUGUSTUS S. ROSE: What is the explanation for the stiff neck?

DR SCHWAB: Involvement of the meninges in the spinal canal with neoplasm.

DR JAMES C. WHITE: One type of tumor in a man of this age that would give these symptoms is medulloblastoma.

CLINICAL DIAGNOSIS

Encephalitis?

Bronchopneumonia

DR SCHWAB'S DIAGNOSIS

Metastatic tumor in brain, left frontal region, and in spinal cord

ANATOMICAL DIAGNOSES

Glioblastoma multiforme of left temporal lobe, with metastases to spinal cord and spinal nerves

Bronchopneumonia

PATHOLOGICAL DISCUSSION

DR KUBIK: I believe that Dr Schwab's diagnosis is by far the most logical one. Multiple tumors of the central nervous system usually mean metastases, symptoms of which not infrequently appear before any prominent symptoms of a primary tumor have been noted. That is particularly true of bronchiogenic carcinoma.

This, however, was not carcinoma but another condition, which Dr Schwab also mentioned as a possibility — that is, a glioma with "metastases"

or implantations, which were disseminated through the subarachnoid space. Although this is not too uncommon in cerebellar medulloblastoma, it occurs quite infrequently with glioma of the cerebral hemispheres and is almost never diagnosed except when it is discovered at post-mortem examination.

The primary tumor, measuring approximately 6 cm in diameter, was situated in the left temporal lobe (Fig 1) below the Sylvian fissure, which was displaced upward. It invaded the inferior part of the lenticular nucleus, and, in the region of the hippocampus, it extended to the medial surface of the temporal lobe, where it broke through the pia and

FIGURE 1 *Glioblastoma Multiforme, Left Temporal Lobe*

invaded the subarachnoid space. It was from here, presumably, that tumor cells floated through the spinal fluid to seed themselves in distant parts of the subarachnoid space.

There was one, measuring approximately 1 cm in diameter, on the dorsal surface of the spinal cord in the midthoracic region, and another, 1.3 by 0.8 by 0.2 cm, on the ventral surface in the upper lumbar region (Fig 2). These were the largest nodules; there were a number of smaller ones, including several on the roots of the cauda equina (Fig 2).

The tumor invaded the left third cranial nerve, thus explaining the enlargement of the left pupil.

There were two nodules, the larger one measuring 0.8 cm in diameter, on the surface of the right cerebellar hemisphere, and several on the spinal cord and spinal nerves.

There were no metastases to any other organs.

The primary tumor and implanted nodules were indistinguishable from each other in histologic appearance. Both were composed largely of slender

and plump fusiform cells with slender, elongated and broader, oval nuclei, which varied considerably in size. There were many multinucleated forms, a fair number of mitoses and numerous foci of necrosis. Connective-tissue and reticular stains revealed no stroma outside the blood vessels. The nodules

FIGURE 2 Metastatic Nodules on the Spinal Cord and Spinal Nerves

invaded the underlying spinal cord and adjacent spinal nerves and arachnoid membrane. In some places there was diffuse infiltration of the subarachnoid space by tumor cells without nodule formation.

The tumor was clearly a glioma, which I should classify as glioblastoma multiforme.

CASE 35492

PRESENTATION OF CASE

A fifty-nine-year-old man was admitted to the hospital complaining of repeated hematemesis during the preceding twenty-four hours.

About five years before admission the patient began to have two-day to three-day periods of "indigestion" characterized by sharp epigastric pain, bloating and sour eructations coming on two or three hours after a meal, relieved by soda but not by food. The day before admission he noted the sudden onset of warmth, sweating and weakness, and he vomited about a liter of dark blood and clots without any pain or nausea. He was given a hypodermic injection by a physician and remained in bed for the rest of the day without any further symptoms. On the day of admission at about 4:45 a.m., he was awakened with a second hematemesis and shortly afterward passed a large, tarry stool. At 6:00 a.m. and again at 9:00 a.m. he also vomited blood, and arrived at the hospital in moderate shock.

The past and family histories were noncontributory.

Physical examination showed a well developed, moderately well nourished man. The skin was pale, cold and clammy. The abdomen was soft, with an ill defined, nontender mass, 6 by 8 cm., in the right upper quadrant.

The temperature was 100.6°F, the pulse 94, and the respirations 22. The blood pressure was 88 systolic, 68 diastolic.

The urine was normal. The hemoglobin was 8.5 gm per 100 cc. The prothrombin time was 57 per cent of normal. The nonprotein nitrogen was 78 mg., and the total protein 5.2 gm per 100 cc. A limited gastrointestinal series on the third hospital day showed no evidence of esophageal varices or tumor, but revealed widened gastric folds, an inconstant duodenal deformity and a questionable crater.

The patient received 2500 cc of blood on the first hospital day, with a rise in hemoglobin to 11.5 gm. Transfusions of 500 cc per day were continued, but he remained weak and hypotensive. Therefore, on the sixth hospital day, after preparation with Hykinone and further transfusion, a subtotal gastrectomy was performed. Pathological examination of the specimen showed only mild chronic gastritis. The patient did well until the second postoperative day, when he began to vomit small amounts of blood, and blood was noted in the gastric drainage tube. This persisted until the sixth postoperative day, when there was massive hematemesis of 2400 cc with resultant hypotension and incipient shock. Following this he was re-explored.

DIFFERENTIAL DIAGNOSIS

DR. PERRY CULVER* We are presented here with the problem of the differential diagnosis of upper-gastrointestinal-tract hemorrhage that was sufficient to put a man into shock. The age is that of a person who could have cancer, ulcer, gastritis,

*Assistant in medicine, Massachusetts General Hospital

varices or anything else, so I do not think the age is going to help to any extent.

The five-year story of indigestion is a vague one. This symptom could have been due to ulcer, and the epigastric pain would also be in keeping with such a diagnosis. Ulcer would also explain the bleeding and sour eructations. It is unusual for food not to relieve ulcer pain but it does not always do so in every case. I think that fact is of importance in this case, however. The nebulous diagnosis of gastritis is one that continually pops up in a situation like this. There is a great deal of argument about whether gastritis may cause symptoms. Enthusiasm for this diagnosis waxes and wanes. At times people have had the impression that symptoms of gastritis were not due to gastritis but to some underlying condition. On the other hand, we have seen cases of gastritis sufficiently severe to cause profuse bleeding without any symptoms whatsoever. The textbooks will tell one that the symptoms of gastritis are those of peptic ulcer except that food does not relieve gastritis. If one wishes to accept textbook experience, gastritis fits this case perfectly — ulcer pain not relieved by food. That is a rather weak nail to hang one's hat on, but I mention it in passing.

It is of interest to speculate upon what part of the symptoms may be attributed to a nervous stomach, but it is unusual for nervous-stomach symptoms, whatever they are to appear at this age. They occur usually in much younger persons. I think this patient had an organic disease. A nervous stomach does not cause hemorrhage. It is a little unusual for cancer of the stomach to bleed so massively, and the history of a five-year period of indigestion would make me less likely to favor cancer.

These are the main diseases that I can think of that might cause both symptoms of this nature and hemorrhage. I will take up other causes of hemorrhage when we come to the x-ray studies.

The history, subsequently, was that of massive hemorrhage with shock. No further comment is needed on that. I would like to know one thing about the past history — that is whether there was any history of alcohol intake.

DR TRACY B. MALLORY: I remember seeing a statement that the patient was a moderate drinker.

DR CULVER: That can mean anything.

The physical examination as we might expect in most of these conditions, with the exception of cancer, is of little help. Certainly, ulcer and gastritis cannot be diagnosed on the basis of physical examination. I am very much puzzled about the mass described here. It was 6 by 8 cm. in the right upper quadrant. Does it have anything to do with the diagnosis? Is it a clue, or is it a bit of information that has nothing to do with the case and is a red herring. For the time being, I am going to disregard that mass.

DR MALLORY: Perhaps Dr. Donaldson would be able to give some information about that.

DR GORDON A. DONALDSON: The finding is more prominent in the history than it actually was.

DR CULVER: I was going to ask whether the X-ray Department could see it.

DR DONALDSON: I never felt it. It was a rather vague, indefinite mass.

DR CULVER: I will dismiss it as of no consequence. The laboratory tests were those of marked blood loss, as one would expect. The prothrombin time of 57 per cent was not in the range that is usually considered low enough for bleeding, a prothrombin time of about 20 per cent is the critical level. A prothrombin time below this level is often a factor in prolonged bleeding. We do not have information suggestive of other blood dyscrasias or of disturbances in the clotting or bleeding mechanism. I am inclined to think that such conditions are not involved in this case. A prothrombin level of 57 per cent may indicate that the diet is not quite adequate in vitamin K or that the liver lacks the power to manufacture prothrombin. Have we anything to indicate what the prothrombin time was after Hylanone administration? Is there more information about studies of liver function? They are more of academic interest and do not contribute to the differential diagnosis. The nonprotein nitrogen of 78 mg. per 100 cc. with an apparently normal kidney function leads me to believe that this azotemia was not due to renal failure, and that uremia was not playing a role in the cause of bleeding. The elevated nonprotein nitrogen was due probably to dehydration plus blood in the bowel. In this case, we have to depend upon the x-ray films, possibly gastroscopy, and, finally, an exploratory laparotomy. Review of the x-ray films is the next obvious move.

DR STANLEY M. WYMAN: All the films we have were taken on the original examination. They are spot films. The patient was very sick, and we were not able to keep him in the department long enough to take conventional large films. The esophagus, however, is well seen and appears normal. There is a definite suggestion of a hiatus hernia on at least one spot film. The stomach itself is not entirely visualized, but on these two films the gastric folds are seen to be more prominent than usual in a diffuse manner.

DR CULVER: Would you want to say that widening of gastric folds is consistent with the diagnosis of chronic hypertrophic gastritis? Is the widening marked enough for that?

DR WYMAN: I do not believe we can make that diagnosis with any degree of certainty. We have seen the same picture in a patient with atrophic gastritis proved by gastroscopy. The mucosa was parchment thin, and yet the picture was identical with this. This is what one sees with hypertrophic gastritis, but I do not believe such a diagnosis

can be made with certainty. The duodenal cap is only partially visualized, and I can make no definite statement about it. I do not see a crater. All in all, the examination is very incomplete of necessity. I think it leaves many questions completely unanswered.

DR CULVER: I think it helps in ruling out esophageal varices. It helps us to eliminate cancer of the stomach and gastric ulcer. Would you agree to that?

DR WYMAN: And it reveals the hiatus hernia.

DR CULVER: Yes, that is an important bit of information and one that I should have considered in the differential diagnosis of things that might cause symptoms in the epigastrium. There is no mention that lying down made the symptoms of indigestion worse than sitting up.

From the x-ray films I think we are still in the dark about the cause. We obviously could not rule out ulcer completely by gastroscopy because the patient was too ill for such a procedure.

I take it that the third form of further diagnostic measure was necessitated as an emergency procedure. At exploration, if I may project myself into the mind of the surgeon, he may or may not have found a scarred duodenal cap. I suspect that he did not, and considered that there was hemorrhage from the stomach. I do not know what he saw when he opened the stomach, but perhaps he found a diffusely inflamed stomach with no definite bleeding point but with a generalized ooze consistent with the type of bleeding seen in gastritis. The usual treatment for gastritis that causes massive bleeding, and these patients can bleed massively, is a subtotal gastrectomy.

The possibility of some obscure cause of bleeding has to be considered here. One thing may be gastric varices. There is nothing to help make that diagnosis. Gastric varices can occasionally occur without esophageal varices. Another rarity is telangiectasia involving the stomach, with bleeding from a telangiectasis. This man was too old. There was no history and no suggestion of telangiectasis on physical examination. We can forget that.

We can come back again to gastritis or ulcer. There is the possibility of bleeding gastritis in the hiatus hernia, and sometimes hiatus hernia can become strangulated. The resulting congestion causes it to bleed. The patient had an operation, and then he started to ooze on the second postoperative day and continued to ooze. That makes me think, more and more, that the lesion was probably in the remaining portion of the stomach as well as in that portion of the stomach resected. Was this continued bleeding arterial in type? Arterial bleeding, such as that from a bleeding ulcer, should be massive, and it ceases as the artery contracts. In this case the continuous bleeding makes me suspect the capillary type, which would be consistent with gastritis in the remnant of stomach,

possibly in a portion of stomach caught in the hiatus hernia.

There is one other possibility, and I am sure it entered the surgeon's mind on the sixth postoperative day when the patient had a massive hematemesis. It is the possibility of a suture sloughing off an artery with a hemorrhage from that source. It is something to be considered, and I suppose the surgeon might want to look for that.

Finally, if there were an ulcer and a subtotal gastrectomy did not include the ulcer, I suppose there could be further oozing and massive hemorrhage from that source. Such a possibility seems unlikely, or the surgeon would have done something other than a subtotal gastrectomy for this ulcer when the patient was bleeding.

The most likely diagnosis is hemorrhage from gastritis in the gastric remnant. I doubt if the mass described in the protocol was ever found.

DR DANIEL S. ELLIS: Do we know what was found at the time of the first operation?

DR DONALDSON: This patient was on the wards for about ten days and called forth a tremendous amount of effort on the part of the House Staff. He was given twenty-five or thirty transfusions. The excuse for not having more adequate laboratory studies was that at each turn our hand was forced because of the bleeding. The first gastrointestinal series was done on a Sunday morning in an attempt to find a bleeding point. Our diagnosis before the first operation was gastritis. Gastritis causes about 5 per cent of massive hemorrhage in this hospital. We were also worried about the definite hiatus hernia and the questionable duodenal defect as shown in the x-ray picture.

At the time of operation there was a great deal of old blood in the small bowel. The duodenum did have a scar on the anterior wall just beyond the pylorus. The stomach, itself, was somewhat thickened. There was a definite hiatus hernia. With these findings we thought that our preoperative diagnosis was probably still right. We went ahead and did a subtotal gastrectomy. At the time the upper segment of stomach was explored, the clamp was removed, and with retractors in place we were able to look and feel around inside. The mucosa was thickened, and the rugae were coarse. We could find no bleeding point. No blood was found in the segment at that time, and we still thought that we were dealing with gastritis — and so completed the operation.

One unusual fact that was noted by the men at the table was that the arteries were unusually arteriosclerotic — the gastroduodenal particularly. The second operation was forced on us by the subsequent massive hemorrhage.

DR ELLIS: Did you resect the scar?

DR DONALDSON: Yes, it was just beyond the pylorus on the anterior wall and was resected. When the subsequent massive hemorrhage occurred,

the patient was in such straits from blood loss that we attempted to control the bleeding by placing a balloon in the stomach segment and by applying traction on the end of the tube as it escaped from his nose. We thought we had stopped the hemorrhage long enough to allow us to operate on him. This led us to believe that the bleeding came from the hiatus hernia or nearby, certainly. He was taken to the operating room in this condition, and exploration was carried out through the chest. There were no varices on the gastric wall, and again the arteries were noted to be unusually sclerotic — the left gastroepiploic and the left gastric itself. We did not open the stomach, but went ahead and took out the remnant and anastomosed the esophagus to the jejunum, taking down our previous resection.

DR MALLORY Have you any further opinion Dr Culver?

DR CULVER I think it still has to be gastritis but I am probably wrong.

DR ELLIS Would you consider the possibility of stomal ulcer in six days?

DR CULVER It was too soon for a stomal ulcer, which usually develops in four or five weeks. With the history of arteriosclerosis as striking as Dr Donaldson suggests, I am more inclined to think of the possibility of a ligature eroding through a blood vessel and causing bleeding.

DR DONALDSON That is a good possibility and we considered it. The fact that the balloon stopped the bleeding made us feel better about it.

DR CULVER I still think it was gastritis.

CLINICAL DIAGNOSES

Gastric hemorrhage from arteriosclerotic vessel
Subtotal gastrectomy
Resection of gastric remnant

DR CULVER'S DIAGNOSES

Gastritis
Gastric artery eroded by ligature

ANATOMICAL DIAGNOSIS

Cirroid aneurysm of branch of left gastroepiploic artery, with rupture and massive hemorrhage

PATHOLOGICAL DISCUSSION

DR MALLORY In the second resected specimen we found a very definite bleeding point (Fig 1)

The first specimen showed only mild gastritis. This is the second, showing that the mucous membrane is shallowly eroded, but the erosion extends into the wall of a large sclerotic artery. There is a fresh thrombus at the point of erosion. Even in this very small section, not much more than a cm in length, the artery has been cut across four different times, indicating that it was very tortuous and must be classified as an arteriosclerotic cirroid aneurysm. This is not an extremely rare source of massive gastric hemorrhage. This is, I believe, the

FIGURE 1

third case that we have had with essentially the same picture.

A PHYSICIAN Where in the stomach was it located?

DR MALLORY Close to the lesser curvature.

DR DONALDSON In retrospect, I would like to ask if gastritis would cause hemorrhage without any previous bleeding of a mild nature. We thought afterward that it might have helped.

DR CULVER Four cases were reviewed by Dr Fairlie last spring. All 4 patients bled massively, and no explanation other than gastritis was found. Some bled fairly acutely. In each of these, some other cause may have been missed. I think the whole problem of diagnosis of gastritis and the significance of gastritis is still open to question. But on the basis of experience, I would say that perhaps it could cause hemorrhage, as in this case.

MAN VERSUS THE GOOD EARTH

THE REVEREND THOMAS MALTHUS died suddenly of heart disease at sixty-eight a little over a hundred years ago. He was much abused, though a gentle character personally, because of his ominous warning that "population has a tendency to increase faster than food." The fear of world-wide hunger, however remote, has been present ever since. Neo-Malthusians can point to the threefold increase in world population in the past hundred years (at the moment, possibly at the rate of 20,000,000 a year), and to the 1,000,000,000 underfed of the earth's 2,250,000,000 people. Here in the United States although the divorce rate and the fertility per family are viewed with alarm and worry about letting in or keeping out displaced persons and disagreement about birth control are

widespread, the Government has been aggressively wooing the friendship and seeking to influence a man and a nation with a real population problem. If Nehru's India continues to increase its present 355,000,000 at a rate of several million a year, its problem will be that of the United States as well, to say nothing of a 12,000,000 increase in the European population despite an estimated total war loss of 30,000,000. Furthermore world-wide sanitation, production of new and better antibiotics and new antimalarial drugs are eliminating "nature's pruning hooks."

Some astonishing and somewhat unpleasant facts are submitted by Calder* in a British country newspaper. The British are strictly dependent upon food from overseas and are therefore properly concerned about wastage anywhere, whether in Africa or Australia or the United States. The famous methods of production of this country are, in some agricultural cases, infamous methods of waste "soil unbroken for a thousand years in Oklahoma was lost in a single generation."

Americans are chagrined to be reminded of their erosion problem and its absence in countries intensively cultivated for generations. It is chastening to learn, moreover, that a British farmer can get twice as much wheat from an acre as an American farmer and four times as much as an Australian. For the American and for the Australian the problem is too few persons on the land. Erosion is not "due to overworking but to undernursing." In India, where the problem is too many on the land, the anticipated industrialization will draw people from the land and not only offer but also demand modern methods of intensive cultivation and conservation since modern medicine and sanitation are committed to increase the life expectancy at birth in Eastern countries, which is now only half that in the United States.

Medical scientists need to familiarize themselves with some new terms, such as "biotic potential" (soil yield in terms of living growth for the use or comfort of man) and "environmental resistance" (unfavorable climate or man's abuses, or both). As world citizens, Americans applaud the Nobel committee for its award of the peace prize to John

*Calder, R. World food resources. *The Field* London, August 27 1949

Boyd Orr, the distinguished Scottish agricultural economist. He is reported as one of those "who say that with science and common sense the world could feed twice and twice again, its present population." Perhaps, as Calder hopefully adds, if biotic potential can be made to match environmental resistance, "the world can nourish, clothe, and house as many people as the human race can produce." Should this end be achieved, men of Lord Orr's stamp will be needed since, aside from guiding the United Nations Food and Agricultural Organization, he is head of the World Federalists.

PILOT CLINIC

SEVEN months ago, when the principle of the health-protection clinic was first discussed in these pages, the proposition was looked upon in various quarters with considerable doubt and some disfavor. Even such specific and circumscribed propositions as cancer-detection clinics were encountering heavy weather in their efforts toward general acceptance, and the combining of isolated screening procedures so that they could be done on the same patient in one place and at the same time seemed altogether too radical.

The acceptance of pilot studies that might at least explore the debated area seemed not too wide an entering wedge, however, and so it was voted by the Council of the Society at its annual meeting on May 23. The progress that has been made in the short time elapsed since then speaks for the alacrity with which the able subcommittee on pilot clinics has acted, and the interest shown in the proposal by other agencies.

A preliminary report of the subcommittee appears in the Massachusetts Medical Society column in this issue of the *Journal*. A first "multiphasic screening clinic," to employ the somewhat redundant terminology offered by science, has already been established at the New England Center Hospital, and a trial run to break in the machinery has just been completed. As New Year, 1950, fades into history, the bona fide test of the clinic will begin.

SCHOOL PHYSICIANS MOBILIZE

ACTING on the time-tested principle that "united we stand," and having read the writing on the blackboard, the school physicians of Massachusetts have banded themselves together into their own organization. Such a union is long overdue and in the very nature of its purposes is a praiseworthy undertaking.

Formed in order "to work for the betterment of school health services, to encourage the meeting together of school physicians in Massachusetts, to exchange experiences and to discuss problems pertaining to any phase of school health service, and to promote a better understanding between the school physicians and the community," the Association cannot but add dignity and prestige to a very vital medical responsibility.

Obviously only a small percentage of school physicians are employed on a full-time basis, in most communities part-time service is all that is required or needed. All the more necessary is it for the school physician, then, to look upon this segment of his activities not as a pot-boiling auxiliary appendix to his major income-producing labors, indifferently accepted and grudgingly discharged, but as a specialized and valuable department of practice.

It is understandably hard to eradicate from the medical mind, filled with the traditions of the physician as one devoting many and long hours to the care of the sick, the idea of bedside practice as his only really noble function. The austerity of medical science came early to share this admiration, but public-health practice in its various aspects, and administrative and industrial medicine have been more slowly accepted as suitable fields wherein the first-class doctor might deploy his talents.

The nation is undoubtedly interested in the improvement of school health services, and so long as the Association of School Physicians of Massachusetts (itself in its infancy) whole-heartedly follows this single aim, its members will find themselves engaged in a specialty that commands universal respect.

POLIOMYELITIS FUNDS DIMINISHED

A RECENT communication from The National Foundation for Infantile Paralysis, Inc., calls attention to the mounting costs of hospital care for the victims of this disease and the critical state that the financial burden to the Foundation has reached.

This situation has been brought to a head by the epidemic of 1949, as a result of which, for the first time in its eleven years of existence, the Foundation found it necessary to conduct a not altogether successful emergency drive for funds.

Despite the Foundation's continuing support of research and education, the payment for medical care to patients is its greatest expense, and this expense is particularly for hospitalization. Practicing physicians are consequently urged to care for patients with abortive, nonparalytic and mildly paralytic cases in the home, and to avoid prolonged hospitalization for the others. Funds for the "free" care of poliomyelitis patients are low, the dimes will not march again until February, and unnecessary expenses must be avoided.

Messrs Editors, — By the bearer we send you a specimen of diseased lung, which you may call encysted tubercle, osseous composition, or any other name your sense of propriety may dictate, after examining it

Boston M & S J, December 5, 1849

MASSACHUSETTS MEDICAL SOCIETY

COMMITTEE ON PILOT CLINICS

At the annual meeting of the Council of the Society held on May 23, 1949, a motion submitted by the Committee on Public Health approving the establishment in the Commonwealth of not more than five pilot health-protection clinics was adopted. It was further recommended that a subcommittee of the Committee on Public Health be appointed to develop and carry out such a program. This subcommittee was accordingly appointed, consisting of a representative from each of the 18 district medical societies under the chairmanship of Dr. John J. Poutas.

The subcommittee and its executive committee have subsequently held several meetings, with the following results:

The decision has been made to develop a single initial pilot health-protection or "multiphasic screening" clinic. This clinic has been set up at the New England Center and the Joseph H. Pratt Diagnostic Hospital. A local project committee has been established to determine local problems, and a central guiding committee has been set up to act in an advisory capacity.

Dr. Claire F. Ryder, of the Massachusetts Department of Public Health, has been appointed as administrator of the clinic.

It has been decided that, to perform its functions satisfactorily, the Clinic should run for approximately six months, operating four times a week. During this period it should be possible to examine 2000 to 3000 persons, a number that would constitute an impressive sample.

The proposed budget for such a clinic, including adequate pay for the participating personnel, will be \$31,000. The United States Public Health Service will consider this a co-operating clinic and will supply funds to be paid directly to the persons employed in the clinic up to an amount not exceeding \$15,000. Approximately \$12,000 is available through the services and funds of the Massachusetts Department of Public Health, and the remainder is to be raised from the voluntary agencies that have indicated their desire to participate.

Already, since the first of December, a trial run of approximately 100 personnel of the Department of Public Health has been made, extending through four clinic periods, without utilizing any of the funds earmarked for the actual clinic operation, which will begin after the New Year.

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

COMMUNICABLE DISEASES IN MASSACHUSETTS FOR OCTOBER, 1949

Whooping cough			

*Five-year median

COMMENT

The only diseases above the seven-year median for October were poliomyelitis and salmonellosis.

Diseases below the seven-year median included chicken pox, diphtheria, bacillary dysentery, German measles, measles, mumps, scarlet fever and whooping cough.

Although the incidence of poliomyelitis dropped markedly from the high figures for August and September, cases were at the third highest ever reported in October.

Twenty-four cases of salmonellosis this month was the highest ever recorded in October, but in August this year there were 74 cases.

For the second consecutive month, measles was at the lowest level since 1957.

For the fourth consecutive month scarlet fever was at the lowest level ever recorded.

Although whooping cough was still below the seven-year median, this was the seventh successive month in which more cases were reported than in the corresponding month in 1948.

GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASES

Diphtheria was reported from Boston 7 Burlington 1 Rockport, 1, Somerville, 2, Watertown 1 total, 12

Dysentery, bacillary, was reported from Boston, 7, Cambridge, 7, Wrentham, 1, total, 15

Encephalitis, infectious, was reported from Newburyport 1, Springfield, 1, total, 2

Infectious hepatitis was reported from Lawrence, 3 total 3

Malaria was reported from Gloucester, 1, total 1

Meningitis, meningococcal, was reported from Boston 1 Haverhill, 1, Maynard, 1, Peabody, 1, total, 4

Meningitis, Pfeiffer-bacillus, was reported from Attleboro, 1, total, 1

Meningitis, undetermined, was reported from Boston 2 Chelmsford, 1, Fall River, 4, Medford, 1, total, 8

Poliomyelitis was reported from Abington, 3 Adams, 2 Arlington, 3, Attleboro, 3, Auburn, 1, Barre, 2, Belmont, 1, Beverly, 1, Billerica, 2, Boston, 27, Braintree, 3 Bridge-

water, 1, Brockton, 1, Brookline, 3, Burlington 1, Cambridge, 3, Chelmsford 1, Chelsea, 3 Chicopee, 1, Dedham, 1, Deerfield, 2, Dennis, 1, Dover, 1, Dracut, 2, Duxbury, 1, East Bridgewater, 1, Fall River, 3, Falmouth, 1 Framing-

CORRESPONDENCE

MAINE MARITIME ACADEMY CRUISE

To the Editor Last year about this time I wrote to you for assistance in obtaining a medical officer for the annual cruise of the "American Sailor," training vessel for the Maine Maritime Academy. We are again making a cruise during the winter months to the Caribbean and Gulf of

Mexico and are in need of a doctor. Therefore, I am writing to request that you inform your readers of this opportunity for a cruise under very pleasant circumstances. For your ready information I will repeat the substance of my letter of last year which is also applicable now.

The training ship is provided by the United States Maritime Commission and is a very comfortable 400-foot steamer equipped as a training vessel with excellent medical equipment on board. Embarked will be the cadets, faculty and staff of the Academy, amounting to 220 persons. It has been the custom in the past to employ a doctor for this cruise which is tantamount to a vacation for him, owing to the fact that all persons on board are in excellent physical condition. However, we do desire a doctor on board in case of emergencies.

The pay is \$530 a month plus maintenance.

The cruise begins on January 12 and ends on March 26, 1950.

W W WARLICK
Rear Admiral USN (Ret.)
Superintendent

Castine, Maine

BOOK REVIEW

The Basic Neurosis: Oral regression and psychic masochism
By Edmund Bergler, M.D. 8", cloth 353 pp. New York: Grune and Stratton, Incorporated, 1949. \$5.00.

Dr. Bergler, a Freudian psychoanalyst, and a prolific psychoanalytic writer, is well known among psychiatric circles by his papers and books dealing with common sexual problems and their influence on human behavior.

In his most recent work, Dr. Bergler has attempted to demonstrate why he believes that all neuroses if adequately examined and interpreted, will reveal the basic structure of oral regression and psychic masochism. Approximately the first half of the book is groundwork outlining concepts that are presented in the form of clinical pictures in the last half.

The author evidently assumes that the reader is familiar with basic psychoanalytic concepts and tenets because he immediately launches into his writing with terminology that is not necessarily basic. Also the use of the personal pronoun "I," especially in comparison with the name of Dr. Freud, appears to be a bit overdone to have the book in truly good taste.

In the chapter, "Orality and the Myth of the Superior Male," Dr. Bergler appears to have been provoked by editors, publishers and so forth, to whom he variously refers as neurotics of one form or another. This is evidently a contradiction and places him in the neurotic, easily provoked group as indicated from his title entitled "The Nine Point Basis of Every Neurosis" in the third chapter. To clarify this point further it is obvious that the author has used the fifth chapter as a direct retort to the people mentioned above, who obviously provoked aggression and disturbed his ego functioning. This chapter, in its present form, could have been, from the reader's standpoint, profitably omitted.

Aside from these criticisms the book is an excellent presentation of the mechanisms of orality and their influence on personality development.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Pain Syndromes: Treatment by paracervical nerve block
By Bernard Judovich, M.D., instructor in neurology, University of Pennsylvania School of Medicine, and physician-in-charge, Neuralgia Clinic, Graduate Hospital, Philadelphia, and William Bates, M.D., professor of surgery, University of Pennsylvania School of Medicine, consulting surgeon, Babies' Hospital and Philadelphia Home for Incurables, and

POLIOMYELITIS FUNDS DIMINISHED

A RECENT communication from The National Foundation for Infantile Paralysis, Inc., calls attention to the mounting costs of hospital care for the victims of this disease and the critical state that the financial burden to the Foundation has reached

This situation has been brought to a head by the epidemic of 1949, as a result of which, for the first time in its eleven years of existence, the Foundation found it necessary to conduct a not altogether successful emergency drive for funds

Despite the Foundation's continuing support of research and education, the payment for medical care to patients is its greatest expense, and this expense is particularly for hospitalization. Practicing physicians are consequently urged to care for patients with abortive, nonparalytic and mildly paralytic cases in the home, and to avoid prolonged hospitalization for the others. Funds for the "free" care of poliomyelitis patients are low, the dimes will not march again until February, and unnecessary expenses must be avoided

Messrs Editors, — By the bearer we send you a specimen of diseased lung, which you may call encysted tubercle, osseous composition, or any other name your sense of propriety may dictate, after examining it

Boston M & S J, December 5, 1849

MASSACHUSETTS MEDICAL SOCIETY

COMMITTEE ON PILOT CLINICS

At the annual meeting of the Council of the Society held on May 23, 1949, a motion submitted by the Committee on Public Health approving the establishment in the Commonwealth of not more than five pilot health-protection clinics was adopted. It was further recommended that a subcommittee of the Committee on Public Health be appointed to develop and carry out such a program. This subcommittee was accordingly appointed, consisting of a representative from each of the 18 district medical societies under the chairmanship of Dr John J Poutas

The subcommittee and its executive committee have subsequently held several meetings, with the following results

The decision has been made to develop a single initial pilot health-protection or "multiphasic screening" clinic. This clinic has been set up at the New England Center and the Joseph H Pratt Diagnostic Hospital. A local project committee has been established to determine local problems, and a central guiding committee has been set up to act in an advisory capacity

Dr Claire F Ryder, of the Massachusetts Department of Public Health, has been appointed as administrator of the clinic

It has been decided that, to perform its functions satisfactorily, the Clinic should run for approximately six months, operating four times a week. During this period it should be possible to examine 2000 to 3000 persons, a number that would constitute an impressive sample

The proposed budget for such a clinic, including adequate pay for the participating personnel, will be \$31,000. The United States Public Health Service will consider this a co-operating clinic and will supply funds to be paid directly to the persons employed in the clinic up to an amount not exceeding \$15,000. Approximately \$12,000 is available through the services and funds of the Massachusetts Department of Public Health, and the remainder is to be raised from the voluntary agencies that have indicated their desire to participate

Already, since the first of December, a trial run of approximately 100 personnel of the Department of Public Health has been made, extending through four clinic periods, without utilizing any of the funds earmarked for the actual clinic operation, which will begin after the New Year

THE VALUE OF THE THORACOABDOMINAL INCISION IN THE REMOVAL OF KIDNEY TUMORS*

RICHARD CHUTE, M.D.,† LAMAR SOUTTER, M.D.,‡ AND WALTER S. KERR, JR., M.D.§

BOSTON

ALTHOUGH the kidneys are situated below the diaphragm, they lie to a large extent within the thorax, sheltered by the lower ribs. Chiefly because the unyielding bony thoracic cage frequently bars the way to a free and satisfactory surgical exposure of the upper portion of the kidneys when they are enlarged, the lumbar extraperitoneal incision commonly used for renal surgery with or without removal of the twelfth rib, and also the transperitoneal approach often leave a great deal to be desired in the way of exposure when one is dealing with large tumors of the kidney. While searching for an incision that would give better access to and exposure of the kidney and retroperitoneal region, we contemplated using the thoracoabdominal incision. This type of incision in its present form is relatively new. One reason for this is that for its safe performance intratracheal anesthesia with the ability to exert positive pressure on the lung is essential, and this advance in anesthesia has come into use only during the past fifteen years. General knowledge concerning the handling of thoracoabdominal wounds and the use of thoracoabdominal incisions was given a great impetus by the surgical experiences of World War II. During the war one of us (L.S.) removed several traumatized kidneys by this route, which was also utilized by others.^{1,2} Although the thoracoabdominal incision has not come into general frequent use in the last few years it has been used for gastrectomy and esophagectomy, for carcinoma,³⁻⁵ for splenorenal anastomosis⁶ and for splenectomy.⁷ In the light of this knowledge, we decided to make a trial of this incision for the removal of large kidney tumors, and performed our first nephrectomy by this route in January, 1948. (Although Mortensen,⁸ of Australia, had removed a large tumor in this manner in June, 1946,

we were quite unaware of this, since his case report had not yet been published.)

The excellent exposure that was found to be afforded by this approach greatly facilitated nephrectomy in these difficult cases and led to much enthusiasm on our part, our first few cases being reported in May, 1948.⁹ Further experiences with the incision, which has now also been employed with success by several colleagues, have only served to increase our liking for it, and it has now been used in 39 cases for urologic surgery. Twenty of these operations were for renal tumors, and 12 were for the exploration or removal, or both, of kidneys suspected of tumor (mostly large solitary cysts). This procedure has also been utilized to allow nephrectomy when the usual approach to the kidney was blocked by the ribs owing to extreme kyphosis or scoliosis of the spine (2 cases). Furthermore, the particularly excellent exposure of the retroperitoneal region from the diaphragm down that can be obtained by this approach has led to its use, by extension of the incision downward toward the pubis, for retroperitoneal dissection of the lymph nodes along the aorta, vena cava and iliac vessels in cases of carcinoma of the testis (5 cases), and for complete nephroureterectomy in another case, in which the tumor of the renal pelvis involved the ureter. These other uses of the incision in urologic surgery are not discussed further, this communication being confined to a description of the experiences with this approach in the 20 cases of kidney tumor.

The discouragingly low incidence of five-year (15 to 19 per cent) and ten-year (7 to 9 per cent) cures^{10,11} of malignant kidney tumors is obviously due to their high degree of malignancy, coupled with the frequently insidious nature of their onset, especially the renal-cell carcinoma-hypernephroma cases which comprise the majority of these tumors. In this group the blood supply is very rich, and the malignant tissue is in intimate contact with the vascular spaces, and often parts of the tumor actually project into the blood stream. Thus it is that distant metastases from these tumors

*From the Massachusetts General Hospital.
Presented at the annual meeting of the American Urological Association
Los Angeles, California, May 16, 1949.

†Instructor in surgery, Harvard Medical School, associate visiting
urologist, Massachusetts General Hospital, attending urologist, Veterans
Administration Hospital, West Roxbury, Massachusetts.

‡Instructor in surgery, Harvard Medical School, assistant surgeon,
Massachusetts General Hospital, consulting surgeon, Veterans Admin-
istration Hospital, West Roxbury, Massachusetts.

§Assistant in urology, Massachusetts General Hospital.

consulting general surgeon, Wills Hospital, Philadelphia. With a foreword by Joseph C. Yaskin, M.D., professor of neurology, University of Pennsylvania School of Medicine. Third edition. 8°, cloth, 357 pp., with 181 illustrations. Philadelphia: F. A. Davis Company, 1949. \$6.00.

This third edition of a special monograph, formerly called *Segmental Neuralgia in Painful Syndromes*, has been thoroughly revised, and material added on endometriosis as a cause of major backache, the intravenous use of procaine as a method of pain control, technique for aborting attacks of migraine and atypical facial pain. The chapter on brachial-plexus pain has been enlarged by the inclusion of a new summary of etiologic factors, a new outline of etiologic factors and a differential method of examination. The chapter on the anterior-scalene syndrome has been thoroughly revised. The book is well published and should be in all medical libraries and available to neurologists and physicians interested in the subject of pain.

The Venereal Diseases. A manual for practitioners and students. By James Marshall, M.D., M.R.C.S., L.R.C.P., director, Venereal Diseases Clinic, Royal Northern Hospital, London, and consulting dermatologist, Central Middlesex County Hospital. Second edition. 8°, cloth, 369 pp., with 105 illustrations. London: Macmillan and Company Limited, 1948. \$5.50.

In this second edition of a manual first published in 1944 the author has incorporated the use of penicillin, rewritten the sections on nongonococcal urethritis, brought up to date massive arsenotherapy, added a note on Reiter's syndrome and made many minor revisions and corrections. The book is well published, and there is a good index. The volume should prove valuable as a quick reference source.

Safeguarding Motherhood. By Sol T. DeLee, M.D., clinical instructor of obstetrics and gynecology, University of Illinois College of Medicine, and attending obstetrician at the Chicago Maternity Center. 8°, cloth, 135 pp., with 42 illustrations. Philadelphia: J. B. Lippincott Company, 1949. \$2.00.

This manual for expectant mothers has been written by an obstetrician. The chief purposes of the book are to inform them regarding their pregnant condition, the means whereby the body has been prepared for it, the course it will follow and the culmination in the birth of the child. It is to be used in co-operation with an obstetrician. There is a glossary of uncommon and technical words and phrases used in the text. There is a good index. The publishers have produced a beautiful book with excellent illustrations.

Etudes de pathologie foetale et néonatale. By Dr. M. Sorba. 8°, paper, 160 pp., with 14 illustrations. Lausanne: F. Rouge & Cie S.A., 1948.

In this monograph Dr. Sorba discusses the various aspects of fetal neonatal pathology. The text is divided into four parts: lesions of the fetal annexes and the fetus, interpretation of the lesions and syndromes, causes and mechanisms of death, and fetal and neonatal pathology. A bibliography concludes the text. A table of contents takes the place of an index. The monograph is well published and should prove of interest to persons interested in the subject.

Clinical Case-Taking. Guides for the study of patients. History-taking and physical examination or semiology of disease in the various systems. By George R. Herrmann, M.D., Ph.D., professor of medicine, University of Texas Medical Branch. Fourth edition. 8°, cloth, 240 pp. St. Louis: C. V. Mosby Company, 1949. \$3.50.

This manual was first published in 1927 and has been revised and brought up to date. It is intended for ward and bedside practice. The method of interviewing patients—to establish what sort of a human being each one is—has been added in the general outline for all cases, as well as in the section on psychiatry. The significance of personality functions as motivating factors in psychosomatic disorders has been pointed out. There are new sections on pediatrics and surgical case study. The table of contents has been arranged as a working outline, and there is a good index. The book is well published.

NOTICES

HARVARD MEDICAL SOCIETY

A meeting of the Harvard Medical Society will be held in the Lower Outpatient Amphitheater, Massachusetts General Hospital, on Tuesday, December 13, at 8 p.m.

PROGRAM

Spatial Relationships of the Deep Veins of the Lower Extremity. Davitt A. Felder.
Venous Pressures in the Lower Extremity. Richard Warren.
Management of Late Phlebotic Sequelae. Irad B. Hardy, Jr.
Problems in the Management of Portal Hypertension. Robert R. Linton.

GREATER BOSTON MEDICAL SOCIETY

A meeting of the Greater Boston Medical Society will be held in the auditorium of the Beth Israel Hospital on Thursday, December 15, at 8:15 p.m. A symposium on early diagnosis of cancer will be conducted, with Dr. Arnold M. Seligman as moderator. Dr. Monroe J. Schlesinger will discuss "Histopathologic Diagnosis," Dr. Olive Gates "Aspects of Cytologic Diagnosis," Dr. William Fishman "Biochemical and Enzymatic Diagnosis," and Dr. Freddy Homburger "Evaluation of Cancer Tests."

BOSTON CITY HOSPITAL HOUSE OFFICERS' ASSOCIATION

A Tuesday evening lecture sponsored by the Boston City Hospital House Officers' Association will be presented in the Dowling Amphitheater, Boston City Hospital, on December 20 at 7 p.m. Dr. Ephraim Shorr of the New York Hospital and Cornell University Medical College will speak on the subject "The Role of Vasoactive Principles of Liver and Kidney Origin in Experimental Shock, Hypertension and Cirrhosis."

All interested physicians are invited to attend.

NEW ENGLAND SOCIETY OF PHYSICAL MEDICINE

A regular meeting of the New England Society of Physical Medicine will be held at the Hotel Kenmore, Boston, on Wednesday, December 14, at 8:00 p.m. Dr. Stanley J. Sarnoff will speak on the subject "Electrophrenic Respiration with Consideration of the Management of the Respirator Difficulties in Bulbar Poliomyelitis" (with motion pictures, slides and demonstrations of electrophrenic respirator techniques). This will be followed by a general discussion.

There will be a meeting of the Council at 7:30 after an informal dinner in the Empire Room at 6:00 p.m.

Physicians, physical therapists, occupational therapists and corrective therapists are cordially invited to attend this program.

ASSOCIATION OF SCHOOL PHYSICIANS OF MASSACHUSETTS

A dinner meeting of the Association of School Physicians of Massachusetts, which will also be a membership and organizational meeting, will be held at the Pocahontas Club, Lynnfield, on Wednesday, December 21, at 6:30 p.m. The speakers will be Dr. William E. Welch, superintendent of schools in Peabody, and president of the Association of School Superintendents of Massachusetts, and Dr. William M. Schmidt, associate professor of maternal and child health practice, Harvard School of Public Health, who will discuss his postwar experiences in Europe.

LABORATORY COURSES AT COMMUNICABLE DISEASE CENTER, ATLANTA, GEORGIA

A schedule of laboratory training courses will be offered at the Communicable Disease Center, Laboratory Division, Atlanta, Georgia, from January 9 to December 1, 1950. Application forms and further information regarding the subjects, duration and location of the various courses may be obtained from the Chief, Laboratory Division, Communicable Disease Center, 291 Peachtree Street, N.E., Atlanta, Georgia.

(Notices concluded on page xiii)

and often dangerous hemorrhage from the large veins that run over the surface of some of these large renal tumors. It is believed that these veins are often the result of venous stasis and engorgement secondary to obstruction of the renal vein by a tumor thrombus, and that this back pressure accounts for the fact that they bleed so profusely.

By this route, enlarged regional lymph nodes at the renal pedicle and along the vena cava and aorta were removed in 6 cases. In 4 of these, the removed lymph nodes showed malignant spread, but in 2 cases they surprisingly showed no disease. Two other patients had tumors projecting into the renal vein that were successfully removed. In another case the vena cava was opened and part of its wall excised to remove a tumor thrombus going down it for 1 cm and adherent inside it. In another case the vena cava, which was involved by direct extension from a malignant tumor of the right kidney, was ligated just below the left renal vein, and a section of it removed with the tumor. As yet, we have encountered no cases with direct extension to the diaphragm, spleen, duodenum or colon, but we believe that if this situation were encountered, resection of the involved portions of those structures might prove feasible. One tumor of the left kidney had already metastasized to the liver, and a tumor on the right had extended directly into the liver. In the latter case the porta of the liver was involved, and although the kidney was removed, it was believed that the disease in the liver was inoperable. However, if the direct extension had been to a more peripheral region of the liver, resection of the involved portion might have been possible. At the time of operation, 1 patient had already had his arm amputated for a metastasis to the humerus, and 2 patients were known to have pulmonary metastases. In view of the occasional cure of a patient with one solitary metastasis by its removal followed by the extirpation of the primary tumor,¹² the renal neoplasm of the first was removed in the vain hope of a chance of cure, and nephrectomy was performed on the latter 2 for the relief of hematuria and pain.

This incision has been performed on both sides, but somewhat more often on the left side than on the right. On the right, even with very large kidney tumors and with somewhat enlarged livers, the overhanging anterior edge of the liver has been easily retracted upward out of the way, and has not interfered with the performance of the operation.

Owing to the fact that the chest wound is held widely open by the rib retractor, less muscular relaxation is needed, and therefore less ether is used than when a comparable operation is performed through the abdominal musculature alone. This can be an important consideration in older and poor-risk patients.

The patients varied in age from one year (a baby boy with a large cystic teratoma) to seventy-seven

years, and 5 patients were over seventy. Two of these had severe cardiac conditions, compensated only on limited activity, and 3 others had electrocardiographic evidence of coronary sclerosis. Despite these limitations, with the exception of a woman of seventy-seven whose heart decompensated temporarily one week after operation, the postoperative recoveries were uneventful and the length of the postoperative hospital stay was the same as that for uncomplicated lumbar nephrectomies.

In these 20 thoracoabdominal operations for kidney tumor there has been no operative mortality or death in the hospital. Also, there have been no pulmonary emboli or cases of chest or peritoneal infection (These statements are also true for the total of 39 thoracoabdominal urologic operations performed to date.) There were only 2 significant postoperative complications, both of which were due to intrapleural hemorrhage. The first hemorrhage was minor, and the chest cleared after one thoracentesis. The second case continued to ooze intrapleurally, probably from torn pulmonary adhesions, and required several chest taps, as well as blood transfusions, during the first few days after operation. Eventually, the blood in the chest became so thick and clotted that it could not be removed, and it bound down and collapsed the lower and middle lobes of the right lung, making an open surgical decortication necessary. The patient, who was seventy-five years of age, tolerated this procedure well and went home in good condition. There were no other postoperative complications.

Thus, it can be seen that we, as well as our colleagues, have experienced a minimum of complications from the thoracoabdominal incision. We are firmly convinced that the important advantages that it confers through the wide exposure are well worth the added effort of the necessarily more complicated operative procedure and of the more exacting preoperative and immediate postoperative care. Also, whereas at first this approach was suggested only for kidney tumors that were obviously large, with further experiences and in view of the good possibility that local extension will be found at operation on any kidney tumor, it is our opinion that one must always be prepared for extensive surgery in every case with the best possible exposure, and that therefore all renal tumors should be operated upon by the thoracoabdominal route.

At the present time, the series of cases is too small and the length of follow-up study far too short to permit any true appraisal of end results, but the operative technic facilitated by this incision should improve the chances of cure and the end results. The patient who could not be operated on died within a few months, and the patient who had nephrectomy and amputation of the arm for what was hoped to be a solitary metastasis is now dying of widespread metastases to the spine, ribs and lungs. In addition, 6 patients, 2 of whom were

take place via the efferent blood vessels, such as the renal vein. Local lymphatic metastases to the regional lymph nodes, the nearest of which are located in the region of the renal pedicle and along the nearby anterior aspect of the aorta and vena cava, also occur. Therefore, it is not surprising that many patients die of metastatic disease despite removal of the primary tumor, sometimes succumbing even ten years after nephrectomy. A contributing unfavorable factor is the fact that the patient often is not operated on until the disease is in an advanced stage, either on account of the frequent absence of symptoms until late in the disease or because such symptoms as hematuria have been disregarded. It is indicative of the high malignancy and insidious onset of the tumors that at operation only 8 of the 20 patients in this series were found to have no evidence of extension of the disease outside the kidney, despite the fact that many had had symptoms for only a short time.

It also seems very probable that some of the late distant metastases that not infrequently follow the removal of malignant kidney tumors are due to the fact that particles of tumor have been literally squeezed into the blood stream by the manipulations of the operator while he is freeing up a large vascular tumor preparatory to its removal. Thus, ideally, the surgeon performing a nephrectomy in these cases should interrupt the connection of the kidney tumor with the systemic circulation by clamping the renal vein before he handles the tumor and massages malignant tumor emboli into the blood stream. In addition, such a nephrectomy, to be an adequate operation for cancer in accordance with modern concepts of cancer surgery, should also remove — en bloc with the tumor, if possible — regional lymph nodes and also all the perinephric fat and capsule of Gerota, if possible. Such a procedure is analogous to the dissection of the axillary lymph nodes en bloc with the breast in a radical mastectomy for carcinoma. The ability to perform this type of nephrectomy, which, in our opinion, may prove to be an important step in improving the results of the surgery of these malignant tumors, very largely depends on an exposure wide enough to facilitate its easy and safe performance.

The thoracoabdominal incision furnishes the wide exposure needed. It neutralizes the barrier of the bony thoracic cage, inside which the kidney largely lies, by means of creating surgically a broad pathway directly through it right to the kidney. This gives an exposure of this organ and its pedicle that is direct and wide and definitely superior to that afforded by either the lumbar or the transperitoneal approach in our opinion and that of our colleagues who have used it.

When malignant renal tumors are large, and especially when there are involved lymph nodes adherent to the great vessels in the region of the pedicle or when there is invasion of the inferior

vena cava by tumor thrombi, their removal may be exceedingly difficult and dangerous, and sometimes impossible. In such difficult cases the difference between success or failure may depend on whether or not there is good exposure and room to carry out delicate and exacting surgical procedures. As a result of the wide-open approach conferred by the thoracoabdominal incision, both the ease and the safety of the removal of renal neoplasms have been greatly increased, since, even with the largest tumors encountered, the vessels of the pedicle have been fairly easily discovered, and exposed and ligated individually under direct vision. This has decreased the liability to such accidents as uncontrollable hemorrhage and injury to the vena cava, spleen, colon or duodenum, which have sometimes occurred in the past, usually when the surgeon was working in cramped quarters in a deep wound with inadequate exposure and imperfect visualization of important structures. In such cases a lumbar or transperitoneal incision had often been made as long as it was possible to make it, but limitations inherent in the type of incision had resulted in an exposure that was still inadequate for the condition the surgeon was contending with. Those who have operated upon these large vascular tumors under such difficult and unpleasant circumstances will easily appreciate the great value of an exposure that affords both plenty of room and good vision.

As a corollary, it is not surprising that this exposure has allowed the extirpation of large carcinomatous kidneys whose removal had been attempted by another approach but found impossible. In one of our cases a large tumor, whose removal had been attempted unsuccessfully via the lumbar approach by an experienced urologic surgeon, was taken out successfully ten days later via the thoracoabdominal route. The case reported by Mortensen⁹ had also been attempted unsuccessfully by the conventional route. In another of our cases in which the thoracoabdominal approach was successfully employed, a huge kidney was found to be very adherent to the vena cava for a distance of about 5 cm. and had to be dissected off with great care; it seems quite certain that the kidney could not have been removed by any other approach without serious damage to the vena cava. Several other tumors in our series probably could not have been removed successfully through any other incision. In this connection, it is significant that in only 1 of these 20 neoplasms, some of which were very large and adherent with local extension, was the kidney not removed. In this case widespread local extension of the malignant lesion seemed to contraindicate any attempt at nephrectomy.

Another technical advantage conferred by this wide-open exposure is that, by facilitating the early ligation of the vessels of the renal pedicle before very much manipulation or freeing-up of the kidney is necessary, it largely avoids the bothersome

portant to resect the rib as far back toward the spine as this because, if it is resected farther forward, the ligaments binding it to the rib above and the rib below will prevent the optimum spread of

FIGURE 2 Schematic Drawing, Showing the Location of the Incision in Relation to the Kidney

this posterior angle of the wound, which is essential to the maximum possible exposure from this incision. The pleural cavity is entered through the periosteal bed, great care being taken not to injure the underlying lung (Fig 4). There is less

FIGURE 3 Drawing Showing the Incision for Left Nephrectomy, Starting from Near the Spine in Back Running Forward and Downward over the Left Eleventh Rib and Continuing to the Outer Border of the Left Rectus Muscle
The rib is being cleared preparatory to subperiosteal resection

chance of doing this if the pleural cavity is opened anteriorly over the diaphragm. The anesthetist is notified when the pleural cavity is entered. Unless adhesions are present, the lung collapses consider-

ably on opening of the pleural cavity and retracts upward. If adhesions between the lung and the parietal pleura or the diaphragm are obvious and in the way, they are gently separated by sharp dissection, great care being taken to secure complete hemostasis with fine-silk ties or ligatures. During the operation the lung can be walled off by moist gauze and the anesthetist may keep it almost completely expanded. By retracting the chest wall up and the diaphragm down, one can see the phrenic nerve as it courses downward over the pericardium, and it may be crushed with a hemostat at the point where it leaves the surface of the pericardium to enter the diaphragm. This paralyzes the diaphragm and stops its motion, so that it interferes less with

FIGURE 4 Drawing Showing the Left Pleural Cavity Being Entered through the Periosteal Bed of the Left Eleventh Rib
Care is taken not to wound the underlying lung

the operation. The paralysis lasts for about four to six weeks, and the resulting immobility is thought to aid the healing of the diaphragm. However, if the patient has a low vital capacity and it is desirable for him to have the positive muscular action of the diaphragm return soon to help him with respiration, the phrenic nerve is simply injected with a few cubic centimeters of 2 per cent procaine solution, which allows its action to return in an hour or two, and this precaution ensures better postoperative aeration of the lung above. In some cases the phrenic nerve has not been touched, and the motion of the diaphragm has not seemed to interfere with the renal surgery. The diaphragm is then incised in line with the skin incision, the incision also being carried through the peritoneum which is adherent to its undersurface. Care is taken to avoid cutting into any organ that may be adherent to its underside, such as the kidney tumor, or the

known to have pulmonary metastases before operation, have demonstrable metastases to which they will eventually succumb. The other patients are living and apparently well.

The following cases illustrate the problems that occur and show why all renal tumors should be operated upon by the route giving the best possible exposure.

CASE REPORTS

CASE 1 A 59-year-old man, previously in excellent health, noticed bloody urine for the first time in his life and had colicky pains from passing clots. After 10 days of this he entered the hospital, where the diagnosis of a tumor of the right kidney was made after x-ray study, even though no mass could be felt. He was operated upon by the lumbar route, and the tumor was found to be so large, to lie so high and to be covered by large veins that bled so profusely that, after a prolonged attempt to free it up, it was considered inoperable and the wound closed. Eleven days later, on account of continuing intractable hemorrhage and colic, the kidney was approached by the thoracoabdominal route and easily exposed. It was found that there was a tumor thrombus about 1.5 cm in diameter filling the renal vein and extending retrograde downward inside the vena cava for 1 cm. After temporary tension tapes had been applied to the vena cava above and below to control bleeding, the vena cava was opened and it was found that the tumor thrombus had invaded the wall of the vena cava near the entry of the renal vein. The involved portion of the wall of the vena cava was excised and removed with the thrombus and renal vein, after which the kidney was easily removed. The incision in the vena cava was sutured longitudinally with fine silk, and the patient made a very satisfactory recovery. So far he has remained in excellent health for the 4 months since his operation. The microscopic diagnosis was renal-cell carcinoma.

CASE 2 A frail, 77-year-old woman with a poor heart entered the hospital with a 3 weeks' history of colicky pain in the right-kidney region associated with episodes of hematuria. She had lost weight, felt tired and had dyspnea on exertion. Examination showed her to be extremely anemic. A large hard mass, which did not move much, was felt in the right-kidney region. After the anemia had been remedied by multiple transfusions, the patient was operated upon through a thoracoabdominal incision. A huge kidney was found adherent to the liver and the duodenum. It was dissected off these structures, but then it was found that the tumor intimately involved much of the circumference of the vena cava. Since this was below the entrance of the left renal vein, the vena cava was tied off here, and a segment of vena cava removed with the tumor, as well as some involved nodes. After a somewhat stormy convalescence, marked by oliguria for some days and also by cardiac decompensation, the patient made a satisfactory recovery. The microscopic report was squamous-cell carcinoma.

CASE 3 A 67-year-old man had had cardiac decompensation 3 years previously. After several weeks of bed rest and digitalization he recovered enough cardiac compensation and reserve to be able to get along fairly well on limited activity. For 6 months he had noted an occasional streak of blood in the urine, and 3 days before admission he had noticed definitely bloody urine, with some aching in the left flank. Examination showed a moderate-sized, rather fixed mass high up in the left upper quadrant, and pyelograms indicated a good-sized tumor of the left kidney. After a few days of cardiac preparation with digitals, a low-salt diet and quimidine immediately before operation, thoracoabdominal nephrectomy was carried out. A large renal tumor was found, and after preliminary ligation of the renal vein and artery, an egg-sized mass of metastatic lymph nodes in continuity

with the lower pole of the kidney and extending downward along the anterior surface of the aorta was gently dissected free and removed en bloc with the kidney (Fig 1). The patient made an uneventful recovery, having no cardiac embarrassment, and when last examined and given x-ray study

FIGURE 1 *Kidney Tumor, with Attached Metastatic Nodes Removed en Bloc (Note That All the Surrounding Fatty Capsule Is Removed with the Kidney)*

14 months later was well, with no evidence of metastases. Microscopic examination revealed renal-cell carcinoma with extension to the lymph nodes.

OPERATIVE TECHNIC

In preparation for the operation of thoracoabdominal nephrectomy, particular attention is paid to increasing the hemoglobin and red-cell count to normal. Older patients and all who have cardiac abnormalities are seen by a cardiologist, and most of these are put on a low-salt diet, some are digitalized, and almost all are given quimidine preoperatively. If the nephrectomy is to be on the left side, a Levine tube is placed in the stomach immediately before operation, to prevent gastric distention, which can be troublesome in operations on that side.

Under intratracheal oxygen-ether anesthesia, the patient is placed on the operating table with the side to be operated upon uppermost. The incision starts about 1 cm lateral to the spinous processes of the spine in back and runs forward and downward over the entire course of the tenth (or eleventh) rib (Fig 2). When the end of the rib is reached, the incision is continued in the same direction across the abdominal wall as far as the lateral border of the rectus muscle. The incision is deepened through the muscle layers to the rib, which is removed in its entirety subperiosteally, being resected between its posterior angle and the spine (Fig 3). It is im-

main renal artery is exposed, the vein and the artery are individually clamped, sectioned and doubly ligated — as well as any smaller vessels found

FIGURE 9 Photograph Taken at Operation Showing Metastatic Lymph Nodes Dissected from the Aorta en Bloc with the Kidney

In addition to the perinephric fat, all lymph nodes and areolar tissue in the region of the pedicle or adherent to the great vessels are dissected away —

FIGURE 10 Drawing Showing Wound Closure

The anterior part of the peritoneum, from the outer border of the rectus muscle to the diaphragm, has already been closed. The drawing shows the suturing, with interrupted silk stitches, of the diaphragm and of the transversalis muscle, with which it decussates to form a continuous muscle layer for the purposes of closure

being removed en bloc with the tumor, if possible (Fig 9) The ureter is sectioned and ligated, the cut ends being carbolyzed After this, it is a simple

matter to complete the mobilization of the kidney and remove it If there is direct extension to some neighboring structure such as the diaphragm, it is quite possible that enough of this structure can also be excised to eradicate this extension of the malignant process After the kidney has been removed, a few stitches may be taken to cover the raw area with peritoneum and to fix the bowel back in position Then the opening in the peritoneum is closed anteriorly as far back as the diaphragm, a continuous suture of plain O catgut on an atraumatic needle being used When the diaphragm is reached, it is sutured with interrupted stitches of heavy silk (No 2) (Fig 10) Before the chest is closed, 15 cc of eucupine in oil (a long-lasting local anesthetic) is injected hypodermically into the intercostal nerve of the rib resected, and also into the nerve of

FIGURE 11 Drawing Showing Closure of the Pleura and of the Muscles in Layers with Interrupted Silk Sutures

the rib above and below This is done inside the chest behind the angle of each rib It tends to prevent postoperative neuritic pain in the area of the operation, and thus also helps to reduce voluntary "splinting" of the chest after operation with decrease of respiratory exchange The pleura is re-approximated with interrupted silk sutures The last two sutures are placed but not tied until the lung has been completely re-expanded by the anesthetist The muscles are closed in layers with interrupted sutures of No 3 silk throughout, and the skin is closed with silk (Fig 11) An alternative method of closing the pleural cavity is to place a No 18 catheter in the pleural cavity and close the pleura and wound about it, bringing the catheter out in a slanting manner When the wound is all sutured except the skin, the anesthetist re-expands

liver on the right side, and the spleen or colon on the left side (Fig 5) The incision in the diaphragm is carried forward through the decussation of the diaphragm with the transversus abdominis muscle

FIGURE 5 Incision through the Diaphragm and Underlying Peritoneum Carried Forward through the Transversalis and Oblique Muscles to the Outer Border of the Left Rectus Muscle Care is taken not to injure underlying organs, such as the spleen, kidney and colon

and, of course, through the oblique muscles as far as the outer border of the rectus muscle, thus opening the peritoneal cavity widely (Fig 6) A Finochietto rib retractor is used to separate the ribs,

at 8 cm. of negative pressure for forty-eight hours. Thereafter, if there is no further indication for its use, it is removed and the wound immediately covered with a vaseline-gauze dressing to prevent an air leak. A transfusion of 1000 cc. of whole blood is given at the time of the operation. Thereafter, blood is given only as indicated, and is usually not necessary.

The technic on the right side is similar (Fig 12-15).

Postoperatively, the patient is managed as a chest case. The quinidine and penicillin, with digitalis, if necessary, are continued. Streptomycin in addition may be necessary if the type of bacterial contamination from the kidney warrants it. The patient is turned every hour from his operative side to his back to help avoid atelectasis. Oxygen is given by nasal catheter until there is good aeration of both lungs. This may be for several days, but is usually only for twelve to twenty-four hours.

FIGURE 16 Photograph Showing the Healed Wound Ten Days after Operation

This method provides a fair concentration without interfering with the care of the patient as a tent does, or bothering him as a mask does. The Levine tube is attached to suction for a day or two. Morphine should be administered early and frequently, particularly in patients with coronary-artery disease, for by lessening pain it aids depth of respiration, and diminishes the combination of pain and anoxia that leads to undue restlessness postoperatively and may favor coronary occlusion. Care must be taken to give it in amounts that will not depress the respiratory rate unduly. Intravenous administration of fluids is performed slowly without saline solution (except when such a solution is specifically indicated) unless the patient is young and his cardiac status is good. The patient is allowed up usually on the first postoperative day, and is ready to go home in about ten days as a rule (Fig 16).

SUMMARY

The thoracoabdominal approach has been used in 39 cases for urologic operations—in 20 for kidney tumors (19 nephrectomies) and in 12 for

the exploration or removal, or both, of kidneys that were suspected of being malignant but turned out to be benign (usually large solitary cysts). In 2 cases it has been utilized to allow nephrectomy when the usual approach to the kidney was blocked by the ribs in kyphosis or scoliosis of the spine. In addition, by extending the lower end of the incision downward toward the pubis, it has been used for retroperitoneal dissection of the lymph nodes in the region of the kidney pedicle and along the aorta, vena cava and iliac vessels in 5 cases of carcinoma of the testis, and for complete nephroureterectomy in 1 case in which the tumor of the renal pelvis involved the ureter.

The experience with this incision in the surgery of 20 cases of renal tumor is discussed.

It is our opinion and that of our colleagues that the thoracoabdominal incision affords a much wider and better exposure of the kidney and its vascular pedicle than the extraperitoneal lumbar or the transperitoneal approach.

This wide-open exposure confers the following advantages: greater ease and safety in securing the vessels of the renal pedicle, less manipulation of the kidney before the renal vessels are secured, thereby minimizing the probability of squeezing malignant tumor emboli into the blood stream, increased ability to remove all the perinephric fat and capsule of Gerota with the kidney, increased ability to remove large and extensive kidney tumors, some of which have been found inoperable by another approach, increased ability to remove the malignant extension of renal tumors to the inferior vena cava or to regional lymph nodes, thus constituting a more adequate operation for cancer (such extensions were removed en bloc with the kidney in several cases), and, by early ligation of the renal vascular pedicle, elimination to a large extent of the bothersome and often dangerous hemorrhage from large veins that run over the surface of some kidney tumors.

Because the chest wound is held widely open by the rib retractor, less muscular relaxation is needed, and therefore less ether is used than when a comparable operation is performed through the abdominal musculature alone.

In these 20 thoracoabdominal operations for kidney tumor there has been no operative mortality or death in the hospital. Also, there have been no pulmonary emboli or cases of chest or peritoneal infection. (These statements are also true for the total of 39 thoracoabdominal urologic operations performed to date.) There have been only 2 complications, both of which were due to intrapleural hemorrhage. The first was minor, requiring only one thoracentesis, but the second was major, requiring several paracenteses for the removal of blood, as well as transfusions, and eventually a surgical decortication of the lung. The patient made a satisfactory recovery.

the lung with positive pressure, suction is applied to the catheter to empty the pleural cavity, and then the catheter is withdrawn. Great care is taken not to prick the lung with the needle while the pleural

pleural cavity. If there is any doubt, it is always wiser to drain. Drainage is achieved by means of a No. 22 Foley catheter with a 30-cc bag in-

tied off and brought against the chest wall. It is secured by a skin stitch as well. The chest catheter is connected to three-bottle chest-suction drainage

METHOD OF STUDY

The majority of the 77 women had prenatal care in the obstetric clinic or were delivered in this hospital. Eleven of them, however, had been attended and delivered by private physicians or had had no prenatal care and were delivered at home.

Detailed information regarding the maternal syphilitic infection was obtained in an interview with the patient, with special emphasis on the duration of the maternal infection, the results of all the patient's serologic tests and the amount of treatment received during and previous to pregnancy. Data regarding syphilitic infection in marital partners and other children were elicited whenever possible. Supplementary data were obtained from the hospital records, the city or county venereal-disease clinics, the State serologic laboratories and the patients' private physicians.

The diagnosis of congenital syphilis in the infants was based upon clinical findings, repeated quantitative serologic tests for syphilis, spinal-fluid studies, dark-field examinations and roentgenographic examination of the long bones. Approximately 80 per cent of the children showed what we consider to be definite roentgenographic evidence of osseous syphilis—that is, osteochondritis of the medial upper portion of the tibia, osteomyelitis and epiphysitis.⁴ Considerable care was taken in the interpretation of the serologic tests. No infant with latent syphilis was included in this study unless the serologic tests were found to be persistently positive in high titer. Almost all the patients in the group were infected before birth, since most of them showed overt manifestations of syphilis either at the time of delivery or very early in the neonatal period. Some of them, however, may have acquired syphilis by contact with infectious lesions at the time of delivery or in the early neonatal period.

NEGATIVE SEROLOGIC TESTS FOR SYPHILIS IN PREGNANCY

Several of the earlier studies on prenatal syphilis have shown that women with negative serologic tests in pregnancy may bear syphilitic children.² The low sensitivity of serologic tests was thought to be the cause of the negative serologic reaction in most of these patients, particularly in those with long-standing infections and previous therapy. With the increased sensitivity of serologic tests in recent years, such cases have become infrequent, and most workers now believe that women with persistently negative serologic tests will not bear syphilitic children.

Twenty-one patients in this study were known to have a negative serologic test in pregnancy and nevertheless delivered syphilitic children. In only 3 of these 21 patients was insensitivity of the Kahn and Kolmer tests considered to be the cause

of a negative reaction. These 3 women had a history of previous therapy for syphilis, and all of them continued to show negative, doubtful or very low titers in the absence of further treatment. The remaining 18 patients with negative serologic reactions in pregnancy demonstrated high serologic titers by the time of delivery or one or two weeks post partum. We believe that these 18 patients either were in the incubation period of the disease at the time of the negative test or acquired an initial or recurrent syphilitic infection later in pregnancy. Cutaneous manifestations of early syphilis were found in 5 of them at delivery or immediately post partum. Six of the 18 patients had been treated for syphilis prior to conception. Thus, a third of the patients in this series in whom syphilis developed during pregnancy had either a reinfection or a relapse of a previous infection, the remaining two thirds having contracted syphilis for the first time. The possibility that a technical error was the cause of negative serologic tests in pregnancy in these 18 patients is considered unlikely, since almost all of them gave a history of having had other negative serologic tests prior to conception. Moreover, the reactions to both Kolmer and Kahn tests were negative during pregnancy in 14 of the 18 patients.

The presence of active syphilis in the patients with negative serologic tests in pregnancy was not suspected, and no treatment was given before delivery. The diagnosis was made when a routine serologic test was obtained during labor or when the infection was suspected in the child. The lesions of early syphilis did not appear during pregnancy or were so inconspicuous as to have been overlooked by both the patient and the attending physician. Although pregnancy is generally believed to suppress the early lesions of syphilis, it does not produce a reduction in the titer of serologic tests or cause false-negative reactions.⁵ The diagnosis of syphilis in pregnancy could have been made in almost all these women if repeated serologic tests had been taken throughout the period of gestation. Only 2 women had a negative serologic test for syphilis at the time of parturition, both showed a high serologic titer within three months of delivery. The children of these 2 patients may have acquired syphilis before delivery during the incubation period of the maternal infection, or they may have been infected post partum. These children were not found to have syphilis until five to seven months of age, when they showed roentgenographic evidence of periostitis of the long bones.

The fact that clinic patients often acquire syphilis during the late stages of pregnancy has been noted by Beerman⁶ and Goodwin and Farber.⁷ These workers have emphasized the importance of repeating serologic tests during the last months of gestation to detect the presence of syphilis acquired

The patients varied in age from one year to seventy-seven years, and 5 patients were over seventy. The cardiac status of several of the patients was not good, and yet the postoperative recoveries were excellent, with the exception of a woman of seventy-seven who had temporary cardiac decompensation one week after operation.

Three case reports are presented.

This series is too small, and the length of follow-up study far too short to permit any true appraisal of end results, but the operative technic facilitated by this incision should improve the chances of cure and the end results.

On account of the excellent operative results with a minimum of complications and the frequency and unpredictability of local extension of malignant lesions of the kidney, the thoracoabdominal incision is recommended for all kidney tumors. We are firmly convinced that the important advantages that it confers are well worth the added effort of the necessarily more complicated operative procedure and of the more exacting preoperative and immediate postoperative care.

The technic of the operation and the preoperative and postoperative care are described.

We are indebted to Dr. Fletcher H. Colby for his encouragement in this work, and to him and to Drs. Wyland F. Leadbetter and George Gilbert Smith for permission to include some of their cases in this series.

SYPHILIS IN PREGNANCY*

A Clinical Study of Factors Responsible for Congenital Syphilis

ALBERT HEYMAN, M.D.,† AND JOHN R. MCCAIN, M.D.‡

ATLANTA, GEORGIA

THE incidence of infantile congenital syphilis has decreased considerably in the United States during the past two decades, nevertheless, cases continue to appear in significant numbers in most city hospitals.¹ Approximately 77 living infants with congenital syphilis have been treated at Grady Memorial Hospital in the past four years. Since congenital syphilis is preventable, it is necessary to inquire into the reasons for its continued occurrence.

Although several articles on factors influencing the outcome of syphilis in pregnancy have been published, the criteria for diagnosis of infantile congenital syphilis in many of these studies are no longer accepted. Thus, in the largest study reported that of the Clinical Cooperative Group,² the "information regarding transmission of syphilis to the child was limited to that obtained at birth." Similarly, in the study by Gammeltoft,³ a diag-

nosis of congenital syphilis was made when the "child as well as its mother gave a positive reaction, even in the absence of an eruption." Since the serologic test of both the umbilical-cord blood and that obtained in the neonatal period has been shown to have a limited diagnostic value, the accuracy of conclusions concerning the factors responsible for congenital syphilis in these studies is open to question.

Not only has the sensitivity and specificity of serologic tests for syphilis improved since the publication of these papers, but also many of the roentgenographic criteria for the diagnosis of congenital syphilis have undergone considerable modification. The presence of bismuth deposits or nutritional changes in the long bones, for example, was frequently misinterpreted as congenital syphilis.

For these reasons a reconsideration of factors responsible for congenital syphilis seems advisable. This paper presents a review of the syphilitic infection and therapy of the 77 mothers of the infants with congenital syphilis who were treated at the Grady Memorial Hospital in the past four years.

during pregnancy can probably be withheld with safety *provided* one can be absolutely certain that a positive serologic test in pregnancy represents seroresistance of an infection that has been adequately treated and not a recurrent syphilitic infection. This differentiation is often very difficult. Many workers attempt to differentiate on the basis of the height of the serologic titer, but this is not always helpful, since a low titer does not always indicate seroresistance and a high titer does not necessarily mean a recurrent infection. Complete data regarding the syphilitic infection are necessary, and information should be obtained regarding not only the amount and type of therapy received but also the duration of the syphilitic infection before treatment, the status of the patient's marital partner and children, and the changes in serologic tests before conception and during pregnancy. If any doubt exists about the interpretation of these data, retreatment during pregnancy should be instituted.

TREATMENT DURING PREGNANCY AND OUTCOME OF PREGNANCY

A minimal amount of arsenical therapy given during pregnancy has been claimed to be effective in the prevention of congenital syphilis. McKelvey and Turner⁹ have reported that the administration of 12 to 14 injections of an arsphenamine to syphilitic women during pregnancy resulted in noninfected infants in 100 per cent of their cases. It was with some surprise, therefore, that we found that several of our patients had delivered syphilitic children, even though they had received as many as 20 injections of arsenoxide (Mapharsen) in pregnancy. Half, or 16, of the 32 women who were treated in pregnancy had 11 or more injections of Mapharsen, 9 of these had 16 to 20 injections. Only one of these 16 patients, however, began treatment before the fifth month. This patient had 9 injections of Mapharsen early in pregnancy, became delinquent for ten weeks during the sixth to the eighth month, and then received 11 more injections in the last five weeks of pregnancy. It should be emphasized, therefore, that although 10 to 20 injections of arsenoxide are often sufficient to protect the fetus of a syphilitic woman, this amount is not always adequate, particularly when given in the last half of pregnancy. The number of syphilitic children in this series born of mothers who had had what is generally considered "adequate" arsenical therapy in pregnancy is further evidence that this form of treatment should be replaced by penicillin.

Most workers now believe penicillin to be the drug of choice in prenatal syphilis. This form of therapy is not only more effective than arsenicals but also relatively nontoxic and can be given in a short period. Furthermore, it is valuable during the last trimester of pregnancy, a time when arsenical therapy is least useful. Penicillin has been shown

to be effective in the last few days of gestation, even when the child is already infected. We have observed a case in which delivery occurred on the seventh day of penicillin therapy after the patient had received 4,000,000 units of the drug in aqueous solution.¹⁰ The infant had a strongly positive serologic test and showed definite evidence of osseous syphilis by roentgenographic examination. The lesions of the long bones healed spontaneously, and the Kahn titer became and remained negative without further therapy, indicating that the child had received sufficient penicillin before birth for the infection to be cured. Similar cases have been reported elsewhere.¹¹ It must be emphasized, however, that penicillin is not uniformly successful for patients treated late in pregnancy. We have observed 2 patients, not included in this series, who were treated in the last trimester and delivered syphilitic, stillborn infants immediately after penicillin therapy. Death of the fetus was apparently caused by an overwhelming syphilitic infection.

In the present study only 1 patient who had completed the course of penicillin therapy during pregnancy delivered a syphilitic child. This patient received 4,800,000 units of crystalline penicillin G in aqueous solution during the fourth month of pregnancy. At that time the serologic test was positive with 40 Kahn units, and she had secondary syphilis. The Kahn titer fell to 4 units three weeks before parturition, but rose to 40 units two days before the syphilitic child was born, and before retreatment could be instituted. A recurrence of the maternal infection prior to delivery, as in this case, is one of the causes of congenital syphilis in infants born after penicillin therapy. Although it is infrequent, such a possibility should be kept in mind. Serologic tests should be taken at monthly intervals throughout pregnancy, and possibly more frequently near term. Retreatment with penicillin should be given during pregnancy if there is any doubt of the possibility of infectious or serologic relapse.

DISCUSSION

This study was stimulated by an attempt to determine the reasons for the large number of syphilitic infants delivered in or referred to this hospital. The presence of negative serologic tests in pregnancy and the inadequacy of arsenical therapy were responsible for the infection in two thirds of these infants. A number of other factors are believed to be of great importance in the transmission of congenital syphilis. Foremost among these is the failure of clinic patients to come for prenatal care early in pregnancy. One fourth of the 77 patients in this series did not receive any treatment during pregnancy because they came to the hospital just prior to or after the beginning of labor. Still others received inadequate therapy because they sought prenatal care late in pregnancy.

late in pregnancy. This practice, however, has not been a routine procedure in Grady Memorial Hospital. If followed, it should have permitted prevention of syphilitic infection in approximately 20 per cent of the children in our series. Although the need for repeating negative serologic tests in pregnancy is generally recognized, many physicians believe the procedure to be impractical, especially in large obstetric clinics. Repeated tests, particularly in the last eight weeks of gestation, are absolutely necessary, however, if the incidence of congenital infection among a clinic population with a high rate of syphilis is to be reduced to a minimum.

DURATION OF MATERNAL SYPHILIS AND OUTCOME OF PREGNANCY

It has been observed that women with early syphilis are more likely to bear syphilitic children than those with late syphilis. Nevertheless, there are numerous reports of transmission of congenital syphilis as long as ten to twenty years after the mother acquired the disease. Although most of these reports are not well authenticated, conservative opinion holds that antisyphilitic therapy should be given during each pregnancy, regardless of the duration of the maternal infection.

Information regarding the duration of syphilis in the patients in our study was based chiefly on serologic tests and dark-field examinations made in this hospital or in the venereal-disease clinics. Most of the patients had attended the hospital clinics for many years, and a number of routine serologic tests had been taken prior to their pregnancies. The results of these tests and the clinical history of syphilis as obtained from the patient enabled us to determine with reasonable accuracy the duration of syphilis in 57 of the 77 patients. It was noted that 53 of the 57 patients in whom the duration of the disease could be determined had acquired syphilis or an infectious recurrence less than five years before delivery of the syphilitic child. This information was based on a definite record of negative serologic tests within five years previously or on a positive dark-field examination during that period. Fourteen of the 53 patients had acquired an initial syphilitic infection as long as eight years or more before delivery of the syphilitic child. These 14 patients, however, received sufficient treatment to produce a negative serologic test within four years prior to delivery, and then had either a relapse of the initial infection or a reinfection that was transmitted to the infant.

Only 4 patients were known to have a persistent infection for more than five years prior to the birth of a syphilitic child. This information is based on a record of a positive serologic test five or more years before delivery. Two of these 4 patients had had syphilis more than six and seven years before delivery and were among those discussed above as having had negative and doubtful serologic re-

actions in this pregnancy resulting from insensitivity of the tests. The remaining 2 women with late syphilis had acquired the infection about seven and eleven years previously and had never received treatment prior to delivery of the infected child. The fact that patients such as these, with late syphilis, can deliver infected children, appears to support the current practice of treating syphilis in pregnancy regardless of the duration of the disease.

TREATMENT BEFORE PREGNANCY AND OUTCOME OF PREGNANCY

The pregnant syphilitic woman has always been regarded as a potential source of infection for the fetus, even though she may have had sufficient treatment to prevent the transmission of the disease to her marital partner. For this reason, re-treatment of syphilis in pregnancy has been advised regardless of the amount of therapy the patient may have received previously. Recently, this concept has been questioned, and antisyphilitic therapy in pregnancy has been deliberately omitted in a series of selected patients who had had what was considered adequate arsenical or penicillin therapy prior to pregnancy. Goodwin and Farber⁷ have reported the outcome of pregnancy in 385 patients, 22 of whom had been treated with penicillin alone. These patients have been observed through 570 pregnancies, none of which resulted in a syphilitic infant. The adequacy of penicillin in protecting the fetus from syphilitic infection in subsequent pregnancies has also been studied by Ingraham and his associates,⁸ who found that none of 52 women treated for syphilis before, but not during, pregnancy delivered syphilitic children. These workers emphasized that the patients in whom treatment in pregnancy is to be omitted should be carefully selected and that constant observation should be made during pregnancy for evidence of serologic or infectious relapse.

Approximately three fourths of the 77 women in our study had not received any treatment for syphilis before the pregnancy that resulted in a syphilitic child. Only 5 patients were thought to have had "adequate" treatment before pregnancy,⁴ of these had been given from 16 to 32 injections of an arsenical and bismuth preparation each, and 1 patient had been treated with more than 2,000,000 units of penicillin. In all 5 women, however, the syphilitic infection recurred (manifested by either infectious lesions or serologic relapse) just prior to or during the pregnancy that resulted in a syphilitic infant. None of the women had received any treatment for the recurrent infection before pregnancy.

It appears, therefore, that the interpretation of what constitutes "adequate" therapy before pregnancy depends not so much upon the amount of treatment administered as upon the course of the disease after therapy. Treatment of syphilis

THROMBASTHENIA AND THROMBOCYTOPENIC PURPURA*

Report of Case Demonstrating Qualitative and Quantitative Inadequacy of Platelets

BENJAMIN ALEXANDER, M D,† AND GRETA LANDWEHR, S B ‡

BOSTON

RECENT advances in the knowledge of blood coagulation clarify understanding of the hemostatic defect underlying various hemorrhagic disorders. The pathogenesis of hemorrhagic disease is usually attributable to disturbed retractility of the small blood vessels, as in vascular and allergic purpura, thrombocytopenia, deficiency of anti-hemophilic "globulin" — hemophilia[§], insufficiency of prothrombin or its accessory factors — for example, hypoprothrombinemia, parahemophilia,² deficiency of prothrombin A³ and accelerator globulin deficiency⁴, fibrinopenia, and presence of circulating anticoagulants — heparin⁵ or heparin-like substances.⁶

There are, however, clinical conditions in which the nature of the hemostatic dysfunction is obscure, such as those designated as "hereditary hemorrhagic thrombasthenia"⁷ and "pseudohemophilia"^{8,9}. Glanzmann⁷ ascribed hemostatic failure in his subjects to a qualitative abnormality of the platelets because of their bizarre appearance and delayed clot retraction. Von Willebrand and Jürgens⁸ also described platelet abnormalities in their patients, and concluded that the hemorrhagic phenomena were due to defective platelet agglutinability.

The purpose of the present communication is to report data in a patient with pseudohemophilia that demonstrate that the hemorrhagic tendency was associated with a qualitative defect in the patient's platelets despite their normal number. Subsequently, the patient developed thrombocytopenia suggesting a possible relation between purpura of the Glanzmann and von Willebrand type and idiopathic thrombocytopenic purpura.

CASE REPORT

A 40-year-old married truck driver (P B B H 384)¶ was admitted to the Peter Bent Brigham Hospital on March 27, 1949, because of hemorrhage. One month before, he had noted bleeding from the palate, gums and nose, and expectoration of blood-streaked sputum. Six days prior to admission he experienced corvza and slight cough, and observed small red spots on his leg. He took several "four-way cold tablets" (aspirin, quinine, magnesium hydroxide and phenol-

phthalein). He was also aware of easy bruising and some hematuria. Except for a bilateral epistaxis 2½ years before admission there had been no hemorrhagic phenomena.

The family history revealed no bleeding tendency in the parents, or in 3 sisters and 1 brother.

At age of 18 the patient had gonorrhea, and he remembered an indurated, painless "cold" sore on his lip that could have been a chancre. After the incidental discovery of a positive serologic test in 1943 he received 4 courses of Mapharsen and 5 courses of bismuth. In 1945, because of a persistently abnormal spinal fluid, he was given 10 paroxysms of malarial fever and 13 2-gm doses of Triparsamide. There had been no neurologic, cardiac or genitourinary symptoms.

For several years the patient had been taking 1 teaspoonful of "Bismarex" or "Bisodol" daily because of epigastric postprandial distress. (These antacids contain bismuth subcarbonate.) The past history was otherwise irrelevant. There had been no exposure to other drugs or toxic chemicals, and there was no allergic history.

Physical examination revealed a well developed, well nourished man with confluent purpura over the arms, hips and thighs. The pupils were Argyll-Robertson in type. The mouth showed petechial hemorrhages on the hard palate, upper gums and buccal mucosa. The lower gums, which revealed some gingivitis, bled on pressure. There were a few small cervical submandibular and left axillary lymph nodes. The lungs and heart were normal. The liver and spleen were not palpable. Reflexes were normal. The blood pressure was 135/70. X-ray study of the abdomen and bones was negative.

The urine was normal except during the first several days, when the sediment was packed with red cells. Examination of the blood revealed a red-cell count of 4,200,000, with a hemoglobin of 14.1 gm per 100 cc, a hematocrit of 43 per cent and a normal white-cell count. For the first several days the smears showed abundant platelets.

On March 28 the platelet count was 204,000, the bleeding time (Duke method) 65 minutes and the clotting time 6 minutes (Lee-White method). The clot failed to retract within 32 hours. The prothrombin time was 17 seconds (control, 17 seconds). Capillary fragility (Rumpel-Leede technic) was markedly positive. On April 3 the bleeding time was 25 minutes, and the clotting time 9 minutes, clot retraction again was poor. On April 9 capillary fragility was again markedly increased. On April 13 the platelet count was 8000. On April 23 the bleeding time was 5 minutes, and the clotting time 8 minutes, the clot failed to retract. No platelets could be seen on the blood smear. On April 5 the platelet count was 25,000. A bone-marrow aspirate showed numerous megakaryocytes by direct smear and in fixed section. Two protamine-heparin titration tests were normal.

The stools consistently showed + to ++++ tests for occult blood.

Because he showed progressive clinical improvement despite the thrombocytopenia that developed, the patient was discharged on April 5 to return to the Out-Door Department for further observation. The low platelet count, high bleeding time and increased capillary fragility have persisted till the present time.

Studies of the Coagulation Defect||

Methods. Platelets were counted by the Rees-Ecker method.¹⁰ Recalcification times were determined at room temperature on oxalated plasma (1 part of one-tenth molar sodium oxalate to 9 parts of blood) to which was added one-fifth volume of 1 per cent calcium chloride solution.

Plasma prothrombic activity was determined by the modified one-stage procedure of Rosenfield and Tuft,¹¹ in which

¶It is still uncertain whether hemophilia is referable to a deficiency in anti-hemophilic globulin or to a circulating anticoagulant anti-cephalin or both.

¶We are indebted to Drs. Clement Finch and Stuart Finch of the Peter Bent Brigham Hospital, Boston, for making this case available for study. The data in the case report are from the records of that hospital.

or became delinquent after a few treatments. Although the use of penicillin in such patients would have prevented some of the congenital infections, there is no doubt that the prevention of congenital syphilis is largely a matter of public-health education. Women should be urged to seek prenatal care early in pregnancy.

In a few cases the attending physician did not establish the diagnosis of syphilis sufficiently early or did not institute immediate or vigorous anti-syphilitic therapy. Several of our patients were attended by private physicians, who neglected to take blood for serologic tests.

SUMMARY

A clinical study of the factors responsible for the transmission of infantile congenital syphilis was made by a review of the records of 77 women who delivered syphilitic infants.

Approximately a fourth of these women had negative serologic tests for syphilis in pregnancy and, for this reason, had not received any prenatal treatment for syphilis. The majority of these patients are believed to have been in the incubation period of the disease at the time of the negative test, or to have acquired an initial or recurrent syphilitic infection later in pregnancy. The importance of repeating serologic tests near term to detect syphilis acquired late in pregnancy is emphasized.

The duration of the maternal infection was almost always less than five years prior to birth of the syphilitic infant. An occasional patient transmitted syphilis to her child even though she had

had the disease for as long as eleven years previously.

Half the women who were given prenatal treatment had received 11 to 20 injections of arsenoxide during pregnancy. The inadequacy of arsenical therapy given late in pregnancy is pointed out. Penicillin therapy is believed to be the treatment of choice in prenatal syphilis and will probably result in a considerable reduction in the incidence of congenital infection.

The most important measure, however, in the prevention of congenital syphilis is greater education of pregnant women, who should be urged to seek prenatal care early in pregnancy.

the family does not exclude this interpretation since in many cases a positive family history cannot be elicited.⁹

The experimental data, obtained during this time, also were like those found in thrombocytopenic purpura — namely, high residual serum prothrombic activity and prolonged recalcification time. Since normal platelets added to the patient's deplateletized plasma rectified this clotting defect, and conversely, addition of the patient's platelets to normal plasma deprived of its platelets did not correct the abnormality thus induced, one must conclude that the patient's platelets were inherently defective and unable to function normally. The addition of normal platelets to thrombocytopenic blood similarly corrects its clotting defect.¹³ Thus, except for the normal number of platelets, the patient's blood was indistinguishable from thrombocytopenic blood.

Progression of the disease to thrombocytopenia is of considerable interest. Had the patient been first seen at this point, a diagnosis of idiopathic thrombocytopenic purpura would have been considered correct. It is difficult to relate the underlying condition to the syphilis or to possible acquired sensitivity to bismuth, which the patient had been taking in the form of antacids. The finding of a normal bone marrow containing numerous megakaryocytes helps exclude thrombocytopenia on the basis of chemical destruction.

The sequence of thrombocytopenia following thrombasthenia suggests the possibility that idiopathic thrombocytopenic purpura is sometimes preceded, if only for a short time, by abnormal platelets that are removed from the circulation. In this connection, previous observations¹³ on a patient with thrombocytopenic purpura treated by splenectomy may be significant. Although the platelet count in this subject returned to normal after the procedure, coagulation was still abnormal, suggesting some qualitative inadequacy of the platelets. She suffered a relapse within a few months.

Means are now available to detect functional abnormality of platelets in patients with hemorrhagic phenomena. The finding of abnormally high residual prothrombin in the serum indicates inadequate conversion of prothrombin to thrombin. A normal plasma prothrombin time will exclude as its cause deficiency of any factor in the prothrombin constellation — labile factor, prothrombin A, accelerator-globulin, factor V or the factor of Fantl and Nance¹⁷ as well as fibrinogen. Subnormal prothrombin conversion can then be referable only to inadequate evolution of thromboplastin that is due to hemophilia, which can be readily excluded, thrombocytopenia, thrombasthenia or circulating anticoagulants. The last is easily demonstrable by the prolonged clotting time as well as the retarding effect of the plasma in question on the clotting time of normal blood or plasma.

No method for precise measurement of the functional capacity of platelets has yet been devised. On the basis of the above observations one might propose the following procedure: addition of the platelets in question to normal plasma, drawn and deprived of its platelets with meticulous precautions against platelet breakdown according to the technic of Brinkhous.¹⁴ The mixture of normal platelet-free plasma with the platelets to be studied could then be recalcified, and residual serum prothrombic activity determined. Normally no prothrombin should be demonstrable. The amount of prothrombin remaining in the serum should be a measure of thromboplastin evolving from the platelets since all other clotting factors important in prothrombin conversion will have been provided or adequately controlled. This method is being evaluated.

SUMMARY

Functional inadequacy of platelets (thrombasthenia) associated with hemorrhagic phenomena occurs. This was demonstrated by observations on a patient with purpura, elevated bleeding time, increased capillary fragility, poor clot retraction, normal platelet count and normal clotting time. He showed a coagulation defect indistinguishable from that observed in thrombocytopenic purpura, reflected in an elevated recalcification time and high residual serum prothrombic activity.

This could be rectified by the addition of normal platelets to the patient's deplateletized plasma, whereas the patient's platelets were unable to correct the coagulation defect induced in normal plasma by deprivation of its platelets.

The platelet count, at first normal, later dropped to thrombocytopenic levels. This suggests a possible relation between thrombasthenia and idiopathic thrombocytopenic purpura.

The detection of thrombasthenia is discussed. A method for measuring the functional capacity of platelets is proposed.

normal plasma rendered prothrombin-free by adsorption with barium sulfate is used as a diluent for the test plasma. Residual serum prothrombic activity was similarly measured on serum from blood allowed to clot spontaneously, or from oxalated plasma that was recalcified.¹² The serum was separated 1 hour after coagulation, oxalated (1 part oxalate to 4 parts serum), and then incubated for 15 to 30 minutes at 37°C to inactivate thrombin.

Results On March 29 the patient had 275,000 platelets per cubic millimeter of oxalated plasma (well within the normal range in our laboratory). Plasma prothrombic activity was 90 per cent, whereas the residual serum prothrombic activity (one-stage method) was 130 per cent. This observation, in agreement with those obtained in thrombocytopenia,¹³ indicated a distinct coagulation defect despite the normal platelet count and clotting time.

Further studies were done in which the patient's platelets were transferred to deplateletized normal plasma and normal platelets transferred to deplateletized patient plasma. On March 31 oxalated plasma (158,000 platelets per cubic millimeter) from the patient and from a normal subject (182,000 platelets per cubic millimeter) were centrifuged at 15,000 r p m in the multispeed attachment of the International Centrifuge for 15 minutes at 7°C. The supernatant

The following additional observations were made on April 4 the patient's platelet count was 212,000 per cubic millimeter of whole blood, and plasma prothrombic activity was 106 per cent, whereas residual serum prothrombic activity was 95 per cent. On April 7 the plasma contained 84,000 platelets per cubic millimeter. The patient's residual serum prothrombic activity was still elevated (80 per cent of the parent plasma). On April 11 the platelet count was 57,000 per cubic millimeter of capillary blood and 50,000 per cubic millimeter of oxalated venous blood.

The accelerating effect of the patient's plasma on the coagulation of blood from a patient with known hemophilia was normal. This helped exclude a diagnosis of hemophilia.

It is thus evident that early in the course of the disease, despite the normal platelet count, the patient's blood showed the following evidence of defective coagulation: prolonged recalcification time and high serum prothrombic activity. This could be rectified completely by the addition of normal platelets to the patient's deplateletized plasma, whereas the patient's platelets could not correct the abnormality induced in normal plasma by removal of its platelets.

Within 2 weeks of admission thrombocytopenia developed and has persisted until the present.

DISCUSSION

Although the role of platelets in the hemostatic mechanism is not entirely understood, certain facts have been clearly established. Reduction in platelet number is associated with hemorrhagic phenomena, prolonged bleeding time, abnormal clot retraction and disturbed capillary retractility. Also, a clotting defect has recently been demonstrated in spontaneous thrombocytopenia and in blood from which the platelets are artificially removed: coagulation is retarded,¹⁴ prothrombin consumption is reduced, and residual prothrombic activity in the serum is elevated.^{13, 15} This is in accordance with the general opinion that the platelets are required for the elaboration of thromboplastin.

The degree of thrombocytopenia necessary to induce the clinical and laboratory manifestations of purpura varies from patient to patient,¹⁶ and suggests that qualitative differences in the platelets are important. Furthermore, the existence of normal platelet counts in cases demonstrating many features commonly associated with thrombocytopenic purpura raises suspicion that the quality of the platelets in these subjects may be poor.

The observations in the case reported above indicate that such aberrations in platelet function actually occur. Early in the course of his disease the patient showed the salient clinical manifestations of thrombocytopenic purpura despite normal platelet counts: bleeding into the skin and from the mucous membranes, increased bleeding time, normal clotting time, increased capillary fragility and poor clot retraction. Although this case may have been unique, these features justify a diagnosis of "thrombasthenia" or "pseudohemophilia," since in this syndrome the platelet count is usually normal, the bleeding time is variable, the clotting time of venous blood may be normal or increased, clot retraction is usually normal but may be poor, and capillary fragility may be normal or markedly increased. The absence of a bleeding tendency in

plasmas, carefully separated from the platelet pellets, contained 14,000 and 18,000 "platelets" per cubic millimeter respectively.

The sediments were washed twice with physiologic saline solution. The patient's platelets were then dispersed with vigorous agitation in a volume of platelet-poor normal plasma equivalent to the plasma from which the patient's platelets were derived, giving a mixture with a final platelet count of 167,000 per cubic millimeter. Similarly, the normal platelets were suspended in the patient's plasma, yielding a final count of 235,000 per cubic millimeter. Recalcification times and residual serum prothrombic activities were determined.

The recalcification time of the patient's whole plasma was distinctly greater than normal (Table 1). As anticipated, removal of platelets from both types of plasma retarded coagulation considerably. Addition of normal platelets to the patient's deplateletized plasma restored the recalcification time to normal. In contrast, the recalcification time of the normal plasma containing the patient's platelets was abnormally prolonged, and was the same as that of the patient's whole plasma.

The prothrombic activity of serum obtained from recalcification of the patient's whole plasma exceeded that of the parent plasma, as did serum from the patient's blood allowed to clot spontaneously (as described above). In contrast, serum similarly derived from whole normal plasma showed no prothrombic activity. Recalcification of normal plasma deprived of its platelets yielded serum that contained substantial prothrombic activity. This was somewhat reduced when the patient's platelets were added to the platelet-poor normal plasma. However, serum obtained from a mixture of normal platelets with the patient's platelet-poor plasma was devoid of prothrombic activity just as serum obtained from whole normal plasma.

not between right and wrong, but between good and better, and so discrimination and good taste are continually sharpened and polished by practice. Most serious educators will still agree with the thesis that the main purpose of education is to teach one how to think rather than what to think. Yet modern education seems more and more exclusively to offer opportunities for the simple accumulation of usable facts. Such factual knowledge, without the wisdom to apply it, is of limited value. Osler once made the following penetrating statement:

After all, the greatest difficulty in life is to make knowledge effective, to convert it into practical wisdom. We often confuse the two, and we think they are identical. But, far from being one, they often have no connection whatever.

Wisdom is the result of experience in a man who can profit by it because he has cultivated the ability to use his mind well. Unfortunately for the future, the medical student is a tender plant more often watered with a jet of "scientific method" than with the gentle rain of culture, so knowledge grows while judgment withers.

It is a reflection on the critical faculty of physicians that a spark, kindled in 1928 by Fleming, was allowed to smoulder unheeded for over ten years before it burst into therapeutic flame, and that Mendel's doctrine was allowed to hibernate for thirty years before it saw the light of recognition. Again, the Schemm regime is often thought of as an innovation. It is overlooked that, as Dr Schemm himself recalls, Sir Thomas Witherly reported in 1690 his winecooper who cured his own prodigious dropsy by ingesting 14 quarts of water in ten hours.

Such flowers of progress are left to blush unseen in the dark, unfathomed recesses of the library stacks, while doctors busy themselves about their little, self-important papers, intent on adding their special "gem" to an already embarrassing wealth of publications. They are apt to forget that the empty vessel makes the greatest sound. Such a premium is set on "getting something published" that the journals are too often full of forests of trivialities in which one cannot see true landmarks for the trees.

Finally, a classical education can be of help by giving an interest in a really beautiful study: the study of peoples in their prime, of civilizations at their best, of poetry and drama in their heyday. This may seem flat and unprofitable to the exclusive moneymaker, but it is an interest that time does not destroy. Education is the only worldly possession that cannot be lost until one loses one's senses. Moreover, the average patient prefers to consult a doctor with an education and a soul — and so it has even its material reward.

When the soured, thrombosed moneymaker retires to live on his store of gold, how empty is his existence compared with that of his colleague who has developed "occupations that will render life more dignified and useful." He must either fall into the spinsterly prerogative of minding other people's businesses or else resign himself to stale and weary boredom. As Osler said so well, "You may find too late, with hearts given away, that there is no place in your habit-stricken souls for those gentler influences which make life worth living."

ACRIBIA

HENRY J L MARRIOTT, M A, B M (Oxon)*

BALTIMORE

THE practice of medicine is said to be an art as well as a science. Certainly at its best it is a happy blend of both. But today science is nurtured at art's expense, with the unhappy result that doctors are more and more enthralled by numbers and devices, and less and less concerned to cherish precision of their own. Yet this personal precision is as much to be desired as it is sorely lacking, both in clinical skill and in literary expression. The Greeks, as usual, had a word for it, *ἀκρίβεια*, whose shades of meaning have been well translated "exactness, literal accuracy, precision, niceness of sense." Hippocrates, who called medicine "The Art" (and there was little that one would call "scientific" in his art), emphasized the need for this faculty. This need is as great today as it was yesterday.

With so much in medicine that is still inexact, it is the greater pity that inaccuracies have been allowed to taint the medical vocabulary. When a disease is named, for instance, one should be sure one knows what the adopted word means. Yet "erythromelalgia" has recently been attached uncomfortably to a form of headache. This is as good, or as bad, an example as one can hope to find of the crime that Oliver Wendell Holmes called "verbiage." In this particular case there is less than usual excuse, because Weir Mitchell, in his original description of the disease, adds an explicit footnote to his title, "the foot and hand disorder I am about to describe may be conveniently labeled Erythro-mel-algia, ἐρυθρός, red, μέλος, a member, ἄλγος, pain." Thus the new syndrome, "erythromelalgia of the head," can only mean, if words mean anything, "pain in the red limbs of the head," which is anomalous to say the least. If an affection of the head, analogous to erythromelalgia, is to be given a name, "erythrocephalgia" is all that is required. Another lapse is the not infrequent use of "anhidrosis" for "absence of sweating." This is a natural enough mistake, supposedly because the writer believes that the word is compounded from the stem hydro- (water), it is of course derived from ἰδρῶς (hidros), sweat,

and the word is, and has been for 2400 years since Hippocrates used it, anidrosis, or often with the "h" retained, anhidrosis. "Pruritis" is another misbegotten child, the word is pruritus, and has nothing to do with the "-itis" that usually connotes inflammation. Its ending is the same as that in tinnitus and exitus, and it has survived and been used by medical writers since the time of Pliny (70 A.D.). Therefore, it deserves at least the respect of age.

Such inaccuracies may seem trivial, and, indeed, in themselves, they are. But they are a symptom of a too prevalent syndrome, the etiology of which is indifference for literal accuracy, and indeed for any education that aims at "niceness of sense" without being strictly utilitarian. If the matter is given any careful thought, however, there are many apparent reasons why a cultural, nonscientific education, including a more than passing knowledge of the classical languages, is of great and lasting value to physicians. It is an asset that will accumulate interest with the passage of the years. For "the real object of education is to give children resources that will endure as long as life endures, habits that time will ameliorate, not destroy, occupations that will render sickness tolerable, solitude pleasant, age venerable, life more dignified and useful, and death less terrible."

First, and least important, a classical education makes the understanding of medical terms easier and more interesting, and therefore encourages a more exact and careful usage of them.

Secondly, it teaches the English language better than any other form of education. The mental gymnastics that are inevitable (because of the entirely different classical idiom) in construing from Latin and Greek into English, and vice versa, teach one the meaning and use of one's own tongue as nothing else can. The writings of medical men are consistently referred to as "literature," but that dignity is seldom deserved.

Thirdly, the classics are a real education in the sense that they teach one *how* to think. No other training so constantly involves the exercise of judgment. There is always a decision to be made,

physiologic role of vitamins, as well as leading to the discovery of new substances, but the limitations of this review permit no more than occasional reference to them. Answers to the questions posed will be approached through the following major subdivisions: standards of minimal and optimal vitamin intake, nutritional surveys and subclinical vitamin deficiency, reports of specific therapeutic uses of vitamins, newer vitamins, toxicity of vitamins, and antivitamins and vitamin imbalance.

STANDARDS OF MINIMAL AND OPTIMAL VITAMIN INTAKE

A knowledge of the minimal requirements for the various vitamins is an aid in evaluating the need for wholesale supplementation of the American diet with multivitamin capsules. Commercial advertising frequently stresses a widespread inadequacy of vitamins in food intake. The validity of these claims is open to question when the available information about minimal requirements and limitations of vitamin therapy is reviewed. Opinion varies about what constitutes the minimal requirement for any given vitamin. One theory is that the minimal requirement is the smallest amount sufficient to prevent clinical manifestations of deficiency. This value can be determined for thiamine, vitamin C and with less certainty for vitamin A, riboflavin, niacin and vitamins D and K—that is, vitamins in whose absence or deficiency specific signs or symptoms of avitaminosis have been recognized in man. In view of the fact that most deficiencies are multiple,³⁻⁶ the clinical determination of minimal requirements has depended upon the experimental production of a specific deficiency by restriction of that vitamin. An objection to this approach is that such conditions are abnormal and, with thiamine at least, reduction of intake may affect body metabolism and secondarily its thiamine requirement.¹¹ I believe that such an objection is more theoretical than actual and that determination of minimal vitamin requirement by the experimental production of a clinical deficiency is a valuable technique.

The clinical investigation of requirements for the other known vitamins is limited by the absence of specific signs or symptoms of deficiency in man. Large body stores of some vitamins and endogenous synthesis of others add to the difficulties of establishing the minimal demands.

There are many investigators who believe that the minimal requirement for a vitamin should prevent subclinical deficiency,³⁻¹² a state of physiologic and biochemical derangements that cannot be detected clinically.¹¹ The need for more delicate methods for defining subclinical deficiency has led to biochemical and biologic measurements of blood and urinary excretion levels for some of the vitamins. There is great variation in the analytical methods

and little agreement concerning what level of tissue saturation represents the critical point of subclinical deficiency for any given vitamin. I wonder if the biochemical level below which a subclinical deficiency exists varies with the emotional bias of the investigator toward clinical or subclinical deficiency standards and with his enthusiasm for vitamin therapy. Moreover, the blood levels of vitamin A¹³ and the urinary excretion values of riboflavin, N-methyl nicotinamide, biotin and folic acid may remain relatively constant for long periods in spite of changes in intake or may fluctuate greatly without correlation with intake or with physical status of the patient.¹⁴⁻²⁰ For these reasons it is difficult to establish by laboratory methods which levels indicate the minimal requirement of various vitamins necessary to prevent a subclinical deficiency.

Vitamin A

Man has such large stores of vitamin A in his liver²¹ that determinations of the minimal requirement by experimental development and prevention of clinical signs of vitamin A deficiency have been difficult and few. On the basis of animal studies, Embree⁷ has estimated that the minimal requirement of vitamin A is one tenth of the optimal requirement. If this estimation can be applied to man, the minimal requirement might be 500 to 600 international units per day. By maintaining a normal subject on a vitamin A deficient diet for approximately 598 days, producing a significant fall in the plasma vitamin A level from 133 to 76 IU, Hartzler²² found that administration of 2000 to 3500 IU of vitamin A per day was sufficient to stabilize the plasma level or even raise it slightly.

Using the maintenance of normal dark adaptation as the end point, another investigation²³ showed that the minimal requirement for vitamin A averaged 40 IU per kilogram of body weight in 5 subjects (range, 25 to 56 IU). For a man weighing 70 kg this would require 2800 IU of vitamin A. However, many investigators think that the dark-adaptation method is unreliable. These limited studies suggest that any intake above 3000 IU of vitamin A per day is adequate, but, in calculating the intake, one must make allowance for the large proportion of unavailable carotene in vegetables.²³

Thiamine

Studies of minimal requirements have been more extensive for thiamine than for other vitamins, possibly because the symptoms of thiamine deficiency dominate the picture of vitamin B inadequacy.¹⁴ If the minimal requirement is based upon prevention of clinical symptoms, two reports²⁴⁻²⁵ from China and the Philippines agree that 0.4 mg of thiamine per 1000 calories is the critical level of intake, below which frank beriberi appeared. The re-

MEDICAL PROGRESS

VITAMIN SUPPLEMENTATION IN HEALTH AND DISEASE*

PERRY J. CULVER, M.D.†

BOSTON

THE importance of vitamins in nutrition has been so forcefully and repeatedly stressed by radio, newspaper and word-of-mouth advertising that the general public is most receptive to the inclusion of vitamin supplements in daily diets. Any report that implies or promises alleviation of chronic or incurable illness by the use of a vitamin preparation excites further demand for vitamins. The magnitude of vitamin consumption in this country is evidenced by the fact that the annual sale of vitamins in the United States amounted to \$188,000,000 in 1947¹. There was a 300 per cent increase (from \$15,000,000 to \$45,000,000) in the sale of costly, high-potency preparations between 1945 and 1947. The commercial outlets for vitamins¹ showed that a considerable proportion of the sales are for self-prescribed vitamins rather than for those on physician's prescription. Of the total \$188,000,000 sales in 1947, \$26,000,000 were made through mail-order houses, department stores, grocery stores and variety stores.

That the public is not alone in its intense interest in vitamins is manifest. In the last four years since the subject of vitamins was reviewed,² three or four thousand articles covering various aspects of vitamins have appeared in medical journals throughout the world. Among these were several careful surveys of specific topics.

Cowgill³ presents a conservative but thought-provoking discussion of some of the clinical applications of research in the field of vitamins. Salient points include a consideration of the causes for great individual variation in vitamin requirements, the controversial topic of subclinical vitamin deficiency, the nonspecificity of the so-called signs of vitamin deficiency, and mention of some vitamin interrelations and of antivitamins. Cowgill's paper does not pretend to be encyclopedic, it is, rather, a delightful discussion of some recent advances in the knowledge of vitamins.

A concise, factual tabulation of all the vitamins, with brief outlines of their chemistry, indications and requirements, is presented by Harris.⁴ Useful information about the members of the vitamin B complex is completely reviewed by Elvehjem.⁵ This paper deserves attention. Gnipwall⁶ emphasizes

subclinical states of vitamin B deficiency and discusses etiologic factors but data to support some of his statements are lacking. In addition, he is inconsistent. He indicates the need for massive doses (20 to 40 mg) of thiamine and then discusses a case of ariboflavinosis that developed after therapy with thiamine. He appears to recognize vitamin imbalance but does not consider it in his therapeutic advice.

The role of the fat-soluble vitamins is discussed in a brief but fairly complete review by Embree.⁷ The history of folic acid up to 1947 and its therapeutic uses are covered by Sargent.⁸ One final review is an excellent summary of antivitamins. Wright⁹ discusses this complex subject in simple, understandable terms.

In view of the large number of conflicting reports concerning the beneficial effect of various vitamin supplements, another review of the vitamin literature published during the last four years, with emphasis upon vitamin requirements and on the value of vitamin supplements, seems timely. The following questions are considered.

Is there objective evidence to justify such a tremendous use of vitamin supplements?

Does the promiscuous ingestion of vitamins benefit public health or promote recovery from disease?

Can overindulgence in vitamins cause harm beyond deflation of the public pocketbook?

It is difficult to answer these questions without emotional bias. There are increasing manifestations that the vitamin fad is passing and that a more conservative view of their therapeutic value is developing. Several recent reports stress a well balanced diet as preferable to purified vitamin supplements.^{3, 5, 6, 10} It is my opinion, however, that as long as the public believes in the magic of vitamins, the physician will be forced to prescribe them, although he may not anticipate any benefit beyond a psychologic one. Moreover, practitioners are carefully informed of all progress in the therapeutic use of vitamins by manufacturers who, for obvious reasons, favor reports that stimulate sales.

In this review, the continued reports on small numbers of well recognized specific deficiency states are not discussed. The results of animal and bacteriologic experimentation are slowly revealing the

in the urine in twice the quantity excreted when it was taken in equal amounts between meals³⁵

Further investigations indicated that thiamine requirements may be increased for the first week after severe burns or injury, as shown by low urinary excretion in spite of daily intakes of 3 mg of thiamine^{36, 37}. Confirmation of these observations will require further investigation with larger supplements of thiamine to prove that the post-traumatic decrease in urinary excretion is due to increased thiamine utilization and not to other factors. I have not discovered any other controlled studies within the last four years that demonstrate an increased demand for thiamine during various disease states. The apparent effect of an elevated metabolic rate upon increasing thiamine utilization has been summarized previously.³⁵

On consideration of all these reports on various investigations into the minimal requirement for thiamine and into the factors that may modify it, it seems justifiable to conclude that an intake of 0.26 to 0.35 mg per 1000 calories with consumption of at least 0.7 mg per day, is a reasonable approximation of the minimal requirement for thiamine.

Riboflavin

The amount of riboflavin required by man to prevent clinical or subclinical deficiency has not been determined with any certainty. During the last four years there have been no reports of success in the experimental production of clinical riboflavin deficiency. Volunteers have lived on 0.3 mg per 1000 calories for one hundred and sixty-one days⁴⁴ and on 0.28 mg per 1000 calories for more than a hundred days⁴⁹ without any evidence of ariboflavinosis. Either a much greater restriction of riboflavin intake or the introduction of other unknown factors is required for the development of the clinical findings characteristic of riboflavin deficiency.

It is impossible to define subclinical deficiency on the basis of the urinary excretion of riboflavin because many factors in addition to the quantity of riboflavin consumed affect urinary excretion. Oldham et al.⁴⁰ found that there was a striking inverse relation between urinary riboflavin excretions and nitrogen balances. Under conditions of a constant intake of riboflavin, the urinary excretion varied from 40 to 60 per cent of the intake during periods of strong negative nitrogen balance to only 7 per cent when the subjects were in positive nitrogen balance. These observations confirm and extend the work of Andreae et al.,⁴¹ who showed that there was a retention of 0.3 mg of riboflavin with each gram of nitrogen retained. Moreover, this nitrogen-riboflavin relation explains the marked fluctuations in riboflavin excretion subsequent to burns and injury^{36, 37, 41} and opens to question any

statements about the increased requirement for riboflavin after trauma.

There is ample evidence of intestinal synthesis of riboflavin, which can be greatly modified by the type of diet ingested.⁴² During periods of low riboflavin intake, fecal excretion of riboflavin may exceed the amount provided in the diet.³⁹ The demonstration of considerable amounts of "free" riboflavin in the feces suggests the possibility of utilization of riboflavin synthesized in the intestine when oral intake is low.⁴² To date no one has proved that the riboflavin from intestinal synthesis is absorbed. In view of these nondietary factors which may alter the level of urinary excretion of riboflavin it is surprising to note the agreement of different investigators concerning the correlation of urinary excretion with the quantity ingested when the dietary intake of riboflavin is 1.4 mg or less.⁴² Regardless of the factors that complicate interpretation, there have been attempts to estimate the riboflavin requirement proceeding on the assumption that urinary excretion reflects tissue saturation. Davis et al.³⁹ found that there was urinary excretion of 40 per cent of the increment in riboflavin intake between 1.02 and 1.23 mg. At higher levels of intake approximately the same percentage of the increment was excreted whereas at intake levels below 1 mg very little of the increment was excreted. These findings are interpreted as indicating that there is tissue saturation with riboflavin at an intake of 1.23 mg per day and that this quantity of the vitamin meets the human requirement. Brewer et al.⁴³ observed a similar change in urinary excretion of riboflavin when the intake exceeded 1.3 to 1.5 mg per day. They define this level as the "optimal" intake of riboflavin or upper limit at which there is economical utilization of the substance.

A final comment about the requirement for riboflavin is the change from computing it on the basis of caloric intake to computing it on the basis of 0.020 mg per body weight.⁴⁴ To summarize the observations on riboflavin requirements, I believe that 1.0 mg per day is more than adequate to prevent subclinical ariboflavinosis.

Niacin

There are very few data about niacin requirements in man. Niacin (nicotinic acid) and nicotinamide are equally effective therapeutically.⁴⁵ In practice nicotinamide is preferred because its administration is not associated with the unpleasant side effects caused by niacin. In this discussion, the word niacin refers generically to both substances.

The experimental production of clinical niacin deficiency in man has not been reported. No signs or symptoms of niacin lack were observed in a group that consumed 5.8 mg per day for fifteen to eighteen weeks.⁴⁶ Tissue stores of niacin may be sufficient to meet ordinary demands for long periods and in-

quirement in both these reports was probably somewhat higher than that under normal conditions because of poor, unbalanced diets, diarrhea and the increased demands of pregnancy.

On the basis of experimental development of symptoms of thiamine deficiency by restricting the intake at varying levels, Foltz et al²⁶ concluded that the minimal daily requirement for young men ranged from 0.33 to 0.45 mg per 1000 calories. In a carefully controlled study lasting one hundred and sixty-one days, Keys et al¹⁴ observed that a thiamine intake of 0.185 mg per 1000 calories, together with restriction of other B vitamins and a 3300-calorie diet, was without significant effect on "fitness," health and personality. After four weeks at this level of intake, there was a 0 urinary excretion of thiamine. That the body reserves of thiamine were being depleted during this period of restriction was evidenced by the rapid deterioration of these subjects when there was further restriction of the thiamine intake to 0.008 mg per 1000 calories. The rapidity of this deterioration was striking in comparison with that in a control group that had been receiving a supplement of 1 mg of thiamine per day before the acute restriction to 0.008 mg per 1000 calories. On the basis of their studies, Keys et al¹⁴ are of the opinion that 0.23 mg of thiamine per 1000 calories is adequate.

In another well controlled investigation with restriction of thiamine to 0.5 mg per day as well as reduction in the intake of other B vitamins and protein, Berryman et al²⁷ observed symptoms of deficiency within fifteen to eighteen weeks. Supplementation with crystalline thiamine alone did not relieve these symptoms. Hathaway and Strom²⁸ found that 0.84 mg of thiamine per day allowed 3 women to live symptom-free and with a sense of well-being. Using the reaction-time technic, Tuttle et al²⁹ noted no aberration from normal unless the thiamine intake was less than 0.625 mg per day.

Values for the urinary excretion of thiamine at any given level of intake vary considerably among different observers, and there is an even greater variance of opinion in the interpretation of these results. Zero excretions of thiamine were observed at intakes of 0.5²⁷ and 0.61 mg per day¹⁴. On the other hand, other investigators²⁰ found some urinary excretion (10 to 29 gamma per day) of thiamine with intakes as low as 0.28 to 0.40 mg per day. When subjects ingested 0.7 mg of thiamine per day, Oldham et al²⁰ observed a sudden increase in the urinary excretion level to 35 to 78 gamma per day. At a daily intake of 0.84 mg,²⁸ the urinary excretion was 90 to 112 gamma per day. By some standards this value for urinary excretion is above the lower limits of "normal."

Alexander¹¹ was dissatisfied with the method of restriction of dietary intake for determining

minimal thiamine requirements. Instead, he made a thiamine balance study, which established a minimal thiamine requirement of 0.7 mg per day on a 2400-calorie diet, or 0.29 mg per 1000 calories if allowances were made for the urinary excretion of partial breakdown products of thiamine. Holt et al²⁰ employed a refinement of the urinary-excretion technic whereby increments of the thiamine intake were added and subtracted until a critical point of minimum urinary excretion was found. The higher excretion rate above this point was believed to represent a surplus above minimum physiologic needs. By this method the minimal thiamine requirement for adults was 0.6 mg per day, and that for infants was 0.14 to 0.20 mg per day.

A final biochemical approach to the problem of determining the minimal thiamine requirement was the use of a complex index based upon changes in blood lactic and pyruvic acids after glucose administration and exercise.³¹ Subjects with a daily thiamine intake of 0.4 mg were found to be at the borderline of biochemical abnormality. Probably, a lower level for the minimal thiamine requirement is obtained by this method because the pyruvic acid metabolism seems to remain constant even when the urinary-excretion level of thiamine has reached zero.¹⁴

In arriving at the value or values for minimal thiamine requirements, one must consider other factors. The generally accepted theory that an interrelation between carbohydrate intake and utilization of thiamine exists is questioned by Keys et al,¹⁴ who suggest that the actual thiamine requirement may be a constant as well as an amount proportional to the total fat calories and may be somewhat less than 0.61 mg per day, regardless of calories. This theory is opposed to the common idea that fat spares thiamine. It is unlikely that intestinal synthesis of thiamine plays a role in determining the minimal requirement because thiamine is not absorbed from the colon.^{11, 27, 32} Contrary to popular opinion that the demand for thiamine is increased during the consumption of alcohol, an isocaloric substitution of alcohol for carbohydrate resulted in increased thiamine excretion.³² This was interpreted as indicating a thiamine-sparing action of alcohol.

In a case of an American prisoner of war with severe beriberi, symptoms recurred when he was shifted from parenteral to oral vitamin therapy, but when hydrochloric acid was given in addition, he could be maintained fully on oral intake alone.³³ This observation is merely a clinical impression and is at variance with a better controlled study, which showed no effect of gastric anacidity on thiamine absorption as determined by the urinary excretion level.³⁴ Other experiments demonstrated that thiamine ingested with meals was excreted

is striking in view of the long period of maintenance at a given level of intake in one study and the brief period in the other. The lower values and steady decrease observed by Haines et al.⁵³ are difficult to reconcile with the results of the other two investigations.

Although these biochemical determinations prove a definitive relation between tissue saturation with vitamin C and the level of intake, there is difficulty in establishing the level below which subclinical deficiency occurs. A fasting plasma ascorbic acid level below 0.6 mg per 100 cc is considered by some to be the critical level necessary for normal vitamin C metabolism.⁵⁴ This would require an intake of approximately 50 mg of vitamin C per day. Moreover, plasma levels below 0.25 mg

development of tensile strength and healing in surgical wounds. The only dissenting report was that of normal healing of experimental wounds with a vitamin C intake of only 11 mg per day over an eleven-month period.⁵²

After considering these reports, I believe that a vitamin C intake of 30 mg per day is more than adequate to meet the minimal requirements in man except during periods of stress.

Fat-Soluble Vitamins

Vitamin D The minimal requirement for vitamin D in adults is approximately zero⁶¹; 400 I U of vitamin D is ample for children because this amount produces no greater calcium retention than 800 I U.⁴⁴ An increased demand for vitamin D has been shown in cases of steatorrhea.⁶⁴ Oral doses of as much as 12,000 I U of vitamin D per day may be insufficient to maintain calcium balance in steatorrhea, but the same quantity of vitamin D administered intramuscularly becomes effective.⁶⁵ There have been reports of rare cases in which the absorption of vitamin D was satisfactory but in which clinical rickets, resistant to the normal quantity of vitamin D, required 150,000 to 1,500,000 units daily for cure.^{66, 67}

Vitamin E The essentiality of vitamin E in human nutrition has not been established as yet. Although specific manifestations of vitamin E deficiency have been demonstrated in animals, no similar deficiency syndrome in man is known. Likewise, the human requirement, if there is one, has not been determined. Several series of measurements of the blood plasma level of vitamin E in normal human subjects show a range of 0.39 to 2.02 mg per 100 cc.⁶⁸⁻⁷⁰ Much lower plasma levels of vitamin E have been found in persons with malnutrition, sprue and impaired fat absorption.^{63, 70} The significance of decreased levels of vitamin E in the plasma is not known.

Vitamin K The minimal requirement for vitamin K is 1 mg per day or less. The quantity needed is usually supplied in sufficient amounts by the diet and by intestinal synthesis.^{44, 61} To prevent hemorrhagic manifestations in the newborn, it is advisable to give supplements of vitamin K to the mother during the last month of pregnancy.⁴⁴ When prothrombin deficiency occurs, as in cases of impaired intestinal absorption, 2 mg of vitamin K per day is more than enough to restore the prothrombin level to normal.⁷¹

Recommended Dietary Allowances

The National Research Council constantly reviews data derived from investigations into nutritional requirements, such as those surveyed above, and publishes revisions of recommendations for dietary allowances from time to time. In keeping with advancing knowledge about minimal requirements for vitamins, it is interesting to note the

TABLE 1 Relation of Daily Vitamin C Intake to Plasma Level

INTAKE mg/day	PLASMA LEVEL* mg/100 cc	PLASMA LEVEL† mg/100 cc	PLASMA LEVEL‡ mg/100 cc

*Data of Dodds and MacLeod.¹¹ A seven-day to ten-day adjustment period on each intake preceded these plasma values which represent two-day and six-day averages.

†Data of Johstoe et al.⁴⁴ The subjects were maintained for six to nine months at the various levels of intake.

‡Data of Haines et al.⁵³ The values recorded are those for the sixth week after the beginning of the various intakes which had been preceded by a saturation period. At each level of intake observed, there was a steady decrease in the plasma level during the six weeks of study.

§Determined after three days at an intake of 400 mg per day.

per 100 cc or intakes below 22 mg per day are believed to be in the deficiency range.^{54, 55, 59} Complete saturation of tissues and white blood cells with vitamin C was found to be accomplished by intakes slightly in excess of 70 mg per day,^{53, 59} but it has never been proved that complete tissue saturation is necessary for optimal health. In fact, as a result of saturation tests, it has been postulated that the body economy is more wasteful of its vitamins when they are in good supply.⁶⁰ When fully saturated, the body is estimated to contain $\frac{1}{4}$ gm of vitamin C.^{67, 69} Another approach, which has been introduced by Slobody et al.,⁵⁵ is the determination of tissue saturation with vitamin C by the rate of decolorization of dichlorophenol indophenol injections into the skin. As yet, its clinical application has not been tested.

A greatly increased demand for vitamin C in persons with burns and severe injury has been well demonstrated.^{36, 37} Experimental studies on wound healing in human subjects depleted in vitamin C⁶¹ have confirmed earlier observations^{67, 68, 69} of the need for additional vitamin C to promote

crease the difficulties of producing a state of experimental deficiency.¹⁷ The type of diet also alters niacin requirements. For example, tryptophane acts as a precursor for niacin,⁴⁶ whereas the probable presence of an antiniacin factor in corn would increase the need for niacin when corn products are ingested.⁴⁷

Determination of the urinary excretion of niacin or its metabolic derivative N-methyl nicotinamide has little value in establishing requirements for niacin. With intakes ranging from 6.9 to 25 mg per day in 12 subjects, the urinary excretion of niacin was found to be almost constantly 1.0 mg per day, and the fecal excretion 1.0 to 1.9 mg per day.²⁰ The N-methyl nicotinamide excretion in the urine was observed to be the same with intakes of either 12 or 22 mg per day.¹⁴

For lack of better data, the closest estimate to the minimal daily requirement for niacin is 5 mg, with an increase to 7.5 mg if there are corn products in the diet.⁴⁴

Lesser Known Members of the Vitamin B Complex

There are practically no data on the human requirements for the lesser known members of the vitamin B complex. Specific deficiency states for pyridoxine, pantothenic acid, para-amino benzoic acid, biotin, choline and inositol have not been discovered. Lack of folic acid and vitamin B₁₂ may contribute to the development of macrocytic anemias. It is most probable, however, that some of these lesser known or even some as yet unidentified components are essential to adequate human nutrition. This was demonstrated by experiments that showed incomplete recovery or even aggravation of some existing deficiency symptoms when depleted persons were given supplements of crystalline thiamine, riboflavin and niacin only. It was only after restoration of a full diet or addition of brewers' yeast that there was complete relief from all deficiency stigmas.^{24, 27}

The few scattered reports on lesser known members of the vitamin B complex are summarized as follows. The production of suggestive pyridoxine deficiency with manifestations of depression, mental confusion and leukopenia was reported to occur within two months on a synthetic diet containing supplements of the other known vitamins in crystalline or purified form, but the quantity of pyridoxine needed to "cure" was not determined.⁴⁸ The "burning-feet" syndrome described in a number of nutritional surveys of prisoners of war is attributed to pantothenic acid deficiency.^{24, 49} The possibility of pantothenic acid deficiency in man is questionable, however, on the basis of work that revealed excretions to approximate intakes ranging from 2.1 to 4.7 mg per day.²⁰ It is suggested either that no pantothenic acid is destroyed in the body or that intestinal synthesis compensates for the destruction in the tissues.²⁰ A study of human

utilization of biotin showed urinary and fecal excretion to be three to six times that of intake, the excess probably coming from intestinal synthesis.¹⁸ Consequently, human biotin deficiency is unlikely. On the basis of animal studies, the human requirement for folic acid is estimated to be 0.1 to 0.2 mg per day.⁴⁴ The hematologic response of patients with Addisonian pernicious anemia suggests that man requires less than 1 gamma of vitamin B₁₂ per day.⁵⁰

Any concern about meeting the human requirements for the lesser known members of the vitamin B complex can be allayed when it is known that the ordinary diet supplies these factors in adequate amounts when foods that contain the major components of the vitamin B complex are ingested.⁴¹

Vitamin C

In contrast with vitamin A and the B complex, the amount of vitamin C required to prevent clinical scurvy has been established with some accuracy,⁵² and several investigations have correlated the degree of tissue saturation with the quantity of vitamin C taken in.⁵³⁻⁵⁵

Investigators from the British Medical Research Council demonstrated, during an observation period of four hundred and twenty-four days, that a daily intake of 11 mg of vitamin C prevented the development of clinical scurvy.⁵² It is possible that an even lower level of intake would prevent scurvy because after 3 subjects had been on an 11-mg intake of vitamin C for one hundred and sixty days, they were maintained for one hundred and ninety-five days on intakes that were reduced still farther to 3.2 to 4.5 mg of vitamin C per day without the appearance of clinical signs of scurvy.⁵² In 6 cases of clinical scurvy developed during an intake of only 1 mg of vitamin C per day for seven months, 10 mg of vitamin C per day effected a slow cure after that period. It is interesting to note that the plasma levels of ascorbic acid fell with the same rapidity and to the same low levels of 0 to 0.05 mg per 100 cc both in the group whose daily intake was 1 mg of vitamin C and in the group that received 11 mg per day. Although 11 mg per day prevented the appearance of scorbutic manifestations, this intake of vitamin C did not eliminate such vague symptoms of deficiency as fatigue. To satisfy ill defined additional needs and to allow a margin of safety, it was suggested that a daily vitamin C intake of 30 mg be regarded as the requirement of a normal adult.⁵² This recommendation agrees with the League of Nations daily minimum requirement for vitamin C of 30 mg⁵⁶ and is close to the maximal daily utilization of 30 to 40 mg found by Crandon et al.⁵⁷

The correlation between plasma vitamin C levels and intake as found by different investigators is summarized in Table 1. The close agreement between the results of Johnstone et al.⁵¹ and Dodds⁵⁵

is striking in view of the long period of maintenance at a given level of intake in one study and the brief period in the other. The lower values and steady decrease observed by Haines et al.⁵³ are difficult to reconcile with the results of the other two investigations.

Although these biochemical determinations prove a definitive relation between tissue saturation with vitamin C and the level of intake, there is difficulty in establishing the level below which subclinical deficiency occurs. A fasting plasma ascorbic acid level below 0.6 mg per 100 cc is considered by some to be the critical level necessary for normal vitamin C metabolism.⁵⁴ This would require an intake of approximately 50 mg of vitamin C per day. Moreover, plasma levels below 0.25 mg

development of tensile strength and healing in surgical wounds. The only dissenting report was that of normal healing of experimental wounds with a vitamin C intake of only 11 mg per day over an eleven-month period.⁵²

After considering these reports, I believe that a vitamin C intake of 30 mg per day is more than adequate to meet the minimal requirements in man except during periods of stress.

Fat-Soluble Vitamins

Vitamin D The minimal requirement for vitamin D in adults is approximately zero⁵¹; 400 I U of vitamin D is ample for children because this amount produces no greater calcium retention than 800 I U.⁵¹ An increased demand for vitamin D has been shown in cases of steatorrhea.⁶⁴ Oral doses of as much as 12,000 I U of vitamin D per day may be insufficient to maintain calcium balance in steatorrhea, but the same quantity of vitamin D administered intramuscularly becomes effective.⁶⁵ There have been reports of rare cases in which the absorption of vitamin D was satisfactory but in which clinical rickets, resistant to the normal quantity of vitamin D, required 150,000 to 1,500,000 units daily for cure.⁶⁶⁻⁶⁷

Vitamin E The essentiality of vitamin E in human nutrition has not been established as yet. Although specific manifestations of vitamin E deficiency have been demonstrated in animals, no similar deficiency syndrome in man is known. Likewise, the human requirement if there is one, has not been determined. Several series of measurements of the blood plasma level of vitamin E in normal human subjects show a range of 0.39 to 2.02 mg per 100 cc.⁶⁸⁻⁷⁰ Much lower plasma levels of vitamin E have been found in persons with malnutrition, sprue and impaired fat absorption.⁶⁸⁻⁷⁰ The significance of decreased levels of vitamin E in the plasma is not known.

Vitamin K The minimal requirement for vitamin K is 1 mg per day or less. The quantity needed is usually supplied in sufficient amounts by the diet and by intestinal synthesis.⁴¹⁻⁵¹ To prevent hemorrhagic manifestations in the newborn, it is advisable to give supplements of vitamin K to the mother during the last month of pregnancy.⁴¹ When prothrombin deficiency occurs, as in cases of impaired intestinal absorption, 2 mg of vitamin K per day is more than enough to restore the prothrombin level to normal.⁷¹

Recommended Dietary Allowances

The National Research Council constantly reviews data derived from investigations into nutritional requirements, such as those surveyed above, and publishes revisions of recommendations for dietary allowances from time to time. In keeping with advancing knowledge about minimal requirements for vitamins, it is interesting to note the

TABLE 1 *Relation of Daily Vitamin C Intake to Plasma Level*

Intake mg/day	Plasma Level* mg/100 cc	Plasma Level† mg/100 cc	Plasma Level‡ mg/100 cc

*Data of Dodds and MacLeod.⁴⁴ A seven-day to ten-day adjustment period on each intake preceded these plasma values which represent two-day and six-day averages.

†Data of Johnstone et al.⁴⁵ The subjects were maintained for six to nine months at the various levels of intake.

‡Data of Haines et al.⁵³ The values recorded are those for the sixth week after the beginning of the various intakes which had been preceded by a saturation period. At each level of intake observed there was a steady decrease in the plasma level during the six weeks of study.

§Determined after three days at an intake of 400 mg per day.

per 100 cc or intakes below 22 mg per day are believed to be in the deficiency range.⁵¹⁻⁵³⁻⁵⁹ Complete saturation of tissues and white blood cells with vitamin C was found to be accomplished by intakes slightly in excess of 70 mg per day,⁵³⁻⁵⁹ but it has never been proved that complete tissue saturation is necessary for optimal health. In fact, as a result of saturation tests it has been postulated that the body economy is more wasteful of its vitamins when they are in good supply.⁶⁰ When fully saturated, the body is estimated to contain 4 gm of vitamin C.⁵⁷⁻⁵⁹ Another approach, which has been introduced by Slobodov et al.,⁵⁸ is the determination of tissue saturation with vitamin C by the rate of decolorization of dichlorophenol indophenol injections into the skin. As yet, its clinical application has not been tested.

A greatly increased demand for vitamin C in persons with burns and severe injury has been well demonstrated.³⁶⁻³⁷ Experimental studies on wound healing in human subjects depleted in vitamin C⁶¹ have confirmed earlier observations⁵⁷⁻⁶²⁻⁶³ of the need for additional vitamin C to promote

downward trend of recommendations in the latest 1948 National Research Council revision.⁵¹ The specific vitamin allowance recommendations for those vitamins for which definite deficiency states have been recognized are summarized as follows

Vitamin A—5000 I U per day, 8000 I U per day during lactation

Thiamine—10 mg per day for sedentary persons to 18 mg per day for those doing heavy labor

Riboflavin—15 to 18 mg per day, 30 mg per day during lactation

Niacin—12 mg per day for sedentary life to 18 mg per day for heavy labor

Vitamin C—70 to 75 mg per day, 150 mg per day during lactation

Vitamin D—400 I U per day during childhood, adolescence, pregnancy and lactation, minimal amounts for adults generally

Vitamin K and folic acid are recognized, but no quantitative recommendations are made

The report points out that food supplying adequate thiamine, riboflavin and niacin will inherently supply sufficient quantities of the remaining components of the vitamin B complex.⁵¹ In my opinion, this statement constitutes a strong argument for utilizing food to combat deficiency states and for eliminating the use of crystalline, synthetic or purified vitamin supplements, which cannot contain all nutrients in balanced quantities

In discussing these recommended dietary allowances, Jeans⁴⁴ emphasizes that they are not in any way a yardstick of requirements, but are definitely above average requirements, sometimes reaching twice the minimum. The allowances are a goal for ensuring good general nutrition, but "persons ingesting less than the allowances are not deficient *ipso facto*"⁴⁴

It is my opinion that many claims that the American diet is inadequate are based upon use of the National Research Council's recommended dietary allowance, as if the levels appearing there were minimal requirements rather than above average. Jeans believes that the over-all American dietary intake is much more sufficient in the vitamins than is often stated

Such a lengthy review of recent data about minimal requirements seems justified because they are the foundation for evaluating the adequacy of diets. If food intake does not supply the minimal requirement of essential vitamins, supplements are justified. If, on the other hand, dietary intakes meet the minimal requirements, supplements are of little value, unless they cause an improvement in health and well-being beyond that resulting from an unsupplemented diet. These two alternatives will be examined in the next section of this review

(To be continued)

CASE 35501

PRESENTATION OF CASE

A seventy-year-old man was brought to the Emergency Ward in shock by the Fire Department.

He was feeling relatively well until one and a half hours prior to entry, when he suddenly collapsed while waiting in the office of his physiotherapist. A physician found the patient cold and clammy and sweating profusely without obtainable pulse or blood pressure. Oxygen was given, and tourniquets were applied to the legs. Soon afterward he regained consciousness and stated that no pain preceded this episode.

Twelve years prior to admission he had a cerebrovascular accident from which a mild left hemiparesis remained and since that time his blood pressure averaged 220 systolic, 140 diastolic. Seven years before entry he suffered a myocardial infarction and was treated at a community hospital. His recovery was complete as confirmed by an electrocardiogram made six months before entry. This showed normal rhythm at a rate of 70, left-axis deviation, normal PR and QRS intervals, small upright T waves in the limb leads and upright T waves in the precordial leads. For the past twelve years he had led a quiet life and at no time complained of symptoms of congestive failure or hypertension. One month prior to entry he developed a generalized muscular achiness that was somewhat improved by physiotherapy.

Physical examination revealed a very pale, cold, sweaty, moderately obese man in profound shock but not unconscious. There was no cyanosis of the face or distention of the neck veins. The pupils were constricted but reactive. The lungs were clear except for a few moist basal rales. The heart was not grossly enlarged, and the sounds were barely audible but regular. There was no gallop and no murmurs. The abdomen was prominent, soft and hyperresonant in the left upper quadrant. There was moderate tenderness beneath the left costal

margin and a firm fullness over the descending colon, but no obvious masses were felt. There was no ankle edema. The legs were cold, pale and pulseless.

Neurologic examination showed a slightly increased muscular tone of the left arm over the right, and the spontaneous arm movements were easier on the right than the left. The reflexes were not remarkable except for a decreased response of the left knee jerk.

The temperature was 99°F, the pulse 90, and the respirations 22. The blood pressure was 95 systolic, 75 diastolic.

Urinalysis revealed no abnormalities except for a +++ test for albumin. Examination of the blood disclosed a white-cell count of 28,700, with 82 per cent neutrophils, 15 per cent lymphocytes, 2 per cent monocytes and 1 per cent eosinophils. The hemoglobin was 11.5 gm per 100 cc. (three weeks prior to this determination it was 14 gm). The nonprotein nitrogen was 49 mg per 100 cc and the prothrombin time was 15 seconds (normal, 15 seconds). An electrocardiogram showed sinus tachycardia at a rate of 110 with a PR interval of 0.17 second and a QRS interval of 0.08 second. There were prominent Q waves in Lead 2, 3, and AVF. The T waves were flat in Lead 2 and V₁, inverted in Lead 3 and AVF and upright in the other leads. Another electrocardiogram taken on the second hospital day disclosed normal rhythm at a rate of 95 to 100 with moderate left-axis deviation, inverted T wave in Lead 1 (for the most part late), flat T wave in Lead 2, and slightly elevated ST segment and deep Q₁ wave in AVF. The precordial leads showed low T waves with slightly late notched TV₄, and late inversion of the T wave in V₆.

Shortly after admission the patient improved. The blood pressure rose to 110 systolic, 95 diastolic, and the pulse became more firm, however, he remained in shock. Because of persistence of collapse four hours later a slow blood transfusion was administered, after which he became rested and slept quietly. On the second hospital day the patient awoke lucid, appearing dramatically improved, but the blood pressure remained low—100 systolic, 80 diastolic. The hemoglobin had decreased to 9 gm, and the white-cell count to 19,800. He complained of aches all over when moving and mentioned that his "bowels hurt."

On the third hospital day he was restless and disoriented, and he suddenly began to breathe heavily and went into shock, the blood pressure and pulse became unobtainable, and shortly thereafter he died.

DIFFERENTIAL DIAGNOSIS

DR ROBERT S PALMER* When a person faints, one cannot say right off whether or not it is benign

*Associate physician, Massachusetts General Hospital

fainting When fainting occurs in an elderly man whose subsequent course excludes fainting of the benign or transient sort, many people think of myocardial infarct, and so do I. In elderly persons particularly myocardial infarction may be without pain and may be heralded by syncope. Although it is unusual, sudden collapse may happen at the onset in cerebral hemorrhage, and also may be caused by overwhelming infection, an acute condition of the abdomen, or internal hemorrhage. This man's blood pressure was not the ordinary wide-pulse-pressure type seen in hypertension of the elderly, which we think is due to large-vessel sclerosis. The diastolic pressure was elevated and may have been due to chronic vascular nephritis. I have here the electrocardiogram taken seven years before entry, a feature of which is a high ST segment in Lead 3, with late inversion and elevated ST segment in Lead 2. If the clinical course were characteristic I should think we might accept the given diagnosis of posterior myocardial infarction at that time. Recovery seemingly was satisfactory, and an electrocardiogram made six months before entry had returned to normal in respect to T-wave changes. Coming back to the conditions that can cause shock, I wonder about an acute condition of the abdomen and hemorrhage. From the physical signs given here, I can see nothing that really helps me definitely to rule abdominal disease in or out. When a patient is in profound shock, of course, the signs of an acute condition of the abdomen are equivocal.

The neurologic examination suggests the residua of an old cerebral thrombosis. In summary, the background of this patient, admitted in profound shock, is one of arterial hypertension with diffuse vascular disease cerebral, cardiac and renal.

Do the laboratory data help to settle the differential diagnosis of shock due to myocardial infarction, overwhelming infection, acute abdomen or hemorrhage? The white-cell count of 28,700 was high for shock and for hemorrhage, it was not too high for an overwhelming infection. It was rather high for myocardial infarction. The hemoglobin was definitely lower than three weeks earlier. Could he have lost 2.5 gm of hemoglobin from shock alone, or was it an indication of hemorrhage and shock in a person who had lost enough blood so that he did not concentrate since ordinarily in a shock state one expects hemoconcentration? The nonprotein nitrogen of 49 mg per 100 cc, perhaps slightly elevated, may have been a manifestation of shock, although it possibly was related to chronic vascular nephritis. The admission electrocardiogram, which I have here, is the usual complete tracing and should help us.

In Lead 3 there is a suggestion of elevated ST segment and definite late inversion of the T wave, and in the precordial lead there is low QRS voltage and a low T wave. Previously we did not have

unipolar limb leads nor a precordial lead in the sixth position, but we know from the previous electrocardiogram at least that the T wave in the conventional third lead was low upright, whereas it was inverted on this one later tracing. This would be consistent with the expected change of a posterior myocardial infarction. The second tracing, taken on the next day, showed in addition a rather depressed ST segment in Lead 1 and late inversion of the T wave. In Lead 3 the T wave is now upright, which is disturbing if we are thinking of posterior or basal infarction. There are slight changes in the unipolar limb leads, which may be seen in posterior or basal infarction. The sixth precordial lead shows an additional change. There is quite good QRS voltage, with late inversion of the T wave. It is far enough out so that it may be close to but not directly over an area of infarction at the base of the left ventricle.

Regarding progress while the patient was in the hospital, blood was given. Transfusion is good therapy for shock and not infrequently may be indicated in the shock of myocardial infarction. The hemoglobin was still lower on the second hospital day. If we can trust the laboratory determinations, this patient had lost about a third of his hemoglobin. The white-cell count was now 19,800. I do not know what the "aches all over" represented and whether or not they were connected with the same complaint of a month prior to admission. I find nothing specific enough in the statement that his "bowels hurt" to help me.

This elderly man with hypertension and cerebral, cardiac and renal sclerosis had suffered an old posterior or basal myocardial infarction and a cerebral thrombosis with a left hemiparesis. When a person is found in shock, and the shock persists, there is no way of telling from the signs whether or not shock was due to a heart condition, an acute overwhelming infection, rupture of a hollow viscus or hemorrhage. The appearance and indeed the symptoms of these different conditions sometimes cannot be told apart. He may have had another attack of coronary thrombosis, and if so, from the diffuse changes in the electrocardiogram, it must have been a large one. Could he have had an acute condition of the abdomen? There was no sign of peritoneal irritation and nothing to indicate ileus, and there was nothing in the past history to suggest ulcer or gall-bladder disease or anything that would make us think that he had a rupture of a hollow viscus. Did he have internal hemorrhage? I have been fooled by an elderly person who I thought was having a mild attack of coronary insufficiency, and subsequently was proved to have had hemorrhage into, of all things, a hepatoma, which was quite large. Did this patient bleed into the gastrointestinal tract? In my experience a person of middle age or older who has a known ulcer and who is known to be bleeding and dies in uncontrollable

shock sometimes proves to have had a silent myocardial infarction. If this patient had gastrointestinal bleeding we should have seen or heard of blood at one end or the other of his intestinal tract. It is still conceivable that he may have bled somewhere, which is not apparent to me from the data at hand.

Let us see where we stand. Did he have a coronary thrombosis? Somewhat against this diagnosis is the syncope but it is not too unusual, especially in an elderly man. He did not have pain. At least when he became conscious he said that he had no pain. Again this is unusual but does not exclude the diagnosis. He had a very high white-cell count—higher than in most cases of myocardial infarction, let us say. The electrocardiographic picture is not complete enough for me to be actually sure of a diagnosis, perhaps because he did not live long enough to develop the complete pattern. Perhaps the exploring electrodes were near but not directly over dead muscle. Did he have hemorrhage? The high white-cell count and the loss of one third of his hemoglobin are in favor of hemorrhage. A hematocrit and other blood studies would have helped since I do not like to depend on the hemoglobin determinations alone. Since we have nothing to point to an acute overwhelming infection or peritonitis and since we do not know where he bled, I am inclined to discard these possibilities and to suggest that he had extensive myocardial infarction, posterolateral or posterior, perhaps involving the septum extensively.

DR BERNARD JACOBSON: When he entered the Emergency Ward, examination revealed nothing in the rectum, and the small bit of stool that was obtained was brown and guaiac negative.

DR PALMER: That is evidence against hemorrhage into the gastrointestinal tract. What would happen if a person ruptured the ventricular septum, I do not know. Did he die of ventricular fibrillation? If he had extensive old myocardial disease and an additional fresh infarction he may have had ventricular fibrillation, and no specific immediate cause for death was found. Finally, did he have overwhelming pulmonary embolism? He was an old man, who had been in bed three days in profound shock, not moving very much, and he had had tourniquets on all four extremities. I think he may have had a pulmonary embolism as a final episode.

A PHYSICIAN: If this were a gastrointestinal hemorrhage, could the shock produce changes that would be consistent with these electrocardiograms?

DR PALMER: It's a wonderful suggestion. If he was anemic and his hematocrit was low he would have very few red cells circulating. That might cause myocardial ischemia and alteration in the electrocardiogram. I do not know, but I suppose it could cause such electrocardiographic changes

and therefore might be misleading. I think that is a good point.

DR SAMUEL GOLDFARB: Do you suppose the hemoglobin levels are correct? This man had a hemoglobin of 14 gm before his accident and 11.5 gm on admission, going down to 9 gm the next day, without taking into consideration that he probably received 500 cc of blood. How often do we see myocardial infarction produce rapid and sudden loss of hemoglobin?

DR PALMER: I do not know whether it could happen. I think hemoglobin values alone are doubtful but since the hemoglobin went from 14 gm to 11 gm and then down to 9 gm it almost makes me think something like that has happened.

A PHYSICIAN: Could aneurysm rupturing the septum occur without pain?

DR PALMER: I suppose it could, though I do not know.

DR JACOBSON: There is a slight correction to the record. I saw the patient at a physiotherapist's office downtown and found him completely unconscious in profound collapse, and I want to pay tribute to the Fire Department of the City of Boston for the prompt arrival of oxygen in one minute flat. I transferred him here as soon as possible. The statement is made that as soon as he regained consciousness he said he had no pain. He was unconscious when I saw him at quarter to two in the afternoon and he remained unconscious until seven o'clock the following morning. Thereafter he complained of slight tenderness on palpation of the left lower abdomen.

A PHYSICIAN: It was mentioned that the pulsations in the legs were absent on one examination. Did that come back or remain absent?

DR JACOBSON: The dorsalis pedis and posterior tibial pulsations had been absent for the past year or more.

DR GOLDFARB: Is this history compatible with dissecting aneurysm?

DR PALMER: I suppose dissecting aneurysm could occur without pain. I have known of one patient, a man in the Home for Aged Men with no history of pain, but when he died of something else, the evidence of former dissection was found.

DR JACOBSON: Dr Bland saw the patient on entry to the hospital. We were worried about the 11.5 gm of hemoglobin in a patient with hemocrit concentration of shock. During the following fourteen hours we were considerably worried by the fact that the left abdomen seemed a little tense and the patient winced when we touched it. On the following day when he was conscious his left abdomen was still a little tender but not spastic. No masses were felt. I also might add that he began to urinate eight or nine hours after he entered the hospital and that the urinary output thereafter was adequate.

DR PALMER: That would go with shock.

CLINICAL DIAGNOSES

Arteriosclerotic heart disease
 Infarction of myocardium, due to arteriosclerotic coronary thrombosis

DR PALMER'S DIAGNOSES

Myocardial infarction, extensive, recent
 Old posterior myocardial infarction
 Hypertension, with diffuse vascular sclerosis
 Old cerebral thrombosis

ANATOMICAL DIAGNOSES

Arteriosclerosis, generalized, with ruptured arteriosclerotic aneurysm of abdominal aorta
 Retroperitoneal hematoma, massive
 Infarct of heart, old
 Infarct of cerebellum, old
 Hypertrophy of heart
 Nephrosclerosis

FIGURE 1

PATHOLOGICAL DISCUSSION

DR TRACY B. MALLORY: Autopsy showed that the falling hemoglobin was the key to this case. We found on opening the peritoneal cavity that

the retroperitoneal tissues on the left side of the abdomen way down into the pelvis were filled with clotted blood. This was the result of rupture of a saccular arteriosclerotic aneurysm of the aorta, which lay just above the bifurcation (Fig 1). The clot showed evidence of layering, and I think he must have had several episodes of bleeding at various times. The other findings were merely those of long-standing hypertensive heart disease and severe arteriosclerosis, shrunken kidneys, hypertrophied heart with an old completely healed posterior infarct and marked atheroma of the vessels of the circle of Willis, with a small area of softening of the cerebellum. The extraordinary thing about the story is the lack of obvious pain. Dissection of large amounts of blood through the retroperitoneal tissues in my experience almost always has been associated with the most intense pain. Probably his mental clouding had a good deal to do with the fact that he did not complain of this.

CASE 35502

PRESENTATION OF CASE

A sixty-nine-year-old widow entered the hospital because of extreme weakness for about one year and jaundice for about one month.

The patient dated the onset of poor health from an operation for ruptured appendix followed by peritonitis and drainage at the age of thirty-five. A postoperative ventral hernia was repaired but recurred. At the age of forty-four she received the diagnosis of "pernicious anemia" while seeing a doctor for reasons she did not remember. For this she was urged to eat raw liver, which she was unable to do because of vomiting; injections were discontinued because they were painful, "copper and iron" tablets were taken. She had not had antianemia treatment for years. A subtotal thyroidectomy was performed at the age of sixty-three for "toxic goiter." Radiograms at another hospital at the age of sixty-seven showed an enlarged heart, an electrocardiogram disclosed auricular fibrillation, left bundle-branch block and left ventricular strain. Although she had not considered herself in good health for "many" years, the patient noticed that her usual weakness became more pronounced six months before entry, following the death of a son; anorexia likewise appeared and increased. During this time her weight had decreased from 178 to 158 pounds (several years previously she had weighed 240 pounds but had not tried to reduce). During the four weeks before entry her attention had been called to the gradually increasing yellowish discoloration of her skin, which had steadily progressed. Itching of the skin over the arms and anterior chest was present during the first week of jaundice but then abated. This was not accompanied by pain, clay-colored stools, nausea, vomiting or fever.

The urine was noted to be darker than usual. There was no previous episode of jaundice, no change in bowel habits or stools and no history of exposure to jaundiced persons, chemicals or transfusions. She did not drink alcohol.

Physical examination revealed a moderately icteric woman, lying in bed in moderate distress as evidenced by rapid, forced respirations. Moderate palmar erythema was noted. No spider angiomas were present. The scleras were icteric. The chest was emphysematous, moist rales were present at both bases, more marked on the left. The heart was enlarged, the point of maximal impulse being 2 cm left of the midclavicular line. The rhythm was irregular. The sounds were of good quality, the pulmonic second sound was markedly greater than the aortic, a Grade II, rough systolic murmur was best heard at the lower sternal border. The abdomen was obese. A large ventral hernia occupied the left lower quadrant. The liver was palpated 11 cm below the costal margin in the midclavicular line, the edge was firm, sharp and nontender. The splenic tip was questionably palpable. A ++ pitting edema was present over the lower two thirds of the leg and the sacrum. The knee jerks and ankle jerks were absent, vibratory sense was absent in both ankles and the right knee.

The blood pressure was 92 systolic, 48 diastolic. The temperature was 100°F, the pulse 96, and the respirations 28.

The blood showed a red-cell count of 3,820,000, with a hemoglobin of 10.8 gm. The white-cell count, was 7600, with 88 per cent neutrophils, and later ranged between 12,000 and 16,000. Urinalysis revealed a + test for albumin, and bile. The fasting blood sugar was 124 mg per 100 cc, the sodium 133.9 milliequiv, and the chloride 101 milliequiv per liter. The total protein was 5.6 gm per 100 cc, with an albumin-globulin ratio of 3.3/2.33. The nonprotein nitrogen was 20 mg per 100 cc, and the alkaline phosphatase 12.9 units, reaching 22.3 units on the eighteenth day. The prothrombin time was normal on admission and only slightly elevated later. The van den Bergh reaction was 8.7 mg per 100 cc direct, 13.2 mg indirect. The amylase was 33 units per 100 cc, the cephalin-flocculation test was + in twenty-four hours, ++ in forty-eight hours and, twenty days later, +++ in twenty-four hours and ++++ in forty-eight hours. The cholesterol was 139 mg and the cholesterol esters 54 mg per 100 cc, the thymol flocculation was negative, the thymol turbidity 2.10 units, the urine urobilinogen 3.0 to 7.3 Ehrlich units, and the stool urobilinogen normal. The stools were guaiac negative, and cultures were negative for pathogens. A heterophil-antibody test was negative. The blood culture was negative. The clotting time (without tube) was 9 minutes, and the bleeding time (ear puncture), 1 minute. A bone-marrow aspiration revealed a slight shift to the left in the myeloid and also in the erythroid

series, no megaloblasts or other abnormal cells were seen. An electrocardiogram revealed auricular fibrillation, at a rate of 100, a QRS complex of 0.12 second, low to absent R wave in Lead V₁ and V₄, and left bundle-branch block. A gastric aspiration on the fifth hospital day failed to reveal any free acid, but "pure bile" was present.

Radiographic studies showed left ventricular and left auricular enlargement. The aorta was tortuous and calcified. The right leaf of the diaphragm was elevated but on fluoroscopic examination moved as well as the left. Hepatomegaly and splenomegaly were prominent features. A barium enema was unsatisfactory because of the patient's inability to retain sufficient barium, however, diverticula were demonstrated in the sigmoid region, and the cecum was high-placed. A gastrointestinal series revealed no esophageal varices. A small hiatus hernia was present. No intrinsic abnormality of the stomach, duodenal bulb or duodenal loop was present. The duodenal loop was not enlarged. A small-bowel series was not remarkable, except for one segment of atonic bowel on the three-hour film. It was also noted that the bones were atrophic with fairly marked degenerative changes.

A sigmoidoscope was passed to 13 cm, with great difficulty. The bowel was very spastic and was intensely hyperemic.

The temperature remained elevated in irregular fashion, reaching 104°F on the first, sixth and seventh hospital days, dropping to 99°F and below on the eighth and ninth days, and becoming elevated again, gradually reaching 104°F on the fourteenth day, normal on the fifteenth day and up to 104°F again on the twenty-second and twenty-third days. Although the patient was reluctant to take food and refused to force fluids, she was kept well hydrated, and the caloric intake increased by frequent prompting. It was noted on one occasion that appetite increased, and the patient was subjectively better coincident with a high rise in temperature. Therapeutic measures consisted mainly of Digitoxin, 0.15 mg daily, Crysticillin, 300,000 units daily, Hykinone, 4.8 mg daily, and dihydrostreptomycin, 1.0 gm daily, as well as supportive and antipyretic measures. Mercurhydrin was given on occasion. The patient's general condition grew steadily worse. On the fifteenth hospital day abdominal distention had become an increasingly prominent feature, being only somewhat relieved by enemas and stupes.

A liver biopsy on the twenty-first day was reported as follows:

The portal areas show increase in the number of small-bile ducts and a moderately severe inflammatory reaction in which polymorphonuclears are numerous. Small cholangioles are dilated, and there are foci of pseudotubular change in the liver cords. Two foci of necrosis and degeneration of liver cells are seen. No inspissation of bile in the cholangioles or canaliculi is seen, and there is no bile pigmentation in the liver cells. The findings nevertheless suggest obstruction in the extrahepatic biliary tract.

On the twenty-fifth day it was noted that the jaundice had deepened, and the liver edge was only 4 cm below the costal margin. Stupor increased, and the patient died quietly, without change in the vital signs, on the twenty-sixth hospital day.

DIFFERENTIAL DIAGNOSIS

DR ALFRED L. DUNCOMBE* May we see the x-ray films?

DR STANLEY M. WYMAN The film of the chest taken in the upright position shows the heart to be considerably enlarged to the left probably in the region of the left ventricle. The tortuous, calcified aorta is well seen, and also the elevation of the right leaf of the diaphragm. This appears to be rather localized anteriorly and probably represents localized enlargement of the liver in this region. The spleen is greatly enlarged extending down to the crest of the ilium, and there are a number of round calcific shadows overlying the spleen suggesting phleboliths in the spleen itself.

The kidney shadows are not adequately seen on any film, but they may be small. One film of the attempted barium enema shows nothing remarkable except for diverticula in the sigmoid. The films from the gastrointestinal series show some pressure on the lesser-curvature aspect of the stomach, with depression of the duodenal bulb downward. This is well seen in the spot film. The esophagus itself is quite well demonstrated, and there is no evidence of varices. There is no evidence of pressure on the second portion of the duodenum in its medial aspect. The stasis in the small bowel, I think, may be accounted for by the patient's large hernia, which is seen at this point.

DR DUNCOMBE Will you comment on the barium swallow?

DR WYMAN It outlines an essentially normal esophagus, which is pushed backward by the enlarged heart.

DR DUNCOMBE The problem is that of a woman with painless jaundice of a number of weeks' duration, following a period of increasing poor health, which went on to a rather rapidly fatal termination.

There are several things in the past history that should be mentioned and disposed of. The diagnosis of pernicious anemia was made twenty-five years before admission — incidentally, that was two years ahead of the publication of Dr Minot's paper. Perhaps it is an error in the history. She probably did not have pernicious anemia at any time. Her blood picture was not that of pernicious anemia and the bone-marrow biopsy did not show the findings of pernicious anemia. She had a toxic goiter removed six years previously, with weight loss of some 50 or 60 pounds since that time. The possibility of recurrent thyrotoxicosis should be considered, but there is no other evidence for it.

Then she was known to have had heart disease of some type for a few years. The heart was enlarged

chiefly in the region of the left ventricle. She was fibrillating. There was no history of hypertension. Her blood pressure in the hospital was low — 92 systolic, 48 diastolic. The electrocardiogram is of no value in the diagnosis of the heart disease but confirms the presence of fibrillation. She had a relatively loud systolic murmur heard best at the lower border of the sternum. This murmur is consistent with disease of the aortic valve in a person who has developed failure and a fall in blood pressure and is acutely ill. I think it most likely that the autopsy showed disease of the aortic valve and a large left ventricle.

Is it possible that the heart disease was a major factor in her present hospital admission? It seems unlikely. She had a fever. She went downhill rapidly. The blood culture was negative. It seems unlikely that subacute bacterial endocarditis should be seriously considered. Disposing of the three things in the past history we have to consider the problem of painless jaundice at the age of sixty-nine. Perhaps the most important of the x-ray findings is the presence of a large spleen. This was questionably palpable, but the x-ray examination confirms that there was a large spleen. Dr Jones said earlier this morning at Medical Grand Rounds that a large liver and large spleen in the presence of jaundice means that there must be intrinsic liver disease, and not obstructive jaundice. Extrahepatic obstruction should not give this large spleen.

Before dismissing the possibility of biliary obstruction, one would have briefly to consider carcinoma of the head of the pancreas and carcinoma of the bile duct or of the ampulla of Vater with resultant damage to the liver. Against carcinoma of the ampulla of Vater is the absence of a positive guaiac reaction in the stool. The majority of cases should have blood in the stool. Certainly, a common-duct stone can produce jaundice, a large liver and intermittent fever and can go on to a fatal termination without any significant degree of pain, but we have already concluded from the presence of a large spleen that the primary difficulty was within the liver.

What type of liver disease could she have had that would end up with this clinical picture and fatal termination? There was no history that suggests the usual etiologic factor in producing alcoholic cirrhosis. Apparently, the patient had been a neurotic type of person. She may well have had a poor diet, but she certainly was not alcoholic. The possibility of biliary cirrhosis should be considered. The usual term "Hanot's cirrhosis" is confusing. It apparently has been a catch-all for a number of poorly understood conditions. In recent years it has been shown that following virus infections of the liver, chronic hepatitis, progressing to a type of biliary cirrhosis that is consistent with this clinical picture, can develop.

The laboratory findings, as so often happens in the presence of jaundice, are confusing. At least they are to me. She had bile in her stools because

*Assistant in medicine, Massachusetts General Hospital

they were not clay colored on admission, and there is no mention of clay-colored stools later on. She had normal urobilinogen in the stools and only moderately elevated urobilinogen in the urine. This indicates that there was not a high degree of extrahepatic obstruction. The alkaline phosphatase, being moderately elevated and rising, is suggestive of extrahepatic obstruction. The cephalin-flocculation test was strongly positive, suggesting a considerable degree of liver damage. The cholesterol was very low, as were the cholesterol esters. These indicate severe hepatic damage rather than extrahepatic obstruction.

I am sure the problem on the ward was whether this was extrahepatic or parenchymatous jaundice. Finally, a biopsy was done, which I do not believe can completely answer the question. There was evidence of proliferation of the small bile ducts and an inflammatory reaction, but inspissation of bile in the cholangioles that would ordinarily be seen in extrahepatic obstruction was not present. However, to the pathologist, the findings suggested obstruction in the extrahepatic biliary tract. In spite of that, I believe that the primary difficulty must have been within the liver and that she had some type of cirrhosis, probably biliary cirrhosis.

The other problem is the high, localized elevation of the diaphragm, which raises the question whether this woman had developed a hepatoma. The biopsy did not show it, but it could well have been missed and I think the pathologist is the only one who can answer that.

A PHYSICIAN: Does the fact that the liver border went down from 11 cm to 4 cm mean anything to you?

DR DUNCOMBE: I think that it suggests an acute or subacute infection of the liver with cirrhotic changes of the type that has been described following virus infection.

A PHYSICIAN: Would you comment on the peculiar fever that this woman ran?

DR DUNCOMBE: There was some statement here that meant nothing to me. It was noted on one occasion that her general sense of well-being and appetite improved with the high fever. People with severe liver disease and particularly people with cancer in the liver can have a high, irregular, septic temperature, and I assume that it is on the basis of severe liver disease, possibly with a hepatoma.

DR RICHARD J CLARK: Would you consider cholangitis in itself as possibly being the background?

DR DUNCOMBE: Whatever the terminal illness causing jaundice of six weeks' duration, some difficulty had been present for some months previous to that period. I do not see how one can rule that in or out completely.

DR TRACY B MALLORY: The discharge diagnosis from the wards was subacute atrophy of the liver. I wonder whether there is anyone who wishes to defend that?

DR BENJAMIN CASTLEMAN: I believe they made that diagnosis because the liver shrank so rapidly. At least the same examiner thought so.

CLINICAL DIAGNOSES

Subacute yellow atrophy of liver
Arteriosclerotic heart disease

DR DUNCOMBE'S DIAGNOSES

Biliary cirrhosis of liver, probably secondary to virus hepatitis
Aortic stenosis
Hypertrophy, left ventricle

ANATOMICAL DIAGNOSES

Cholelithiasis
Fistula, cystic duct to duodenum
Obstructive biliary cirrhosis
Splenomegaly, Banti type
Cardiac hypertrophy

PATHOLOGICAL DISCUSSION

DR MALLORY: At autopsy we found that the liver certainly could not have shrunk much in size because it was still very large, weighing 2520 gm. The apparent shrinkage was due essentially to elevation of the diaphragm.

A large gallstone was found in the common bile duct just above the ampulla, an adequate cause for the development of an obstructive biliary cirrhosis. With further dissection we found that the biliary tree had spontaneously drained itself, that the gall bladder had become a narrow tube with thick fibrous walls but that the cystic duct was dilated to equal diameter and a fistula had developed between the cystic duct and the duodenum. Evidently, drainage had been re-established after a very prolonged period of obstruction of the common duct. At the time of autopsy the inflammatory infiltration in the liver had become more impressive than it was in the biopsy. Either it had extended or perhaps the biopsy was not representative. The surface of the liver was quite finely granular, and the tissue was very firm, and cut with a great deal of difficulty.

The spleen was very large, weighing around 800 gm, and showed on microscopical examination minimal but, I believe, distinct changes suggesting portal hypertension. This is the Banti type of spleen, something that is very rarely seen with a biliary cirrhosis, only with one of very long standing.

The heart was much enlarged, weighing 600 gm, and we could find no reason for it other than an accumulation of a great deal of pericardial fat. There were no valvular lesions, no coronary-artery narrowing, no myocarditis and no evidence that the patient had ever had hypertension. Although heart disease must have been present, I cannot give it a name and say what kind it was.

HOLIDAY

THE holiday nearest to the hearts of the western world comes opportunely at a time when practically everyone needs a rest after the weeks spent in arduous preparation for Christmas. Unfortunately the long-anticipated day has itself become so exhausting that a second holiday is necessary a week later to recover from the observance of the first—were this provision not rendered ineffective for many by the necessity of dedicating New Year's Day to the task of recovering from the indiscretions of New Year's Eve.

The traditional festival season is long anticipated and unmistakably merry but something of an ordeal.

After all, as some astute philosopher has suggested, it is not so much a rest that man needs in his holidays as it is a change of direction, and this the major festival season of Christianity provides, not only in the intellectual and some of the physical habits of man, but in his point of view as well.

Man is essentially a materialistic being who suspects that in concrete possessions he may find peace and contentment. And still he knows, when he stops to consider it, that nothing is farther from the truth. More radios, more amusements, more automobiles and other faster and more potentially lethal forms of transportation go parallel with more unhappiness, more broken homes, more crime and an increasing loss of true moral values. Those who link their hopes of happiness to ownership are doomed to frustration. Man enters the world naked, it has been said and naked he leaves it, an observation that has frequently been confirmed in the silent watches by many a family doctor.

With the extremes of poverty and wealth of discomfort and comfort, of misery and luxury that exist in the world today greater than ever before, and a general lack of that security that cannot be purchased, it becomes apparent that some other type of currency must be used that is available to all, in the purchase of human peace and understanding.

Coldly scientific or blindly emotional as man may be, still the only currency he can use that cannot be depreciated is one that is measured in spiritual values only.

With which the *Journal* wishes its readers a Merry Christmas, replete with candy canes, and a Happy New Year equipped with flexible but shatterproof resolutions.

MASSACHUSETTS GENERAL HOSPITAL LOOKS AHEAD

THE spirit of research has prevailed at the Massachusetts General Hospital since the founding of the hospital, whose time-honored contributions to medical progress in the nineteenth century are too well known to need reciting. In the first half of the present century also clinical research at the hospital has grown apace. Research laboratories have been set up in every nook and cranny of the Bulfinch Building, and in 1939 a suite of research laboratories was made available for the surgeons with the opening of the White Building.

In 1942 Harvard's Huntington Laboratory moved to the hospital and was given an entire floor in the

old domestic building, where converted kitchens and dining rooms lent themselves well, although far from perfectly, to research purposes. Ultimately most of this building will be devoted to laboratories. The most recent acquisitions of research laboratory space are for the Pediatric and Gynecological services in the Burnham-Vincent Building, which was opened in 1947, and for the Dermatological Service in what was once Ward E and the old Bradley operating theater.

But even this is not enough. Since the last war funds for research have become available to a

RESEARCH BUILDING

degree undreamed of a decade ago, creating increased opportunities to put investigators to work. These workers on their part have been flocking to the Massachusetts General Hospital in ever-increasing numbers from all parts of the earth.

A building devoted exclusively to research became essential, and at long last there is to be one, with the erection of a six-story structure along the Blossom Street edge of the hospital's property, beginning at the corner of Allen Street, where the Director's house now stands. This house must be abolished, which may cause some regret, but progress demands the sacrifice. There was no other convenient place to put the new building.

Acceding gladly to public need, the hospital will devote major research activities in the new space largely to investigations on cancer, cardiovascular disease and arthritis, with one floor utilized exclusively for the most fundamental type of biochemical research — enzymology — under the direction of the world-famous Dr. Fritz Lipmann.

Although the money is in hand to build the Research Building, that for equipping it remains to be raised. And this will be very costly, because

as man gets closer and closer to the facts of life of the cell the more intricate, prodigious and expensive become the implements that he needs to extend the range of his knowledge. No longer can the investigator conduct his studies solely with test tube and old-fashioned microscope. He now needs such items as electron microscopes, ultracentrifuges, electrophoretic apparatus and innumerable radiation detectors. All these and more will constitute the scientific furniture of the Massachusetts General Hospital's new research building. To attempt to set up a research institute without such equipment would be equivalent to sending an army against the enemy equipped only with rifles and hand grenades.

The material of the biologic or medical investigator is living tissue — that of man or of animals, for with no other medium can the way to prevent or cure disease be found. The use of such material, however, imposes great responsibility. In experiments on animals, suffering must be minimized. Studies on man must be planned only with the subject's full understanding and consent, and with every protection against all possible injury.

The top floor of the new research building will be a farm for the animals used in research. An animal lover on the Board of Trustees of the hospital, together with the architect and the staff members, has planned this farm to give its inmates conditions optimal for their welfare.

The participation of human patients in research dates from time immemorial. At the Massachusetts General Hospital it has been greatly facilitated by the installation in 1925 of a special ten-bed research ward. This ward already has had a distinguished career, and it is hoped that one day its history will be written down. Already its contributors have enriched the medical literature. Last March it was finally named the Mallinckrodt Ward 4 in honor of Mr. Edward Mallinckrodt, Jr., one of its principal benefactors. The only fault of the research ward is that it is nowhere near large enough. With the opening of the Research Building certain space now occupied by laboratories will be vacated and can be used to double the size of the Mallinckrodt Ward, which is in close prox-

imity to the site of the new building. This juxtaposition is bound to be fruitful.

Already \$1,750,000 has been raised toward the goal of \$2,750,000 announced last year—almost enough to construct the building without equipment. The current drive terminating on January 1, 1950, is confidently expected to bring the fund to practical completion.

ARTHRITIS AND RHEUMATISM FOUNDATION

CHRONIC arthritis, it is said, has stiffened man's backbone for a period estimated at forty-one thousand nine hundred and forty-nine years. His backbone has now been stiffened, it appears, to the point where he is ready to make some unusual efforts in its behalf.

Little enough has been done for arthritis in these days of multi-million-dollar projects, according to available figures. In spite of the fact that about 7,000,000 Americans suffer from some form of arthritis or rheumatic disease, or about one out of every twenty citizens, only \$200,000 a year is being spent on research into the disease and the care of the patients being studied. In contrast to this figure it is interesting to note that \$10,587,000 is currently being expended in the field of cancer research, that during the past year \$18,665,523 was raised in the annual campaign against tuberculosis and \$18,669,299 in that against poliomyelitis and that \$11,000,000 has been appropriated by Congress for the construction of forest trails (but not for the use of arthritic patients).

The Arthritis and Rheumatism Foundation, determined that at last a united effort shall be made to obtain funds with which to fight the Number 1 crippler of mankind, is now engaged in a nationwide campaign. Started before Thanksgiving it will run until nearly Christmas, with General Lucius D. Clay as chairman. The New England Chapter is doing its share and is in addition making a survey of the arthritis clinics in the State with the assistance of the Department of Public Health, and the approval of the Council of the Massachusetts Medical Society, which has also established a subcommittee on arthritis of the Committee on Public Health.

NEW ENGLAND COUNCIL

NEW England medicine had its day—three of them—at the Copley Plaza Hotel in Boston on the occasion of the previously announced eighth annual postgraduate assembly, on November 9, 10 and 11, 1949. The guest speakers on the excellent program were drawn from such diverse points as New York and Baltimore, Chicago, Philadelphia, Durham, North Carolina, Rochester, Minnesota, and Saskatoon, Saskatchewan. The audience, on the other hand, overwhelmingly New Englanders, made up in numbers what they lacked in geographic distribution. 975 physicians registered for the course.

On the premise that postgraduate education is a major factor in medical organization the New England Assembly rates a high mark in the fulfillment of this function.

The status of the Council of the New England State Medical Societies and the relations that exist between it and the New England Postgraduate Assembly are confused in the minds of many physicians in the area. They are, in fact, mutual enterprises serving the same general ends, but independent in organization. The Council promotes improvement in medical practice throughout New England, the Assembly, organized and conducted for reasons of convenience by a committee of the Massachusetts Medical Society, is a mutual undertaking of the six New England state societies and enjoys the blessing of their Council.

The Council, composed of three representatives from each state society, met during the course of the Assembly and heard reports on hospital care for the chronically ill by Dr. W. A. R. Chapin, of Springfield, on the unsuccessful attempts at establishing working relations between the Massachusetts Medical Society and the Massachusetts Hospital Association by Dr. A. E. Parkhurst, and on the conference on public relations held in Chicago in November by Dr. John R. Conlin. A dinner for the entertainment and enlightenment of the New England senators and representatives in Congress was discussed and planned for December 18, prior to their return to Washington.

If any valid criticism of the New England Council of State Medical Societies exists, it is that its

old domestic building, where converted kitchens and dining rooms lent themselves well, although far from perfectly, to research purposes. Ultimately most of this building will be devoted to laboratories. The most recent acquisitions of research laboratory space are for the Pediatric and Gynecological services in the Burnham-Vincent Building, which was opened in 1947, and for the Dermatological Service in what was once Ward E and the old Bradlee operating theater.

But even this is not enough. Since the last war funds for research have become available to a

RESEARCH BUILDING

degree undreamed of a decade ago, creating increased opportunities to put investigators to work. These workers on their part have been flocking to the Massachusetts General Hospital in ever-increasing numbers from all parts of the earth.

A building devoted exclusively to research became essential, and at long last there is to be one, with the erection of a six-story structure along the Blossom Street edge of the hospital's property, beginning at the corner of Allen Street, where the Director's house now stands. This house must be abolished, which may cause some regret, but progress demands the sacrifice. There was no other convenient place to put the new building.

Acceding gladly to public need, the hospital will devote major research activities in the new space largely to investigations on cancer, cardiovascular disease and arthritis, with one floor utilized exclusively for the most fundamental type of biochemical research — enzymology — under the direction of the world-famous Dr. Fritz Lipmann.

Although the money is in hand to build the Research Building, that for equipping it remains to be raised. And this will be very costly, because

as man gets closer and closer to the facts of life of the cell the more intricate, prodigious and expensive become the implements that he needs to extend the range of his knowledge. No longer can the investigator conduct his studies solely with test tube and old-fashioned microscope. He now needs such items as electron microscopes, ultracentrifuges, electrophoretic apparatus and innumerable radiation detectors. All these and more will constitute the scientific furniture of the Massachusetts General Hospital's new research building. To attempt to set up a research institute without such equipment would be equivalent to sending an army against the enemy equipped only with rifles and hand grenades.

The material of the biologic or medical investigator is living tissue — that of man or of animals, for with no other medium can the way to prevent or cure disease be found. The use of such material, however, imposes great responsibility. In experiments on animals, suffering must be minimized. Studies on man must be planned only with the subject's full understanding and consent, and with every protection against all possible injury.

The top floor of the new research building will be a farm for the animals used in research. An animal lover on the Board of Trustees of the hospital, together with the architect and the staff members, has planned this farm to give its inmates conditions optimal for their welfare.

The participation of human patients in research dates from time immemorial. At the Massachusetts General Hospital it has been greatly facilitated by the installation in 1925 of a special ten-bed research ward. This ward already has had a distinguished career, and it is hoped that one day its history will be written down. Already its contributors have enriched the medical literature. Last March it was finally named the Mallinckrodt Ward 4 in honor of Mr. Edward Mallinckrodt, Jr., one of its principal benefactors. The only fault of the research ward is that it is nowhere near large enough. With the opening of the Research Building certain space now occupied by laboratories will be vacated and can be used to double the size of the Mallinckrodt Ward, which is in close proximity

in the night was disregarded by her physician. One week before admission, headaches without localization developed, followed by slow speech and increasing drowsiness. Consultants considered encephalitis or some form of poisoning. Death occurred about forty-eight hours after admission to the hospital. There was a cystic glioblastoma multiforme, 4.5 cm in diameter, in the right frontal lobe. The vague initial symptoms were due to the neoplasm itself, and the terminal episode to the sudden enlargement of the cyst.

It should be emphasized that events such as those in these cases can occur in tumors other than glioblastoma multiforme but are more frequent when that tumor is present. Enlargement of a cystic tumor or progressive growth of a tumor in the region of the aqueduct of Sylvius can lead to relatively sudden death as the result of acute hydrocephalus.

Slowly growing neoplasms occasionally cause unexpected death when they involve areas of the brain from which few or no localizing signs are produced. Atrophy and condensation of the brain compensate for their presence until the size of the tumor precludes further adjustment. Death may then be sudden, usually the result of pontine hemorrhage, as in the case of a sixty-nine-year-old man who died three days after a fall, in which he had injured his neck and lost consciousness. He was thought to have sustained a cerebral laceration or a fracture of the spine. Autopsy showed a very large parasagittal meningioma and pontine hemorrhage. Further study of the history uncovered several episodes suggestive of a minor cerebrovascular accident over the few months preceding death.

Small hemorrhages scattered through the pons often result when the vessels of that region become excessively distorted as a consequence of an expanding lesion within the skull. They are the most frequent cause of death in neglected subdural hematoma and, far more often than is usually supposed, in intracranial tumors, regardless of location.

Intracranial tumors are often discovered in medicolegal autopsies when they are the precipitating cause of accidents, as in the case just described. Falls, automobile accidents and other forms of trauma occur as the result of the unsteadiness and mild mental confusion that often precede definite clinical symptoms of intracranial tumor. The primary purpose of this note, however, is to call attention to mechanisms by which unexpected deaths are *directly* produced by the tumors.

ORVILLE T. BAILEY, M.D.

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

CANCER FACT BOOK

The Department has just prepared a new edition of the *Cancer Fact Book*, which contains a series of charts and tables for the use of physicians desiring data on cancer. Copies of this booklet may be obtained on request.

The booklet contains information regarding the services of the State and State-aided cancer clinics and the Tumor Diagnosis Service, as well as the epidemiology of cancer.

At the present time there are six times as many cancer deaths among males and three times as many among females as there were at the beginning of the century.

Adjustments to take into account changes in the age distribution of the population showed that the rates for females have been declining for the past fifteen years. This downward trend has been more marked for Massachusetts than for the country as a whole.

The sites of cancer showing a downward trend are the mouth, skin, stomach and uterus.

About 30 per cent of all deaths, among women between the ages of forty and sixty, are from cancer.

About 13 per cent of all new cancer cases in Massachusetts are seen in the cancer clinics.

About 85 per cent of all patients seen at the cancer clinics are sent by physicians.

The median age of cancer patients seen at the clinics is several years older at present than in 1930.

There is a four-month delay between first recognizable symptoms and first visit to physician, and a two-month additional delay before the first visit to a clinic.

Of the cases of cancer in which the patients attended the cancer clinics, 36 per cent were classified as probably curable, 31 per cent as possibly curable, and 33 per cent as incurable.

Of patients with skin cases seen within the first month, 80 per cent were alive ten years after treatment. Of those seen later than one month about 44 per cent were alive ten years after treatment.

Of patients with cancers other than of the skin, seen within one month, 39 per cent were alive ten years after treatment, and of those seen after one month, 20 per cent were alive ten years after treatment.

Although pain usually has not been considered a symptom of early cancer, it was present in an eighth of all cancer patients who came to the clinics within two months after the first symptom was noticed.

light is still too far under the bushel. Active and interested members of the various New England societies are still unaware of its accomplishments, its aims or even its very existence. There is scarcely a New Englander that is not proud of the traditions, the independent sturdiness and the solidarity of his section of the country. So far as medical standards are concerned, the Council is in a position to aid in preserving all of these, but its activity should be better publicized.

It is announced in the papers that Dr Richardson, of Boston, expelled a tape worm from a patient which was 100 feet long!

Boston M & S J, December 12, 1849

MASSACHUSETTS MEDICAL SOCIETY

TWO-WAY MOBILE RADIOS AVAILABLE

The Federal Communications Commission gives preference to physicians for the use of two-way mobile radios.

The installation cost is \$17.75 per month. The charge for completed calls in both directions is \$0.35, the charge for check-in and check-out is \$0.05 and the charge for location reports is \$0.05. Physicians within a 30-mile radius of the State House who desire to have one of the 300 available units in their automobiles, should communicate at once with American Communications Co., Inc., 272 Centre Street, Newton (Tel DEcatur 2-3630).

NOTES FROM THE MEDICAL EXAMINER

UNEXPECTED DEATH DUE TO INTRACRANIAL TUMORS

The symptoms caused by intracranial tumors extend over months or years in the great majority of cases. For this reason, brain tumors would not be expected to appear in the records of the medical examiner except as incidental findings in patients dying of other causes. A survey of records, however, shows that intracranial tumors are found in a considerable number of cases as the principal cause of death. This note is concerned with some of the mechanisms by which unexpected deaths may be brought about by these lesions.

Gliomas that infiltrate and replace cerebral tissue in "silent" areas of the brain, such as the frontal lobes and portions of the occipital lobes, may attain large size without producing symptoms sufficiently clear-cut to justify careful clinical study. Another such region is the corpus callosum. All too often, the early signs are psychic in nature and are regarded as manifestations of mental instability. The number of unexpected intracranial tumors found at autopsy in mental institutions shows that recognizable manifestations may be wholly of this character throughout the course of a long illness. Meningeal tumors pressing on "silent" areas may enlarge slowly over many years without producing clinical symptoms because compensatory mechanisms allow for the increase in intracranial volume.

The point at which distinctive clinical symptoms are produced is the onset of increased intracranial pressure. This is due either to a sudden increase in intracranial volume, which does not allow time for the compensatory mechanisms to come into play, or to a gradual enlargement, which finally taxes these mechanisms beyond their limits, at which point death may ensue very quickly.

The abrupt and unexpected increase in volume of intracranial contents resulting from a tumor is usually due to a large hemorrhage, especially in a glioblastoma multiforme. The blood vessels in this glioma characteristically show atypical proliferation, which predisposes them to rupture. Glioblastoma multiforme has a tendency to replace considerable amounts of brain tissue, thus delaying the onset of increased intracranial pressure until the tumor is large.

A typical case was that of an eighteen-year-old college student who complained of lack of ability to concentrate, blurred vision and headache of three weeks' duration, thought to have been caused by the strain of examinations. After the examinations, he was admitted to the hospital for study. For fifteen days, he was asymptomatic except for mild headaches. On the sixteenth day, the headaches suddenly became very severe, and a tonic convulsion occurred, followed by shock, respiratory failure and death. At autopsy, a huge glioblastoma multiforme was found in the corpus callosum extending into both occipital lobes. There was massive intraventricular and subarachnoid hemorrhage from blood vessels of the tumor.

Many gliomas become cystic. Although neoplastic cysts usually enlarge slowly, they may expand much more rapidly, causing the symptoms to be sufficiently bizarre to make clinical diagnosis difficult and leading to the suspicion of poisoning or trauma to the head.

In such a case a sixty-five-year-old woman was admitted to the hospital because of stupor for twenty-four hours. The statement of a relative that the patient had for some weeks made repetitious comments and had wandered about the house

spring of nondiabetic parents, or to the therapeutic omission of the use of glucose in perhaps the largest series of infants born of diabetic mothers reported from one clinic.

A doctor or student who wishes to investigate a problem in diabetes will find the book full of suggestions.

The book is heartily recommended—minus the diet tables, which could be summarized and thus reduce the cost and make it available to more readers. Moreover, the diet of any diabetic patient varies from day to day according to exercise and mode of life, and he must be taught how to make adjustments.

Practical Aspects of Thyroid Disease By George Crile, Jr., M.D. 12°, cloth, 355 pp., with 101 illustrations. Philadelphia: W. B. Saunders Company, 1949. \$6.00.

This monograph of 355 pages presents in a large measure the personal experience of the author in diagnosis and treatment of diseases of the thyroid gland. In an effort to make the volume succinct and perhaps more practical, the author purposely avoids presenting a study of the much larger accumulated material of thyroid pathology from the Cleveland Clinic gathered under George Crile, Sr., and his associates. In only a few less common pathologic conditions of the thyroid gland does he employ this fuller material in his discussion, this too, however, is interpreted very much in the light of his own personal experience.

The book opens with a brief discussion of the physiology and pathology of the thyroid gland and presents well established concepts generally accepted in the prevention and treatment of endemic goiter. The material is divided into chapters dealing with the diagnosis and the treatment of hyperthyroidism in its various aspects and dealing also with the various complications of treatment of thyroid disease. Antithyroid therapy both as primary medical treatment and as a preparation for surgery is discussed, and a very brief discourse is given on radioactive iodine. The reviewer does not entirely agree with the author that radioactive iodine is "safe, effective and simple," and believes such conclusions are not yet warranted in the light of insufficient experience to substantiate such a statement. The author does, however, advise caution in the employment of this drug but concludes that radioactive iodine bids fair to become the preferred treatment for all patients with Graves' disease. This the reviewer very much doubts and would caution that this material be used only in the hands of those thoroughly trained in the use of irradiated isotopes.

The description of the technic of thyroidectomy is outlined as practiced by the author. In all probability this is not the technic that has been employed in the past in the Cleveland Clinic. The surgical technic as described, however, is sound and practical and, in general, similar to that advocated in other large thyroid clinics in the country. One is glad to note that exposure of the recurrent laryngeal nerves is advocated. The volume proceeds, then, with a discussion of the various pathologic conditions of the thyroid gland such as thyroiditis and carcinoma. A brief chapter is given, also, on the types of anesthesia. It is interesting to note that the old arguments for the use of local anesthesia are still in force, and the dictum is advanced that a more adequate respiratory exchange can be obtained with greater ease under local anesthesia than in patients who are relaxed under general anesthesia. Certainly, this would not be agreed to by everyone, respiratory exchange can be obtained in all types of thyroid conditions under general anesthesia if an endotracheal catheter is used. In the hands of expert anesthesiologists, intratracheal anesthesia can be employed without trauma and without any increased morbidity and certainly adds to the patient's comfort and greatly reduces the possibility of obstruction.

The chapter on carcinoma of the thyroid gland reflects almost entirely the views of the Cleveland Clinic and in a large measure represents the work of Dr. Allen Graham. The descriptions of the various types of carcinoma arising in the gland are in large measure similar to other classifications but perhaps are not quite so practical as the classification given by Warren and Meissner. One also is at a loss to understand whether the author advocates the removal of discrete adenomas, which in so many clinics are thought to be very definite precursors of carcinoma of the thyroid gland or whether he prefers to wait until the clinical diagnosis of carcinoma is made before discrete adenomas are removed.

This discussion does not present a completely convincing argument for or against such now quite universally accepted prophylaxis.

The material is well presented, well organized and extremely well illustrated. It should prove valuable to the general practitioner who does not have a large experience in the treatment of thyroid disease, but it would not be of great help to the internist or surgeon who has had a reasonably large experience in the recognition and treatment of various pathologic conditions of the thyroid gland.

A moderate number of cross references is given. To the critical reader, if he desires, they present sufficient material to clear up certain controversial points that are not entirely clarified in this volume.

The book is well printed and it is to be recommended to the type of reader mentioned above.

Food and Facts for the Diabetic By Joseph H. Barach, 8°, cloth, 113 pp., with 16 illustrations and 21 tables. New York: Oxford University Press, 1949. \$4.00.

This volume consists of 113 pages of text, including tables and index, but also 198 unnumbered pages on which are 232 diets for men and women of the ages of twenty-five and above, as well as diets for children and emergencies. The diets are calculated on the basis of body build—small, medium and large—for 250, 275 and 300 calories per kilogram of body weight respectively. One could hardly blame the patient if he asked why he should purchase so many diets that are not designed for him.

The text is admirable, and one would hope that all diabetic patients would become familiar with it, although the style is rather more for nurses and dietitians and the more intelligent diabetic patients than for the rank and file. The advice given the patients is stated so clearly and is so sound that it would be meticulous and, indeed, unfair to point out the few sentences or even paragraphs, which undoubtedly will be altered in a subsequent edition.

NOTICES

MISSISSIPPI VALLEY MEDICAL SOCIETY

The fifteenth annual meeting of the Mississippi Valley Medical Society will be held at Springfield, Illinois, on September 27, 28 and 29, 1950, under the presidency of Dr. N. G. Alcock, of the University of Iowa.

MISSISSIPPI VALLEY MEDICAL SOCIETY 1950 ESSAY CONTEST

The Tenth Annual Essay Contest of the Mississippi Valley Medical Society will be held in 1950. The Society will offer a cash prize of \$100.00, a gold medal, and a certificate of award for the best unpublished essay on any subject of general medical interest (including medical economics and education) and practical value to the general practitioner of medicine. Certificates of merit may also be granted to the physicians whose essays are rated second and third best. Contestants must be members of the American Medical Association who are residents and citizens of the United States. The winner will be invited to present his contribution before the Fifteenth Annual Meeting of the Mississippi Valley Medical Society to be held in Springfield, Illinois, September 27, 28 and 29, 1950, the Society reserving the exclusive right to first publish the essay in its official publication—the *Mississippi Valley Medical Journal* (incorporating the *Radiologic Review*). All contributions shall be typewritten in English in manuscript form, submitted in five copies, not to exceed 5000 words, and must be received not later than May 1, 1950. The winning essays in the 1949 contest will appear in the January, 1950, issue of the *Mississippi Valley Medical Journal*.

Further details may be secured from Harold Swanberg, M.D., Secretary, Mississippi Valley Medical Society, 209-224 W. C. U. Building, Quincy, Illinois.

POSITION FOR QUALIFIED BACTERIOLOGIST IN VETERANS ADMINISTRATION

A vacancy exists for a qualified bacteriologist in the pathology laboratory of the Veterans Administration Center, Los Angeles 25, California. The laboratory is located in the

CORRESPONDENCE

ON THE SOUNDS OF THE HEART

To the Editor I have admired the painstaking and scholarly quality of Dr. Orias's article on heart sounds in the issue of November 17, of the *Journal*. But is this not an instance of how the attempt to apply graphic instrumental methods has made obscure a matter which is readily clarified by simple observation?

To summarize what I wrote many years ago in the *New England Journal of Medicine*, in an article entitled "The Cause of the First Heart Sound" (200 917, 1929), the first heart sound is a tone produced by the sudden assumption of tension by the structures surrounding the ventricular cavities — namely, the ventricular walls and the mitral and tricuspid valves — as the diastolic collapse of the ventricular walls is converted suddenly to a state of tense convexity by systole.

Simple illustrations of comparable tones are as follows. If one pulls sharply on the edge of a handkerchief, previously in loose folds, a tone is produced. If the sail of a boat is suddenly filled by a gust of wind a tone is produced. Or if one blows sharply into a collapsed paper bag a tone is produced. The similar nature of the first heart sound is unmistakable if one observes the exposed heart of a large dog.

If one looks closely at the freely exposed heart of such an anesthetized dog, one sees that there is, in diastole, an instant of flaccid concavity of the anterior surface (the right ventricle) that flaps suddenly into a hard convexity as systole becomes effectual. And if one listens with a small, lightly applied stethoscope the conclusion is inescapable that it is this sudden resumption of convexity and tension that produces the first sound.

Undoubtedly, if one skilled in delicate physiologic technique were to take multiple lymographic tracings of the ventricular surface and of intraventricular pressure, all synchronized with a phonocardiogram, one would obtain objective confirmation of this. But where the mechanism is so clear to anyone who will look, feel and listen understandingly it seems unnecessary to go farther.

FRANCIS W. PALFREY, M.D.

Boston, Massachusetts

TREATMENT OF THROMBOEMBOLIC DISEASE

To the Editor I was very much interested in the recent article on pulmonary embolism by Roe and Goldthwait in the November 3 issue of the *Journal* and also in the editorial on the same subject appearing in that issue.

I realize full well the importance of statistical analyses, and I also am well acquainted with the fallacy of relying upon them to chart one's course in therapeutics, especially if the statistics do not take into consideration all the pertinent data. It is unfortunate that the authors did not correlate their autopsy statistics with general hospital population according to age and disease and also the magnitude of the operative procedures in the different periods in an effort to determine the true cause of the increased incidence of fatal embolism rather than to blame it on the failure of femoral-vein interruption, as a method of treating thromboembolic disease.

Realizing what an important step in the treatment of thromboembolic disease that interruption of femoral veins has been since Homans first described it in 1934 and for fear that this article will be quoted (as it already has to me as damning evidence that the procedure is of little value in the therapy of this disease), I feel it my duty to point out that the increased number of cases of fatal embolism at the autopsy table in the past five-year period, 1943-1947, certainly is not because this method has failed in the majority of patients that have been so treated. In fact, the inference that should be drawn from the statistics quoted in the article is that more patients should have had their femoral veins interrupted, since in this five-year period interruption was performed in only 10 of the 92 fatal pulmonary emboli. It should also be pointed out that this method of treating thromboembolic disease was not generally accepted throughout the Massachusetts General Hospital. In fact, it was only on the East Surgical Service while Dr. Arthur W. Allen was chief and on his patients and mine and a few others on the private side that a policy was carried out in which femoral-vein interruption was the method

of choice in the treatment of thromboembolic disease in all its various manifestations.

There is no question that this article is an important one, since it draws to the reader's attention that we have not solved the problem of thromboembolic disease. The subject certainly needs further investigation, but until we have better methods at our disposal to prevent massive pulmonary embolism the operation of femoral-vein interruption in the hands of a competent surgeon should not be discarded. Those that recommend it fully realize that it is not a perfect procedure, but let us not incriminate it too severely from this report, when in 92 cases of fatal pulmonary embolism it was not used in 82, or 89 per cent.

ROBERT R. LINTON, M.D.

Brookline, Massachusetts

BOOK REVIEWS

Diabetes and its Treatment By Joseph H. Barach, M.D. 8¹/₂ cloth, 326 pp., with 73 illustrations, 50 tables, and 2 plates. New York: Oxford University Press, 1949. \$10.00.

This book is written by an author who knows diabetes well and deserves the approbation of every physician in the United States for his courage in exposing diabetic quackery wherever found. Unfortunately, the book is expensive, because it contains 326 numbered pages and approximately 200 unnumbered pages devoted to a system of diets for men, women and children, all of which are duplicated in his other book, entitled *Food and Facts for the Diabetic*, which was written for patients. There are 73 figures and 60 tables.

Commendable initiative throughout is shown by the writer. He draws upon his own practice to illustrate the advantages of this or that kind of treatment. The volume is decidedly *suus generis*, although the literature is also very well covered. The text is expressed forcibly, and nearly every page is thought provoking, for example, "Obviously the diabetes that appears at the age of 10 will have many more years to produce changes in the tissues and organs of the body than the diabetes that comes at 60, so that the later in life that diabetes appears, the less chance it has to shorten life." One wonders whether the diabetes that is diagnosed at the age of sixty has not been latent in many cases for a decade or more and, therefore, whether the foregoing really states the situation fairly. Best and Kendall Emerson, Jr., have both intimated the presence of a prediabetic diabetic era and the need for the vigorous and active treatment of such cases. At present this can be done only by the prophylaxis of obesity. The following statement about obesity is worth wide dissemination: "Since there is no known advantage in being overweight, we may very well offer the blanket advice to everyone to avoid obesity." Dr. Barach is equally incisive about the marriage of a diabetic person: "My advice to a young member of my own family would be not to marry a diabetic, and my advice to a diabetic would be not to marry at all, unless other conditions in his or her life are favorable." In dealing with heredity, however, the author inadvertently has given a wrong impression in stating that all the children of two diabetic parents will develop diabetes. Theoretically, they will develop diabetes, but practically they will not do so unless they live long enough to reach the age at which diabetes is likely to break out. The chances have been computed that before those ages are reached at least half the offspring will die of other diseases.

Throughout the volume one finds words of wisdom and new viewpoints when old problems are presented. There is an instructive table of the common complaints of the patient and a novel discussion of weights and diets. Deformities are recognized as occurring quite often in the children of diabetic parents, and the author also calls attention to the frequency with which lesions of the feet of older patients are connected with and often dependent upon congenital deformities of the feet themselves. It is unfortunate that when the 47 per cent mortality and even 45 per cent mortality for thigh operations upon diabetic patients in certain localities are referred to, attention is not called to the low mortality of McKinnick and his group — 5.5 per cent, according to a recent paper in the *Annals of Surgery* (130:826, 1949) — and to their conclusions that transmetatarsal operations make many thigh operations unnecessary. Reference is made to the routine practice of giving glucose to the children just born of diabetic mothers, but attention is not called to the hypoglycemia, which is often found in the off-

GENERALIZED INTESTINAL POLYPOSIS AND MELANIN SPOTS OF THE ORAL MUCOSA, LIPS AND DIGITS*

A Syndrome of Diagnostic Significance

HAROLD JEGHERS, M D,† VICTOR A. McKUSICK, M D,‡ AND KERMIT H. KATZ, M D§

WASHINGTON, D C, BALTIMORE, MARYLAND, AND BOSTON, MASSACHUSETTS

IN 1944, a brief report was made by one of us¹ regarding the association, in 2 patients, of a distinctive type of melanin pigmentation of the oral mucosa, lips and digits with intestinal polyposis.

Since then 10 cases, including the 2 referred to above, have been collected from five different hospitals and are reported here in detail along with a review of pertinent literature and a discussion of the significance of this syndrome.

CASE REPORTS

CASE 1 A 14-year-old American schoolgirl entered the Fifth Medical Service of the Boston City Hospital on March 11, 1939, with the complaint of persistent diarrhea of 6 weeks' duration. There were five or six watery bowel movements each day. No mucus, blood or fat was ever noted in the stools. Intermittently during this period there were bouts of vomiting. Her appetite was good. There was no pain, but the patient noted frequent loud gurgling noises in the abdomen. During the present illness there was a 4-pound weight loss.

Twice in 1935 she had been operated upon at another hospital for intussusception and intestinal obstruction. On the second occasion a portion of the ileum was resected. Polyps of the stomach, ileum and sigmoid were found at that time. So far as could be ascertained the family history was non-contributory. The parents believed the spots on the lips had been present since early childhood and apparently had not changed over the years.

Physical examination revealed a thin, rather undernourished patient appearing acutely ill. The hair and irides were dark brown. The skin was pale. On the face, concentrated about the mouth, and on the lips and oral mucous membrane were numerous small, brown-black spots. Similar areas of pigmentation were noted on the dorsal surface of the fingers (Fig. 1). A few pigmented spots were also observed on the toes. There were two small patches of vitiligo on the back. The heart and lungs were normal. The abdomen was moderately distended, with tenderness over the upper half. Loud borborygmi were present. The liver edge was palpable two fingerbreadths below the right costal

margin. There was slight clubbing of the fingers and toes. Examination otherwise was negative.

The blood pressure was 85/40.

Examination of the blood showed a red-cell count of 2,410,000, with a hemoglobin of 70 per cent, and a white-cell count of 7400, with a normal differential count. The red cells were slightly hyperchromic and macrocytic. The blood Hinton test was negative. The urine was normal. The stools were loose, brown and guaiac negative. Gastric analysis revealed 24 units of free hydrochloric acid and 46 units of total acid. Barium-enema study by the double contrast method showed multiple negative shadows consistent with polyps scattered throughout the large intestine. Many small clusters of two to four polyps in the sigmoid and rectum were directly visualized on sigmoidoscopic examination. No areas of pigmentation were noted.

A regimen of symptomatic measures supplemented by frequent administration of liver extract and iron resulted in disappearance of the diarrhea, with improvement in weight and a subjective feeling of well-being, and with an increase in the hemoglobin to 88 per cent and in red-cell count to 3,300,000. The patient was discharged after 6 weeks in the hospital.

On August 19, she was readmitted to the hospital because of a return of diarrhea during the preceding month. The findings were as on the previous entry, and satisfactory improvement resulted from similar therapy. She was discharged in 3 weeks.

Lobar pneumonia due to a Type I pneumococcus necessitated readmission on November 21. There was no bacteremia. Treated with sulfapyridine and general supportive measures, she failed to show any response and died on December 1.

At autopsy pigmentation of the skin as previously described was noted.

Death was due to lobar pneumonia of the right lung. The pleural cavity was normal, as were the heart and pericardial cavity.

The esophagus was normal. The mucosa of the stomach bore three soft pedunculated polyps ranging from 1.5 to 2.5 cm in diameter, one lying just below the cardiac orifice, a second on the greater curvature, and a third near the pyloric sphincter of the stomach. The mucosa otherwise was normal, as was the duodenum. The jejunum and ileum showed some brownish-black, granular pigment along the edge of the mucosal folds. In addition, a polyp occurred every 50 to 60 cm. These averaged 1 to 2 cm in diameter and were attached to pedicles that were 0.5 to 1.0 cm in length. The terminal ileum contained the largest polyp in the gastrointestinal tract, this measured 4.5 cm in diameter. One mulberry-like polyp measuring 1.5 cm was present in the sigmoid portion of the large intestine.

The liver weighed 1960 gm. It was of normal color and consistence and on section bore the usual geographic markings. Microscopical examination showed lipid vacuolization of the liver cells at the central portions of the lobules.

‡Assistant in medicine, Johns Hopkins University School of Medicine.
§Assistant director, Fifth and Sixth (Boston University) Medical Services, Boston City Hospital; assistant professor of medicine, Boston University School of Medicine.

General Medical and Surgical Hospital of the Center. The position pays \$6400 a year, and the Civil Service classification is known as GS-12.

Applicants must have successfully completed a full four-year course leading to a degree with major study in the biologic sciences in a college or university of recognized standing, with courses totaling at least twenty semester hours in general and medical bacteriology, or any combination of bacteriology and biology including at least ten semester hours in general and medical bacteriology. Applicants must show four years' experience, at least two years of which includes experience in medical bacteriology in a research or clinical laboratory. The other years may include experience in teaching medical bacteriology in a medical school of recognized standing. A doctor's degree in bacteriology or serology may be substituted for the latter experience.

Interested applicants are urged to send Standard Form 57 (blanks can be obtained at any post office) to the Personnel Officer, Veterans Administration Center, Los Angeles 25, California.

FUNDS FOR RESEARCH IN CARDIOVASCULAR DISEASE

A portion of the funds collected during the 1949 Heart Campaign has been set aside for research in cardiovascular diseases, according to C. Sidney Burwell, M.D., chairman of the Research Allocations Committee of the Greater Boston Chapter of the Massachusetts Heart Association.

Applications from institutions in Greater Boston are invited. Inquiries should be addressed to Dr. Burwell at the Peter Bent Brigham Hospital, Boston.

DAMON RUNYON CLINICAL RESEARCH FELLOWSHIPS

The American Cancer Society announces the availability of Damon Runyon Clinical Research Fellowships. These fellowships, inaugurated last year, are made possible by a grant from the Damon Runyon Memorial Fund for Cancer Research to the American Cancer Society. They are administered by the Society upon recommendation of the Committee on Growth of the National Research Council. In most cases a fellowship will provide a period of training in a hospital under the guidance of a qualified clinical investigator. However, fellowships may be awarded for training in a basic science provided that such training is directed toward preparing the fellow for clinical cancer research. They are limited to men and women holding the M.D. degree. It is emphasized that they are intended to promote training in clinical cancer research rather than in cancer diagnosis and therapy.

Applications submitted prior to March 1, 1950, will be acted upon during April. Fellowships approved at that time may become effective July 1, 1950, or at such other time as will meet the convenience of the fellow and the institution. Communications should be addressed to the Executive Secretary, Committee on Growth, National Research Council, 2101 Constitution Avenue, N.W., Washington 25, D.C.

GENERALIZED INTESTINAL POLYPOSIS AND MELANIN SPOTS OF THE ORAL MUCOSA, LIPS AND DIGITS*

A Syndrome of Diagnostic Significance

HAROLD JEGHERS, M.D.,† VICTOR A. MCKUSICK, M.D.,‡ AND KERMIT H. KATZ, M.D.§

WASHINGTON, D. C., BALTIMORE, MARYLAND AND BOSTON, MASSACHUSETTS

IN 1944, a brief report was made by one of us¹ regarding the association, in 2 patients, of a distinctive type of melanin pigmentation of the oral mucosa, lips and digits with intestinal polyposis.

Since then 10 cases, including the 2 referred to above, have been collected from five different hospitals and are reported here in detail along with a review of pertinent literature and a discussion of the significance of this syndrome.

CASE REPORTS

CASE 1. A 14-year-old American schoolgirl entered the Fifth Medical Service of the Boston City Hospital on March 11, 1939, with the complaint of persistent diarrhea of 6 weeks' duration. There were five or six watery bowel movements each day. No mucus, blood or fat was ever noted in the stools. Intermittently during this period there were bouts of vomiting. Her appetite was good. There was no pain, but the patient noted frequent loud gurgling noises in the abdomen. During the present illness there was a 4-pound weight loss.

Twice in 1933 she had been operated upon at another hospital for intussusception and intestinal obstruction. On the second occasion a portion of the ileum was resected. Polyps of the stomach, ileum and sigmoid were found at that time. So far as could be ascertained the family history was non-contributory. The parents believed the spots on the lips had been present since early childhood and apparently had not changed over the years.

Physical examination revealed a thin, rather undernourished patient appearing acutely ill. The hair and irides were dark brown. The skin was pale. On the face, concentrated about the mouth, and on the lips and oral mucous membrane were numerous small, brown-black spots. Similar areas of pigmentation were noted on the dorsal surface of the fingers (Fig. 1). A few pigmented spots were also observed on the toes. There were two small patches of vitiligo on the back. The heart and lungs were normal. The abdomen was moderately distended, with tenderness over the upper half. Loud borborygmi were present. The liver edge was palpable two fingerbreadths below the right costal

marginal. There was slight clubbing of the fingers and toes. Examination otherwise was negative.

The blood pressure was 85/40.

Examination of the blood showed a red-cell count of 2,400,000 with a hemoglobin of 70 per cent, and a white-cell count of 7400, with a normal differential count. The red cells were slightly hyperchromic and macrocytic. The blood Hinton test was negative. The urine was normal. The stools were loose, brown and guaiac negative. Gastric analysis revealed 24 units of free hydrochloric acid and 46 units of total acid. Barium-enema study by the double contrast method showed multiple negative shadows consistent with polyps scattered throughout the large intestine. Many small clusters of two to four polyps in the sigmoid and rectum were directly visualized on sigmoidoscopic examination. No areas of pigmentation were noted.

A regimen of symptomatic measures supplemented by frequent administration of liver extract and iron resulted in disappearance of the diarrhea, with improvement in weight and a subjective feeling of well-being, and with an increase in the hemoglobin to 88 per cent and in red-cell count to 3,300,000. The patient was discharged after 6 weeks in the hospital.

On August 19, she was readmitted to the hospital because of a return of diarrhea during the preceding month. The findings were as on the previous entry, and satisfactory improvement resulted from similar therapy. She was discharged in 3 weeks.

Lobar pneumonia due to a Type I pneumococcus necessitated readmission on November 21. There was no bacteremia. Treated with sulfapyridine and general supportive measures, she failed to show any response and died on December 1.

At autopsy pigmentation of the skin as previously described was noted.

Death was due to lobar pneumonia of the right lung. The pleural cavity was normal, as were the heart and pericardial cavity.

The esophagus was normal. The mucosa of the stomach bore three soft pedunculated polyps ranging from 1.5 to 2.5 cm. in diameter, one lying just below the cardiac orifice, a second on the greater curvature, and a third near the pyloric sphincter of the stomach. The mucosa otherwise was normal, as was the duodenum. The jejunum and ileum showed some brownish-black, granular pigment along the edge of the mucosal folds. In addition, a polyp occurred every 50 to 60 cm. These averaged 1 to 2 cm. in diameter and were attached to pedicles that were 0.5 to 1.0 cm. in length. The terminal ileum contained the largest polyp in the gastrointestinal tract, this measured 4.5 cm. in diameter. One mulberry-like polyp measuring 1.5 cm. was present in the sigmoid portion of the large intestine.

The liver weighed 1960 gm. It was of normal color and consistence and on section bore the usual geographic markings. Microscopical examination showed lipid vacuolization of the liver cells at the central portions of the lobules.

§Assistant director Fifth and Sixth (Boston University) Medical Services, Boston City Hospital assistant professor of medicine Boston University School of Medicine.

The spleen weighed 260 gm. Its capsular surface was dark purple and wrinkled. Microscopically the features of congestion were prominent. Both adrenal glands were considerably smaller and thinner than normal, but showed no abnormality on microscopical examination. The uterus appeared smaller than usual, the left ovary contained two small cysts.

The vertebral bone marrow showed granulocytes in all phases of development, numerous stem cells were present

FIGURE 1 Appearance of the Patient in Case 1

Note the spots distributed thickly on and around the lips and sparsely over the bridge of the nose. Highlight in the photograph prevents the clear view of the spots on the fingers of the right hand.

There were moderate numbers of nucleated red blood cells and occasional scattered hemosiderin-filled macrophages.

Microscopical examination of the jejunal mucosa showed the tips of many villi to be club shaped and filled with macrophages containing large clumps of hemosiderin. Well differentiated adenomatous cells comprised the mucosal polyps.

CASE 2. A 39-year-old housewife of Italian-French descent entered the Boston City Hospital on October 22, 1939. For the previous 9 months she had noted increasing constipation requiring frequent enemas. In addition there was intermittent rectal bleeding. Twenty-four hours prior to entry, a mass, which was very painful and bled on attempts at replacement, protruded from the rectum.

Twenty years previously the right fallopian tube and ovary had been removed because of chronic pelvic disease. Five years before the final admission a cholecystectomy was performed after indigestion and pain in the right upper quadrant of the abdomen of 1 year's duration. Three years later the patient was observed in the hospital because of recent onset of anorexia, nausea and vomiting. A gastrointestinal x-ray series revealed irregularity of the stomach and displacement of the duodenal cap, interpreted as being due to postoperative perigastric and periduodenal adhesions.

The patient's parents and husband were living and well. She had had 4 miscarriages. There were 2 healthy children. A first cousin (Case 4) and this cousin's daughter (Case 5) both suffered from complaints referable to the gastrointestinal system. There was no familial tendency to freckles.

Physical examination revealed a well developed and fairly well nourished woman. There were numerous brown and bluish-brown pigmented spots on the face about the eyes

and the mouth, on the lips and gums and on the fingers and toes. These averaged 1 to 3 mm in diameter (Fig. 2). There was no pigmentation elsewhere on the body. The hair was black, and the eyes dark brown. The head was normal. The lungs were clear. The heart was not enlarged, and the rate was 80, with a regular rhythm and sounds of good quality. A soft systolic murmur was audible at the apex. There were no thrills or rubs. The abdomen was soft and not distended, in the lower abdomen there was moderate tenderness, and a poorly defined movable mass was palpated in the right lower quadrant. The rectum was found to be prolapsed and external hemorrhoids were visible. There was slight clubbing of the fingers.

The blood pressure was 108/70.

Examination of the blood showed a red-cell count of 4,160,000, with a hemoglobin of 85 per cent, and a white cell count of 7500, with a normal differential count. The blood Hinton test was negative, as was examination of the urine. The stools were tarry black and gave a +++ guaiac reaction. A gastrointestinal x-ray series revealed multiple polyps of the small and large intestine.

A series of operations was embarked upon: ileostomy, partial colectomy, fulguration of polyps in the rectosigmoid and anastomosis between the ileum and rectosigmoid. In

FIGURE 2 Appearance of the Patient in Case 2

Note the density of the spots on the lips. Melanin spots on the fingers are readily noticeable in this photograph.

Initially, the patient showed some improvement, but after the last procedure there was considerable intraperitoneal and wound infection, and evidence of the development of a fecal fistula to the abdominal wall. She began to fail rapidly in weight and strength and died on March 14, 1940.

At autopsy pigmentation of the skin as previously described was noted. Examination of the pericardial cavity was negative. The heart was normal in size and weight. The aortic valve was slightly thickened, the right and posterior cusps were fused along the entire length of the commissure. The tricuspid valve contained only two well formed leaflets and appeared identical with the mitral valve. The foramen ovale and ductus arteriosus were closed.

Examination of the pleural cavity was negative. The lungs were of normal size and weight. The right lung contained an azygos lobe.

The peritoneal surfaces were grayish yellow, with a marked amount of thin, foul-smelling exudate. A pelvic abscess was found at the site of anastomosis of the ileum and rectosigmoid. The superior mesenteric artery originated from the celiac axis. The stomach contained a 1.0-cm sessile polyp in the middle portion of the greater curvature, the mucosa was otherwise normal. In the duodenum the mucosa contained 10 pedunculated polyps varying from 0.8 to 2.0 cm in diameter. The pedicles were from 0.5 to 3.0 cm in length and all were approximately 3 to 5 mm in thickness. There was 1 small polyp of the jejunum, and 8 in the ileum, all being pedunculated and varying in size as those described.

in the duodenum. The entire mucosa of the small intestine was brown gray, giving the appearance of fish skin. The rectum contained several cherry-red fungating polyps, 2 or 3 cm in size. The liver, spleen, kidneys and adrenal glands were normal.

Microscopical examination of the jejunal polyp showed it to be composed of acini of tall columnar cells, some of which were goblet cells, radiating from a fibromuscular pedicle.

CASE 3* A 22-year-old woman was admitted to the Rhode Island Hospital, Providence, Rhode Island, on November 16, 1936, because of periodic abdominal pain of 3 months duration consistent with the diagnosis of intussusception.

The family and past histories were irrelevant. No information about the duration of the oral pigment spots in the patient or their possible presence in her forebears was available.

Physical examination of the mouth and face revealed many small melanin spots on the lips and on the mucosa of the inside of the mouth (Fig. 3). Information regarding spots on the hands and feet was not available.

At operation an intussusception of the terminal ileum due to a polyp was found and a hard mass in the small intestine about 50 cm from the cecum proved to be an adenocarcinoma of the ileum. Resection of this lesion and side-to-side anastomosis were done, with good results and an uneventful

FIGURE 3 Appearance of the Buccal Mucosa in Case 3. Note the size and distribution of melanin spots on the buccal mucosa. Those on the lips are readily seen despite the presence of lipstick. Relatively few are present on the skin about the mouth. (Photograph published through the courtesy of Dr. F. Ronchese of Providence, Rhode Island.)

recovery. Polyps of the stomach were said to have been present also.

The patient was seen periodically for follow-up study. In August, 1937, another operation was performed because intestinal obstruction was suspected. A band of tissue was excised. In January, 1939, she again had an episode suggestive of intestinal obstruction. In July 1940, she was operated upon for recurrent abdominal pain. Large polyps were found in the stomach near the pylorus and in the ileum and appropriate surgical therapy was applied. After this she was symptom-free for 2 months.

In November abdominal pain and obstructive signs recurred. At operation intussusception was seen and polyps of the stomach, jejunum and ileum noted. In March 1942, intussusception due to small-gut polyps again necessi-

tated operation, at this time the additional diagnosis of polyposis of the large intestine was added to the patient's record. At the last report in September 1944, the patient was working regularly and free of complaints.

CASE 4 A 30-year-old housewife of Italian ancestry was admitted to the Boston City Hospital on November 2, 1935. She complained of mid-abdominal pain, intermittent and colicky, of 2 days' duration. Two years previously there had been two similar attacks which had subsided spontaneously. There was a history of chronic constipation. Three years previously an appendectomy had been performed.

The family history was irrelevant except for the occurrence of pigmentation of the face, similar to the patient's in her

FIGURE 4 Pigmentary Pattern Similar in Mother (Case 4) and Daughter (Case 5).

Note the main distribution in each on and about the lips.

father and her paternal grandmother, as well as in her own daughter (Case 5) and her first cousin (Case 2).

Physical examination revealed a well developed and well nourished woman who appeared acutely ill. The temperature was 99°F. There were numerous small brown-black pigmented areas on the lips, oral mucosa and nose (Fig. 4), and a few on the fingers and toes. The lungs were clear. The heart was normal. The blood pressure was 120/78. Abdominal examination revealed tenderness immediately above and to the left of the umbilicus where a small, firm mass was intermittently palpable. There was no muscle spasm. The white-cell count was 15,000.

At laparotomy performed shortly after admission an intussusception of the ileum was readily discerned. This was reduced easily, and the darkened color of the intestine improved promptly. A small dimple was seen on the serosa of the ileum at the origin of the intussusception. At this point a mass was palpable within the lumen from which a walnut-sized polyp was excised. The patient made a prompt and satisfactory recovery postoperatively.

Examination of the surgical specimen showed it to consist of a soft mucosa-covered papilloma with a small pedicle. The mucosa was intact and normal in appearance. The cut surface revealed a smooth, gray appearance. Microscopically, the specimen had the characteristics of a benign polyp.

CASE 5† A 9-year-old girl of Italian ancestry was admitted to the Children's Hospital of Boston on December 10, 1937, with the complaint of abdominal pain.

For the previous 2 years the child had had recurrent bouts of severe, crampy abdominal pains localized at the umbilicus.

*Reported through the courtesy of Dr. Francesco Ronchese of Providence, Rhode Island.

†This case and Figure 4 and 5 were made available through the courtesy of the Children's Hospital, Boston, Massachusetts.

They had never been associated with dietary indiscretions or irregularity of the bowels. The pains had been paroxysmal, lasting a few minutes and recurring in a few minutes, usually disappearing entirely after 1 or 2 hours. Occasionally, vomiting had been present with these episodes, but no bloody, tarry or mucus-containing stools had been noted. Typically, the patient was well immediately before and immediately after each attack, and on examination by various physicians and at outpatient clinics after an attack no abnormality had been found.

One hour before this hospital admission the patient again suffered a typical recurrence of crampy abdominal pain, which differed only in that it seemed much more severe than on previous occasions. Instead of disappearing, this pain kept recurring in stronger paroxysms every 1 or 2 minutes, making the child scream with pain. A few minutes after the

FIGURE 5 Close-up Photograph in Case 5, Showing the Density of the Melanin Spots on the Lips and about the Mouth

onset of this illness she began to vomit bile-stained material. Nothing was passed by rectum.

The patient had been a full-term, normal baby. She had been examined on several occasions in the Outpatient Department during the preceding 3 years for attacks of bronchitis and after previous attacks of abdominal pain. The past history was otherwise noncontributory. Her parents were living, the mother (Case 4) had undergone an abdominal operation for intussusception 2 years previously. One brother, 8 years of age, was living and well. Another sibling had been born dead 11 years previously. The patient's mother, and the latter's father and paternal grandmother had all had similar pigmentation of the face about the mouth. Unfortunately, information concerning polyposis in these ancestors was unobtainable.

Physical examination revealed an acutely ill girl. There were numerous blue-brown to black small spots on the face, concentrated about the mouth and on the mucosa of the lips and mouth (Fig 4 and 5). The hair and irides were dark brown. Examination of the heart and lung was negative. The abdomen was not distended, but there was moderate fullness in the left upper quadrant. No direct spasm could be elicited, but intermittently there was tenderness over a transiently palpable tumor in the left upper quadrant. This tumor appeared to be fairly movable in all directions and measured 10 by 5 cm. The liver edge was felt 1 cm below the costal margin. Rectal examination was negative. The white-cell count on entry was 20,150.

Shortly after examination a laparotomy was performed. A jejunoileal intussusception was promptly noted and was reduced. A walnut-sized tumor could be palpated at the site of intussusception, and on opening of the intestine a polyp was removed. *Staphylococcus aureus* septicemia, with pneumonia, empyema and peritonitis developed, and the patient died on January 2, 1938.

At autopsy, in addition to the pigmentation previously noted, there was a generalized petechial eruption. Bilateral bronchopneumonia and empyema were present. The abdominal cavity contained a large amount of brown fluid.

The mucosa of the stomach was thrown up into prominent longitudinal rugae, and on the tips of these rugae four polypoid formations were noted. These varied from mere mucosal elevations to one pedunculated polyp 2 cm in diameter, they were pinkish white and slightly lobulated. The entire small intestine contained numerous polyps of varying size, most of them about the size of a pea and many with pedicles, but occasional ones showing a sessile type of base. These were attached to the intestinal villi. The appendix was 10 cm long, with a reddish-black, bulbous tip. It was retrocecal in position and bound down in an appendiceal abscess. There was no abnormality of the large intestine. The mucosa of the rectum contained a polyp about 2 cm in diameter. A total of twenty polyps of the gastrointestinal tract were counted. The adrenal glands were normal in shape and consistency, the cut surface revealed a normal architecture. There were multiple small cysts of the left ovary, approximating 2 or 3 mm in diameter, and filled with clear, yellow fluid.

Examination of the polyp removed at operation showed it to be 4.3 by 3 by 1.8 cm. Cut section revealed a circular core, which was composed of tough connective tissue. Surrounding this was an abundant amount of glandular tissue. The mucosal epithelium was normal histologically. The lamina propria was markedly vascular, and there was extensive inflammatory cell infiltration consisting about equally of neutrophilic and eosinophilic polymorphonuclear leukocytes, plasma cells and mononuclear cells. At no part of the specimen was there any evidence of cancer.

CASE 6 A 16-year-old Negro boy born on the Outside Obstetrical Service of the Johns Hopkins Hospital had been observed throughout his life at frequent intervals in the various outpatient clinics and on the wards of the Johns Hopkins Hospital.

As far as could be determined the family history was negative for bowel difficulties and for pigmentation of the type under discussion.

The patient had suffered all his life from complications attributed to intestinal polyposis. At the age of 8 months rectal prolapse with a visible polyp had occurred. This recurred repeatedly in spite of removal of several polyps—described grossly and histologically as "papilloma of the rectum."

At the age of 6 years, the boy began to have attacks of periumbilical pain about once a month. In 1946 he was admitted to the hospital for intussusception. A laparotomy was performed by Dr. H. William Scott, Jr. An ileocolic type of intussusception was found. Taxis was unsuccessful. Resection of the ascending colon, half the transverse colon and the ileum back 30 cm from the beginning of the intussusception was performed. The ends of the colon and ileum were exteriorized by the Mickulicz technic and later closed. Two polyps were noted in the ileal portion of the operative specimen. There was no sign of melanosis coli in the specimen.

At the third admission, on June 11, 1947, because of dizziness and shortness of breath on exertion, the patient's diet was found to have been unusually inadequate, having consisted largely of candy and soft drinks. Physical examination revealed pallor and blowing systolic murmurs at the apex and in the pulmonic area. Examination of the blood disclosed a red-cell count of 3,420,000, with a hemoglobin of 4.3 gm, and a hematocrit of 19 mm, giving a mean corpuscular volume of 56 cubic microns, a mean corpuscular hemoglobin of 13 micromicrogm and a mean corpuscular hemoglobin concentration of 23 per cent.

The stools gave negative to +++++ guaiac tests. No parasitic ova or cysts were identified. Preparations for sickling were repeatedly negative. After a detailed gastrointestinal study it was finally concluded that the patient probably had polyps somewhere in the alimentary canal, which our imperfect methods could not demonstrate, and that bleeding from these, together with a grossly inadequate diet, was responsible for the anemia. Lack of absorptive surface as a result of extensive intestinal resection was a possible additional factor. On iron therapy the reticulocytes rose to a peak of 12.8 per cent.

It was on this admission that attention was called to the pigmentary peculiarities and studies thereof were made. On the outside of both lips and extending onto the skin about 1.5 cm from the vermilion border there were darkly pigmented spots of irregular outline and size varying from that

of a pinhead to 2 mm in the largest dimension (Fig 6). They covered the vermillion portions and the entire dental surfaces of the lips. There were a few similar spots on the buccal mucous membranes and lateral edges of the tongue. On the mucous membrane covering the posterior commissure of the upper and lower jaws there was on each side a prominent spot measuring about 4 mm in diameter (Fig 7). The general color of the skin was a very light tan. In the 'butterfly area' of the face there were also a few spots resembling those on the lips (Fig 6). There was a fleck of pigment in the bulbar conjunctiva of the right eye at the limbus at 8 o'clock, and a similar but small spot on the conjunctiva of the left eye at the limbus at 4 o'clock. Fundusoscopic examination revealed nothing remarkable. On the hypothenar

FIGURE 6 Appearance of the Patient in Case 6
The characteristic dense localization of spots on the lips, more marked on the lower lip, is well demonstrated. Note the relative paucity of spots elsewhere on the face.

eminence of the right hand there was a pigmented spot 5 mm in diameter. On both index fingers were numerous dots and under the nail of the left index finger at the point a pigmented area (Fig 8). There was a pigmented macule on the sole of the left foot. Otherwise the body was essentially free of any localized areas of increased pigmentation. All the areas described were not elevated and were perfectly smooth. These areas of pigmentation had been present as long as the patient or his mother could recall and had not changed. Unfortunately, no photographs from infancy or childhood were available. One brother and 2 half sisters did not show the anomaly. None of the mother's family showed it, the father's family lived in a distant state and was not available for observation.

On May 25, 1948, the patient was admitted again with intussusception. On that date a laparotomy was performed by Dr Marshall C Sanford. Two groups of polyps were palpated in the small intestine: one in the upper jejunum

just below the ligament of Treitz, the region being intussuscepted into the jejunum below for a distance of 21 cm, and a second group of polyps approximately 61 cm distal to Treitz's ligament. The jejunum was resected from the ligament of Treitz to below the second group and an end-to-end

FIGURE 7 Photograph Demonstrating Melanin Areas Inside the Mouth in Case 6

duodenojejunostomy performed. At this laparotomy a polyp was felt in the descending colon, and another in the sigmoid about 15 cm below the first. After proper prepara-

FIGURE 8 Photograph of the Right Hand in Case 6
Melanin spots are present on the palm and thumb and especially on the forefinger.

tion of the bowel with sulfasuxidine, a 15-cm length of the left colon including the polyps, was resected as a separate procedure on June 7. The polyps were grossly and microscopically identical with those previously removed.

CASE 7 * A 15-year-old girl had previously been admitted to the Johns Hopkins Hospital in 1937 at the age of 6 years. Eighteen months before that admission the patient had become rundown, pale and anorexic. One year before admission tarry stools were occasionally noticed, and there was the onset of dull abdominal pain present each morning on awakening. This daily morning pain continued until the time of the first admission, and, in addition, there was occasional nausea and vomiting. Sometimes, the pain required morphine for relief. During severe attacks it radiated to the left lower quadrant, where there was said to be a visible mass, and gurgling sounds were audible across the room. The stools were guaiac positive on numerous occasions, and the hemoglobin at one time was 30 per cent of normal.

On admission in 1937 the physical examination was recorded as essentially negative, and the diagnostic impression was Meckel's diverticulum. The spots in the mouth were described, but their diagnostic significance was not appreciated. Two days after admission the patient was seized with severe abdominal pain, which caused her to scream and clutch her abdomen. This was associated with continuous retching. On laparotomy 2 ileocecal intussusceptions and 3 polyps were discovered. The first intussusception was 45 cm above the ileocecal valve and was easily reduced. A polyp was palpated at the head of the intussusception and was removed by elliptical resection. About 76 cm above this intussusception was a second, larger one, which on reduction was found to be an intussusception within an intussus-

drop in hemoglobin to 60 per cent was observed. There was considerable nausea but no vomiting. Two days before, the patient had pain all day associated with considerable nausea but no vomiting.

On admission the physical findings were not remarkable except for the pallor (the hemoglobin was 9 gm) and the spots described below. There was no digital clubbing. The stools were brown and formed, but guaiac positive. Sigmoidoscopic examination, performed by Dr J T Howard, revealed 2 polyps in the lower sigmoid, 1 "the size of a peanut and the other the size of a hazelnut." A gastrointestinal series revealed negative filling defects in the stomach suggestive of polyps. Studies of the small intestine were performed by the passage of barium and then air through a Miller-Abbott tube inserted for the proper distance. By this method several areas suspicious of polyps were visualized. A barium enema by the routine technic and without injection of air was negative.

At operation, performed on October 31 by Dr I R Trimble, the stomach was opened, and 2 polyps were found on the greater curvature in the lower portion of the organ. The larger of these measured about 2 cm in diameter. The entire length of the small intestine was carefully examined by means of palpation and transillumination. In the distal jejunum and proximal ileum several polyps were palpated, and about 122 cm of this portion of the gut was resected. This specimen contained 8 large pedunculated polyps, the largest of which measured about 25 cm in diameter. Histologic examination revealed these structures to be typical benign polyps. Several polyps could be palpated in the transverse colon (the only portion of the large intestine in the operative field), but no operative procedure was attempted in connection with them.

The patient was an only child. Absolutely no history of gastrointestinal disturbance could be elicited among her forebears, nor had any of them, including the parents, shown a pigmentary anomaly resembling the patient's. These spots had been noted almost from birth. There was no family history of freckles. The mother had a photograph of the patient at the age of 3 months showing them quite distinctly. These spots were numerous on the vermilion border and on the dental aspect of the lips. They were perfectly flat areas of hyperpigmentation of irregular outline and variable size. On examination with a magnifying glass some of the spots had a somewhat stippled appearance. Spots of the same description were present on the buccal mucous membrane (Fig 9) bilaterally, but none were seen on the tongue. There were several light spots over the palms and fingers, and there were a few on the feet. The remainder of the body was completely free of any unusual type of pigmentation. No freckles were present—in fact, the skin of the face was exceptionally free of all blemishes except the melanin spots described above.

CASE 8 † A 27-year-old man, second in a family of five the genealogy of which is shown in Figure 10, was a brother of the patients in Case 9 and 10. He was born in 1921. From an early age he has been subject to frequent, in fact almost daily "belly aches," especially after eating. Over the course of about 18 months, in 1938 and 1939, at the age of about 17, he had had some very severe attacks of crampy, intermittent abdominal pain, for which he was admitted to the Harrisburg Hospital on several occasions. Each time, the pain disappeared spontaneously and no satisfactory diagnosis was arrived at. Finally, the possibility of intestinal polyposis, with intussusception, was proposed by Dr C E Moore, who performed a laparotomy on December 18, 1939. At that time an easily reducible intussusception in the upper portion of the jejunum was discovered, and multiple soft masses could be felt in its lumen. About 150 cm of jejunum was resected extending from 10 cm below the ligament of Treitz to below the area where polyps could be felt. End-to-side anastomosis was necessary because of luminal disproportion. The specimen removed was described by the pathologist as showing 30 soft, lobulated polyps. Microscopically, they were the usual adenomatous polyps.

Early in 1945, attacks of crampy abdominal pain began, mainly on the right, increasing in severity and frequency over the course of 3 months. On January 16, 1948, because of these increasingly severe attacks, laparotomy was per-

FIGURE 9 Appearance of the Patient in Case 7

ception with a polyp as the cause of each invagination. These polyps were similarly resected. No others were found.

The patient did well until the following spring, when she had an acute attack of abdominal pain and was operated upon in a South Carolina hospital, where adhesions were reported as the only finding. Thereafter she was well until 1946. During the next year there was a gradual loss of appetite, development of weakness and a loss of about 6 pounds of weight. Two months before this admission the old crampy abdominal pain recurred lasting from 1 to 12 hours at a time. In the 2 weeks before admission in October, 1947, a steady

*This case is reported with the permission of Dr I R Trimble. A report of this case is included in the paper by Ravitch¹⁸ dealing with polyoid adenomatosis of the entire gastrointestinal tract.

†Case 8, 9 and 10 are reported through the courtesy of Dr C F Moore of Harrisburg, Pennsylvania.

formed. Two intussusceptions were discovered. The first was 90 cm proximal to the ileocecal valve, with telescoping of the bowel for 10 cm. At the head of the intussusception was a thumb-sized polyp, which was removed by simple elliptical incision. The second intussusception was ileocolic in type and had its cause, again, in a small polyp the size of an English walnut. This was removed in a similar manner. A very careful examination of the entire gastrointestinal tract was made. No evidence of polyps was found in stomach, duodenum or jejunum, and on this occasion none could be felt in the colon, including the transverse colon where it was thought that a solitary one had been felt in 1943. Histologically, the polyps were not remarkable.

After this operation the patient was asymptomatic up to the time when he was examined by one of us. He was found to be a very muscular young man, perhaps slightly

CASE 9 The sister (born in 1924) of the patients in Case 8 and 10, was 4th in a family of 5, the genealogy of which is shown in Figure 10. Through early adolescence the patient had suffered from recurrent attacks of crampy abdominal pain accompanied at times by vomiting. There was never melena or fresh blood in the stools, and she was never noticeably anemic. At the age of 16, because of this history and because of the previous discovery of polyposis in a brother (Case 8) she was admitted to the Harrisburg Hospital, and laparotomy was performed on June 28, 1940, by Dr C E Moore. The upper 91 cm of the jejunum was found to be somewhat dilated, and many firm nodules were palpated in its lumen, the most proximal one being about 5 cm below the ligament of Treitz. No intussusception was present at the time of laparotomy. The stomach, duodenum, ileum and colon appeared to be normal. The proximal 90 cm

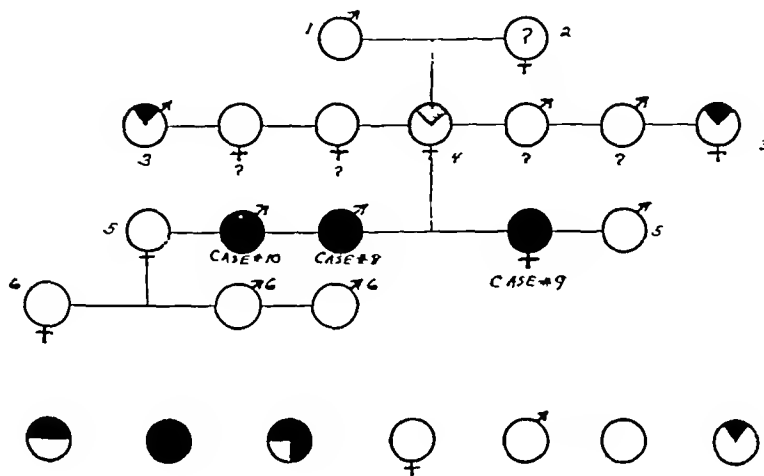

FIGURE 10 Genealogic Table of Harrisburg Family with Pigment Spots and Polyposis (Data Provided through the Courtesy of Dr C E Moore)

Key: Blank circle = normal. One-fourth circle = pigmentation not looked for, probable polyposis. One-half circle = pigmentation, no polyps clinically. Three-fourths circle = pigmentation and probable polyposis. Full circle = pigmentation and proved polyposis.

1 Death from cancer of pancreas at age of sixty-nine. No pigmentation or intestinal polyps at autopsy.

2 No information available except death from "heart attack."

3 Death from "intussusception" in second decade of life. No information about pigmentation.

4 Death from "cancer of intestine" at age of forty. No information about pigmentation.

5 No history of pigmentation or intestinal trouble. Not available for examination (See footnote under Case 10).

6 No history of pigmentation or intestinal trouble. Not available for examination (See footnote under Case 10).

? No information available.

overweight. There was no evidence of anemia. The eyes were dark blue, and the hair brown black. The only unusual feature of the examination was the presence of gray pigmented spots on the vermilion border of the lower lip identical with those in the other cases. The spots were concentrated somewhat toward the commissure on either side. There were no spots on the dental aspects of the lips but on the buccal mucosa in the region of the posterior commissures of the jaw and in juxtaposition to the lower teeth there were small, irregular spots, which had a definite stippled appearance on magnification. There were two spots likewise stippled, on the hard palate (These spots had been noted from the first by Dr Moore, who speculated on their possible relation to the intestinal polyposis). The face, which was deeply sun-tanned was essentially free of freckles. The hands were rough and calloused, but a few small, brown-gray spots were seen on both dorsal and volar aspects of the fingers. The spots on the lips had been present and unchanged as long as the patient could recall.

of the jejunum was resected and the continuity was restored by a lateral anastomosis. The specimen was found to contain 5 polyps, the largest measuring 3.5 cm in length and 2.2 cm in diameter. Histologically, they were the usual polypoid adenomas.

After operation the patient was asymptomatic. When examined by one of us in 1948 she was well developed and adequately nourished without evidence of anemia. She was somewhat darker in complexion than her brothers. The hair was black and the irides dark brown. The only unusual feature of the physical examination consisted of dark pigmented spots on the vermilion border of the lower lip, with a few smaller ones on the cutaneous portion of the lower lip. Those on the vermilion border were quite deeply pigmented and prominent, and only imperfectly concealed by lipstick. In the mouth there were 2 spots on the left buccal mucosa, 3 on the right and a single small pigmented area on the hard palate. All these areas had a definitely stippled appearance. There were a few spots in the butterfly area of the nose and

CASE 7* A 15-year-old girl had previously been admitted to the Johns Hopkins Hospital in 1937 at the age of 6 years. Eighteen months before that admission the patient had become rundown, pale and anorexic. One year before admission tarry stools were occasionally noticed and there was the onset of dull abdominal pain present each morning on awakening. This daily morning pain continued until the time of the first admission, and, in addition, there was occasional nausea and vomiting. Sometimes, the pain required morphine for relief. During severe attacks it radiated to the left lower quadrant, where there was said to be a visible mass, and gurgling sounds were audible across the room. The stools were guaiac positive on numerous occasions, and the hemoglobin at one time was 30 per cent of normal.

On admission in 1937 the physical examination was recorded as essentially negative, and the diagnostic impression was Meckel's diverticulum. The spots in the mouth were described, but their diagnostic significance was not appreciated. Two days after admission the patient was seized with severe abdominal pain, which caused her to scream and clutch her abdomen. This was associated with continuous retching. On laparotomy 2 ileoileal intussusceptions and 3 polyps were discovered. The first intussusception was 45 cm above the ileocecal valve and was easily reduced. A polyp was palpated at the head of the intussusception and was removed by elliptical resection. About 76 cm above this intussusception was a second, larger one, which on reduction was found to be an intussusception within an intussus-

drop in hemoglobin to 60 per cent was observed. There was considerable nausea but no vomiting. Two days before, the patient had pain all day associated with considerable nausea but no vomiting.

On admission the physical findings were not remarkable except for the pallor (the hemoglobin was 9 gm) and the spots described below. There was no digital clubbing. The stools were brown and formed, but guaiac positive. Sigmoidoscopic examination, performed by Dr J T Howard, revealed 2 polyps in the lower sigmoid, 1 "the size of a pea nut and the other the size of a hazelnut." A gastrointestinal series revealed negative filling defects in the stomach suggestive of polyps. Studies of the small intestine were performed by the passage of barium and then air through a Miller-Abbott tube inserted for the proper distance. By this method several areas suspicious of polyps were visualized. A barium enema by the routine technic and without injection of air was negative.

first twin. A recent personal communication from R. H. (a living brother of the twins) states that the second twin died at the age of fifty-two of cancer of the breast. He could supply no data concerning intestinal symptoms. She died at home, and no autopsy was performed. Weber¹ noted no pigmentation in the other members of the twin's family, a point corroborated by the brother, R. H.

Case 3 was called to our attention by Dr. Francesco Ronchese, of Providence, Rhode Island, after publication of the preliminary note concerning Case 1 and 2.¹

The patient in Case 4, a first cousin of another patient (Case 2), and still alive, came to our attention when relatives of the latter were questioned

and intestinal polyposis by a specific title is a paper by Peutz,⁷ of The Hague, who, in 1921, described a family in which several members had pigment spots of the mouth, hands and feet with intestinal polyposis. Reference to this paper is made by Meirowsky,⁸ and the article is also listed in the *Index Medicus* but was overlooked in our earlier, limited search.

No other title under the heading of intestinal polyposis with pigmentation was found in the *Quarterly Cumulative Index Medicus* or *Index Medicus* prior to 1945. Metzger, Ohlmann and Halff,⁹ under another title, reported a case of polyposis with a diffuse type of generalized melanin pigmentation that did not resemble the appearance

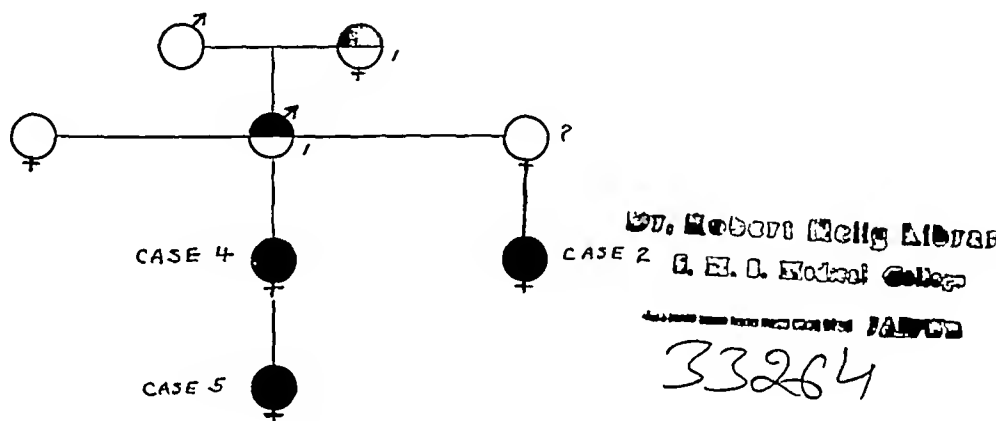

FIGURE 12 Genealogic Table of Boston Family with Pigment Spots and Polyposis

1 Known to have characteristic pigmentation. No information about polyposis available.
2 No information available.

about her family history. She had been admitted to Boston City Hospital in 1935. Adequate data were available in this record.

The patient in Case 4 gave the details for assembling the pedigree of the syndrome in this family (Fig. 12) and led to knowledge of her daughter (Case 5), who had died at the Children's Hospital, Boston, Massachusetts, in 1938.

Case 6 and 7 were noted by one of us at the Johns Hopkins Hospital within a few months of each other.

Cases 8, 9 and 10 are patients of Dr. C. E. Moore, of Harrisburg, Pennsylvania, who, hearing of our interest in this syndrome, called them to our attention and permitted one of us to examine them.

The finding of 10 patients with this syndrome stimulated us to a more thorough search of the literature than the one made in 1944, when Case 1 and 2 were reported briefly.

Apparently the first specific reference in the medical literature concerning this disorder and the earliest to stress the association of pigmentation

in our cases. No mention of this syndrome was found in a representative group of standard textbooks on gastrointestinal disease, or in the standard dermatologic textbooks in English. This does not exclude the possibility that representative cases are reported under titles that would not suggest this syndrome.

As previously stated, Peutz,⁷ of The Hague, in 1921, described a family in which several members had pigmented spots of the mouth, hands and feet. Dr. Peutz¹⁰ has very kindly supplied us with further information on this family, permitting the construction of the fabulous family tree shown in Figure 13. The cases cover three generations, with seven proved cases of the syndrome (intestinal polyps and spots), 1 suspected case and 1 person who presented the pigmentary anomaly without proved polyposis. Two of the family had nasal polyps in addition to the intestinal polyps, and 1 also had bladder polyps.

Figure 14 demonstrates the spots on the dental aspect of the lower lip in 1 of the cases (No. 7 in

cheek. On both the dorsal and volar aspects of the fingers were a number of brown spots. The remainder of the body was free of unusual pigmentation.

CASE 10 The brother of the patients in Case 8 and 9 and 2nd in a family of 5, the genealogy of which is shown in Figure 10, experienced, at about the age of 20, recurrent attacks of mid-abdominal pain occurring especially between 1 and 2 hours after eating and occasionally accompanied by vomiting. The attacks increased in severity and frequency over the course of the next 2 years. In 1942 he was admitted to the Harnsburg Hospital with a particularly severe attack of this description of 2 days' duration. An indefinite tumescence was observed in the region of the umbilicus. At laparotomy, performed on February 16, by Dr C E Moore, an intussusception was found in the jejunum about 76 cm below the ligament of Treitz. This was quite easily reduced. At the head of the intussusception a polyp was palpated, and several others were felt in the jejunum to a distance of 122 cm from the ligament of Treitz. The stomach, duodenum, ileum and colon felt normal. The jejunum was resected for a distance of 122 cm, beginning at a point 15 cm below the ligament of Treitz. Lateral anastomosis was performed, the continuity of the bowel thereby being re-established.

After operation the patient had been completely asymptomatic up to the time he was examined by one of us in 1948. At that time he was found to be a very muscular, slightly overnourished young man with good color and a striking resemblance to his younger brother. The hair was dark brown, and the irides dark blue. In this case, the pigmentation of the lips was the least marked of any of the siblings. There were, however, over the vermilion border of the lower lip, 10 or 12 small dark-brown, pigmented spots concentrated mainly near the commissure on either side. Inside the mouth there were 2 or 3 pigmented spots with a stippled appearance on the buccal mucosa on each side. There was no pigmentation of the hard palate. The face was deeply tanned, but essentially free of freckles. The hands were calloused and roughened, but showed a few spots on the fingers.*

REVIEW OF THE LITERATURE

Interest in this syndrome was first aroused when a patient (Case 1) was seen on the Fifth Medical

FIGURE 11 Identical Twins, Each with Melanin Spots on and about the Lips and on the Buccal Mucosa, as Shown in the Small Insert (Reproduced from Hutchinson²)

Note the similarity of distribution of pigment spots in these cases with those reported in this paper

Service of the Boston City Hospital in 1939 during a study of the association of skin pigmentation with systemic disease.¹ Dr Chester S. Keefer, who

*On January 22, 1949, the youngest member of this Harnsburg family, a 21-year-old man, died a few days after admission to another hospital for an acute abdominal episode. Two operations were performed at which the intussusception due to polyp of the small intestine was discovered. The brothers and sisters of this patient stated that he showed no pigmented spots, but he was actually not examined by us.

had seen the patient on ward rounds, commented later, in a personal communication, on the similarity of this girl's pigmentation to that of twins in the cases reported by Sir Jonathan Hutchinson² in 1896. This report concerned twelve-year-old twins (Fig. 11) with an anomaly described as follows:

a number of black pigmented spots on the lips and inside of the mouth. It was at the age of three that these spots had first been noticed, and the evidence was definite that none had been present at birth. The spots had increased in number and size at exactly parallel rates in the two, and the conditions presented were just the same in each.

No note is made of the presence or absence of pigmented areas on the hands. The striking resemblance between the pigmentary pattern in Case 1 and the twins described by Hutchinson is clearly demonstrated by comparison of Figure 1 and Figure 11.

Hutchinson was not aware of the presence of any intestinal trouble in either of the twins, for he wrote further: "That they [the pigmented spots] are not in any active sense pathological we may safely assure, for they appear to be not aggressive, and their subjects remain in good health." Because of the marked similarity of the process in the twins, Sir Jonathan considered the pigmentation a congenital anomaly.

A brief note on these twins had previously been published by Connor,³ who contributed the significant additional information that the twins were "of dark complexion and anemic." The pigment spots were described as being "of very small size and scattered over the lips (especially the lower), gums and hard palate, but not on the tongue."

The patient in Case 2 was seen at Boston City Hospital later in 1939 and because of similarity to Case 1 was likewise photographed and studied. This second case strongly suggested that this distinctive type of pigmentation in combination with intestinal polyposis was not a fortuitous association but was probably of related significance.

A limited search of the literature at that time revealed a paper by Weber,⁴ who in 1919 reported a follow-up study on Hutchinson's cases. He stated that the spots apparently had not enlarged. However, the most interesting portion of his follow-up observation was this: "One of the twins died at the age of twenty years, from intussusception, at the Metropolitan Hospital (London), but the other (B. H.) is still living and is in good health, now (1919) aged thirty-five years." The Metropolitan Hospital⁵ has no record that an autopsy was performed, a point confirmed by Weber.⁶ However, from a copy of the death certificate obtained for us by Dr L. Forman, British dermatologist, it is known that an operation for intussusception with resection of the gut was performed and that the patient died of "septic pneumonia and pleuritis." Although not specifically stated, there is a strong possibility that intestinal polyposis was the cause of the intussusception in the

obtained from Kisch,¹³ who reports that his original notes are no longer available. However, he confirmed the validity of the statement of Meirowsky.

Four proved and 2 probable cases of this syndrome came to our attention while we were reviewing the quite limited literature of familial adenomatosis of the small intestine.

In 1924 van Dijk and Oudendal¹⁴ from Weltevreden in the Dutch East Indies, reported the cases of a sixteen-year-old Indo-European boy and his twenty-five-year-old sister, both of whom suffered from repeated colicky attacks. During severe attacks both were submitted to laparotomy and found to have intussusception of the ileum due to adenomas. Both patients showed pigmented spots of the lips which had been present from birth and which resembled those found in our patients. The au-

been a patient in this hospital in 1935 complaining of attacks of abdominal pain, with the passage of blood and mucus per rectum." The subsequent course of events was as follows:¹⁶ "This man was admitted to a nearby hospital in Cardiff during 1947 and laparotomy then showed an inoperable carcinoma of the stomach. No further history is obtainable at the moment."

Foster¹⁶ supplied information on a fourth very likely case of the syndrome in this Welsh family:

[The son of the patient just described] was admitted to Llandough Hospital on the 7th of October 1944, as a case of Addison's disease apparently on account of the pigmentation of the lips, oral mucous membrane, and

FIGURE 15 Genealogic Table of a Welsh Family with Pigment Spots and Polyposis (Based on Data of Foster¹⁶ 15)

3 Had the characteristic pigmentation and passage of blood and mucus by rectum. Inoperable carcinoma of the stomach developed

4 Has the characteristic pigmentation as well as frequent attacks of colicky abdominal pain with passage of blood and mucus

No information available

thors did not mention Peutz's publication of 1921 and did not stress the significance of the association of pigmented spots and intestinal polyposis.

In 1944 Foster¹⁵ reported the cases of a forty-three-year-old silversmith and his sixteen-year-old daughter who presented themselves at the Llandough Hospital in Cardiff, Wales, within three years of each other with intussusception, which on laparotomy was found to be due to a single polyp. Foster stated "It was noted that both patients presented a diffuse brownish pigmentation of the lips and face." No further comment was made of the pigmentation. In reply to our inquiry Foster¹⁶ generously sent us a photograph of the daughter. The identity with the other cases is unmistakable.

In his report Foster¹⁵ stated "On investigating the family history it transpired that the father's brother showed similar pigmentation and he had

FIGURE 16 Appearance of a Patient with Melanin Spots (Reproduced from Touraine and Couder¹⁵ with the Permission of the Publisher)

This illustration clearly depicts the appearance of the melanin spots on the mucosa of the mouth

palate. A history of attacks of abdominal pain of a colicky nature, occasionally severe and associated with the passage of blood and mucus per rectum over a period of about nine months was obtained. Since then he has had occasional attacks of abdominal pain with the passage of some mucus per rectum.

Sufficient data were supplied by Foster for us to assemble a genealogic table for this family (Fig 15).

The only other report of the complete syndrome was made by Touraine and Couder,¹⁷ of Paris, in 1945, under the title "Syndrome of Peutz," and elaborated upon in 1946 under the title "Lentiginose péri-orificielle et polyposé viscérale."¹⁸ Their

Figure 13), together with the operative specimen from the ileum showing polyps. Although the face was more extensively involved in each of these

The first soot-coloured or dark-brown skin and lip pigmentation gradually faded in the course of years and even disappeared for the greater part between the ages of twenty-five and thirty, the spots got at least much

- 1 A nun — died of intestinal disease. History suggestive of polyposis. Had characteristic pigmentation.
- 2 Had characteristic pigmentation. Not studied for presence or absence of polyposis.
- 3 Died at age of four. No information available.
- 4 Several abdominal operations for intestinal polyposis. Died with ileus in 1937. Had characteristic pigmentation.
- 5 Had the pigmentation. Died with ileus in 1947. Malignant degeneration of intestinal polyps at autopsy.
- 6 Had the pigmentation. Died with ileus in 1948. Malignant degeneration of intestinal polyps at autopsy.
- 7 Case reported in detail by Peutz⁷ in 1921. Intestinal polyps and characteristic pigmentation. Malignant degeneration diagnosed on surgical specimen.
- 8 Died of ileus in 1940. Polyps previously proved by rectoscopy and x-ray studies. Had characteristic pigmentation.
- 9 Had polyposis of intestine and characteristic pigmentation.
- 10 Had polyposis of intestine and characteristic pigmentation.

cases than in our series the pigmentation of the lips and oral mucosa is identical. The extensive facial pigmentation is similar to that in the cases of Foerster¹¹ and Siemens¹² referred to below

smaller. The rectal and mouth pigmentation did not undergo this fading and becoming smaller [italics ours]

Foerster¹¹ and Siemens¹² have described a total of 5 cases demonstrating extensive spotty pigmentation of the skin, lips and oral mucosa. Four of the cases were in members of the same family. Although the distribution of pigment on the lips, oral mucosa and digits resembled that in our cases, the pigmentation on the skin was much more extensive. Furthermore, these patients were studied only from the dermatologic standpoint, and any evidence of intestinal polyposis, if present, was not included in the reports. It is not clear therefore, whether these patients fall in the group studied by Peutz and ourselves.

Foerster¹¹ suggested that this pigmentary anomaly may represent an atavism. Siemens¹² referred to the spots as "ephilides inversae" because they are located where freckles are not seen at all or are only very sparse. Siemens's terminology aptly fits the distribution of the pigment spots in the cases of Peutz and ourselves.

To some slight extent the syndrome may have been known in Germany. In Jadassohn's *Handbuch*,⁸ Meierowsky, in commenting on Peutz's cases, stated "Professor Bruno Kisch has observed a case which belongs in this group, there were pea-sized spots of the gums, the father had died of ileus, the grandfather had succumbed to obstipation." Unfortunately no further details can be

FIGURE 14 Surgical Specimen and Appearance of Patient in a Case of Pigment Spots and Polyposis (Reproduced from Peutz⁷ with the Permission of the Publisher)

On the left is a resected portion of the small intestine, showing polyps. On the right is a photograph of the patient showing pigment spot on the lips and face. Note that the spots on the face in this patient were much more numerous than those on the face in the cases reported by us.

Regarding changes of the pigmentation with aging of the subject, Peutz¹⁰ has the following interesting comment

The proved, probable and possible cases recorded in the literature or described in personal communications are summarized in Table 1

Although one of us has been looking for such cases for the past eight years, we have personally encountered only 1 case in which a pigment pattern indistinguishable from that of the syndrome being discussed in this paper was noted in a person in whom polyposis could not be demonstrated. A brief report of this case* is as follows

C L., a 57-year-old woman from Pueblo, Mexico, was seen at the Johns Hopkins Hospital because of precordial pain, and was examined by one of us. The family history was negative for pigmentation, but intestinal trouble was present in the form of "strangulated hernia" in the maternal grandfather, chronic indigestion in a brother and fatal gastric hemorrhage in the father.

The patient was an obese woman with hypertension and typical angina pectoris. Intestinal complaints were denied. The pigmented spots of the lips and oral mucosa, which were similar to those in our other cases and are shown in Figure 17, had been present for at least 8 years and possibly longer. This point, however, was not too clearly established. The spots were located on the vermilion border of the lower lip, to a less extent of the upper lip, on the buccal mucosa and on the hard palate. There were a few small light spots on the palms and volar aspects of the fingers, but none were seen on the feet. The spots in and around the mouth varied in dimension from pin-point size to about 6 mm in the largest measurement. They were brown black. On observation under magnification the spots had a definite, stippled appearance similar to that in Case 7, 8, 9 and 10.

Barium enema including a double contrast air study, was negative, as were an upper gastrointestinal study and sigmoidoscopy. The stools were negative for occult blood. No special small-bowel study was made.

Because of the absence of gastrointestinal symptoms and negative studies, it was concluded that the patient probably did not have intestinal polyposis.

*We are indebted to Dr. R. Carmichael Tilghman for calling this case to our attention and for permission to publish it.

(To be concluded)

patient was a fifteen-year-old girl with pigment spots of the lips and buccal mucosa (Fig 16) The parents and a single sister were normal In addition to the typical pigmentation, the patient had habitual constipation and occasional rectal prolapse with defecation Rectal examination revealed an "enormous dilatation of the rectal ampulla and of the sigmoid, 7 cm from the anus there was a mobile polyp, the size of a large nut, which, on biopsy, was a simple adenoma with great dilatation of the glandular cavities but without neoplastic transformation" A study adequate to exclude small-bowel polyposis was not made so that one can only speculate on its possible existence

Touraine and Couder¹⁸ collected from the literature 31 cases of pigment pattern identical with that in the case described by them, by Peutz and by us The term "lentiginose péri-orificielle" was used to describe the pigment portion of the syndrome These cases occurred as follows 22 cases were familial, 8 occurred in three generations

(Peutz⁷), 5 in four generations (Siemens¹²) and 9 in three generations (Ferrari¹⁹) Our original report of 2 cases was apparently not available to Touraine and Couder and not included by them in this tabulation (Its publication in a paper under the general title "Pigmentation of the Skin" made recognition through the index listing difficult) They likewise were not aware of Foster's¹⁴ cases or those of van Dijk and Oudendal,¹⁴ probably because of the misleading titles of these two papers As listed in this tabulation only the 4 cases of Peutz⁷ and possibly the one reported by Touraine and Couder^{17, 18} had the full syndrome

It is of interest that in these various reports of the pigment pattern collected by Touraine and Couder¹⁸ 3 patients had data suggesting polyposis Belote²⁰ reported at a dermatologic meeting the case of a twelve-year-old boy with the characteristic pigmentation who complained of bleeding from the rectum and increasing weakness, tarry stools

had been present occasionally, and examination of the blood demonstrated secondary anemia No further data on studies of the gastrointestinal tract were given Because of the death of Dr Belote it was impossible to trace this case further²¹

In 1912, Crouzon and Chatelin²² reported a case of the pigmentation in an eighty-three-year-old woman on the service of Pierre Marie at the Salpêtrière In addition to the identical pigmentation, the patient was said to suffer from "rather frequent

FIGURE 17 Photograph of a Fifty-Seven-Year-Old White Woman Who Had Melanin Spots of Lips and Mucous Membrane of the Mouth but in Whom Polyps of the Stomach or Colon Were Not Demonstrated

This is a possible case of pigmentary portion of the syndrome without polyposis

attacks of diarrhea (once or twice a month), not accompanied by vomiting"

The remaining suspected case of the syndrome was reported by Hudelo and Rabut²³ in 1927 Their patient manifested the characteristic pigmentation and in addition was said to have suffered from "indigestion, abdominal pains and nausea" Histologic study of a biopsy specimen revealed the pigment to be melanin

was readily mobilized and the vascular pedicle carefully isolated. The renal artery was small and no pulsations could be seen or felt. It was followed toward its origin until it disappeared beneath the vena cava without the demonstration of any pulsating portion. At the hilus of the kidney the artery divided into two main branches. One of these divisions was deliberately cut without clamping and a thin trickle of blood, with no pulsatile quality whatever to the flow, emerged. The artery was then clamped, cut and ligated and the veins similarly treated. The ureter was divided between ligatures and the kidney removed. The flank wound was closed in layers with drainage.

Postoperatively the blood pressure was carefully followed, and during the 9 days in the hospital after operation the systolic pressure varied from 100 to 120 and the diastolic from 60 to 80. Two weeks after discharge the blood pressure was 116/77 and on 9 subsequent occasions up to 17 months postoperatively has never been higher than 120/80 or lower than 110/70. The patient has remained well and vigorously active.

The kidney was subjected to careful pathological examination, and the following is the description of the organ by the pathologist*.

The specimen consists of a right kidney measuring 12 by 5 by 4 cm. The capsule is rather densely adherent to the cortex. On gross section an essentially normal medullary architecture is seen. The entire parenchyma is intensely engorged and deep purple in color. The pelvic mucosa is grossly normal. The extrarenal arteries are patent. In some areas portions of the medullary rays are outlined by interstitial hemorrhage.

Microscopical sections of the kidney have a most striking histologic appearance. The pyramidal portions show extensive necrosis, with hemorrhage extending throughout these zones. There is little evidence of inflammatory exudate surrounding these areas of necrosis. The vessels at the margins are intensely congested. In contrast the cortex appears intact except in one section where a small, fresh infarct is seen. The cortex shows intact glomeruli whose capillaries are engorged. The juxtaglomerular apparatus, particularly the macula densa is unusually prominent in many glomeruli. The convoluted tubules appear small and collapsed, and the epithelial lining is atrophic resembling that seen in the collecting tubules. Frequently, the epithelial cells have a pale, vacuolated cytoplasm. The blood vessels throughout are thin walled. No evidence of local vascular occlusion is seen in the many sections studied.

The histologic changes are those of profound ischemia with infarct-like zones limited almost exclusively to the medulla. The generalized atrophy of the convoluted tubules is undoubtedly secondary to renal ischemia. The apparent prominence of the juxtaglomerular apparatus may be accentuated by the atrophy of the surrounding tubular epithelium which brings out the macula densa especially clearly.

DISCUSSION

It is evident from the foregoing report accurate knowledge of the cause of the proved partial obstruction of the right renal artery is lacking. It is probably justifiable to attribute it to an atheromatous plaque in the aorta at the origin of the renal

artery or in the proximal portion of the renal artery itself.

It was evident that vascular occlusion was present when an anatomically normal kidney with complete loss of function was demonstrated. It was surmised that the obstruction must be incomplete when the blood pressure was found to be rising rather abruptly.

It is interesting to speculate on what would have occurred had the kidney not been removed. The appearance of headache, blurred vision and retinal changes associated with rapidly increasing arterial pressure led me to believe that the entire picture of malignant hypertension would have developed and would have become irreversible as soon as the peripheral arterioles began to show degenerative changes. This belief is strengthened by the experimental observations of Goldblatt¹ and more recently of Selve² of Montreal. Whether the renal cells responsible for the hypertension are in the juxtaglomerular apparatus as Goormaghtigh³ contends or in the descending loop of Henle as Selve² believes is of no importance in this case, since both areas were uninvolved in the necrosis present in the kidney.

A point of some interest for which I do not have an explanation is the appearance of necrosis in the medullary portion of the kidney whereas the cortex remained uninvolved. If the disputed "shunting" vessels of Trueta⁴ actually exist, one would expect the greater damage to be seen in the cortex.

SUMMARY

A case of hypertension due to partial occlusion of the right renal artery with cure of the hypertension by nephrectomy is presented. The case is of unusual interest because it was possible to observe the entire development of the hypertensive syndrome and correlate it with the clinical symptoms produced by the arterial occlusion. A follow-up period of eighteen months revealed no tendency to a recurrence of the hypertension.

HYPERTENSION DUE TO PARTIAL RENOVASCULAR OCCLUSION

Report of a Case

PHILIP M. CORNWELL, M D *

HARTFORD, CONNECTICUT

IN 1934 Goldblatt¹ aroused much interest by the publication of the results of his experimental production of hypertension in dogs by ingeniously reducing the blood flow through one or both renal arteries. Other investigators have abundantly confirmed his findings.

Within a short time of the appearance of this paper clinical case reports of hypertension in human beings, apparently caused by similar circumstances, began to appear in the literature. It became apparent that severe hypertension from such causes was a very real, but nonetheless a relatively rare, entity. Large series of cases of hypertension have been subjected to searching urologic study, only a small proportion exhibiting unilateral renal disease of possible etiologic significance. Clinical study of the problem has indicated that arterial hypertension can result from any type of renal disease that produces a marked reduction, but not complete ablation of the blood flow through the kidney.

The case reported below is unusual in that the pathologic process exactly reproduced the conditions of Goldblatt's experiments and that it was possible to follow the clinical course of the disease almost from the onset of the vascular obstruction.

CASE REPORT

M P was a 35-year-old factory worker. Her past medical history included an osteomyelitis of the left tibia at the age of 14 that had required several surgical procedures before final healing had been attained, this condition had caused no trouble for 20 years. In 1942 she had suffered a bilateral uveitis, which had responded satisfactorily to the removal of several infected teeth and fever induced by intravenous injection of typhoid vaccine. At that time a careful examination of the retinas by a competent ophthalmologist was recorded as showing no retinal abnormalities. The blood pressure was noted to be 132/88. From 1942 until the onset of the illness under discussion she had been entirely well except for several minor ailments for which she consulted her family physician. On three of these occasions he had recorded her blood pressure at 130/80.

On November 4, 1947, at 7 a m, she experienced a sudden severe, cramping pain in the right upper abdomen. Within the next few hours the pain became dull and moved to the midportion of the abdomen lateral to the umbilicus on the right side. She became nauseated and vomited twice. By mid-afternoon she became so uncomfortable that she was forced to leave work and go home. By this time the pain centered in the right costovertebral angle and the right flank, where it remained the rest of the day and all that night. She ate no supper, vomited bile several times during the night and was unable to sleep. On the following morning she called her doctor, who advised hospitalization for study with a tentative diagnosis of acute retrocecal appendicitis.

On admission to the hospital she still had some pain but it was much less severe and entirely in the right costovertebral

angle. She appeared somewhat pale, but otherwise seemed healthy. The head and neck were unremarkable. A few crackling rales were audible at the base of the right lung posteriorly. The heart was of normal size, the rhythm was regular, and no murmurs were heard. There was slight resistance to palpation in the right upper quadrant of the abdomen, and slight tenderness was elicited in the right costovertebral angle. Rectal examination was negative. The introitus was virginal. The extremities were normal, and the deep and superficial reflexes were physiologic.

The temperature was 100°F by mouth, the pulse 60, and the respirations 18. The blood pressure was 110/70.

Examination of the blood showed a white-cell count of 12,850, with 91 per cent neutrophils. The hematocrit was 40 per cent. The urine was acid, had a specific gravity of 1.015 and gave a + test for albumin but contained no sugar, only rare white blood cells were noted in the sediment.

After admission all the symptoms rapidly disappeared. The elevated white-cell count, with a marked shift to the left, tended toward normal. Except for the initial temperature of 100°F the patient remained afebrile. On the 3rd hospital day an intravenous pyelogram showed a normal left upper urinary tract, but no excretion of the Diodrast was noted on the right side in any of the films.

On the 5th day after admission cystoscopy and retrograde pyelography were done. The bladder and urethra were normal. Both ureteral orifices were in their normal location and appeared normal. Urine was seen to emerge from the left orifice in normal peristaltic spurts, but none was seen to issue from the right side. Catheters were passed easily to each kidney pelvis. Indigo carmine injected intravenously appeared promptly in strong concentration from the left side, but there was no drainage whatever from the right catheter although irrigation with sterile water was easily accomplished with no evidence of obstruction of the catheter. Films were made before and after the catheters had been injected with an opaque medium. No calcific shadows were visible in the renal, ureteral or bladder areas. The tips of both catheters were apparently well placed in the renal pelves. The renal parenchymal shadows on each side were equal and normal. The kidney pelves, calyces and ureters were well filled with contrast material and appeared entirely normal.

On the strength of these findings it was believed that the patient had suffered an obstruction to blood flow through the right kidney of undetermined cause. The blood pressure was rechecked on the following day and found to be 160/90 in contrast to the 110/70 recorded on admission to the hospital a week before. Thereafter, daily blood-pressure readings were taken — all by the same observer and all at approximately the same time of day. A steady rise of both systolic and diastolic readings was noted until, on the 13th day after the onset of the illness, a blood pressure of 180/110 was recorded. On the preceding day the patient had complained of throbbing headache and blurring of vision. An ophthalmologist noted moderate straightening and narrowing of the retinal arterioles and early arteriovenous nicking.

At this time the basal metabolic rate was + 6 per cent, and the blood cholesterol 258 mg and the nonprotein nitrogen 27 mg per 100 cc, the blood sedimentation rate was 13 mm in 1 hour, and the white-cell count was 11,300, with 82 per cent neutrophils, the phenolsulfonphthalein test showed 45 per cent excretion of the dye in 1 hour. The prothrombin time was 100 per cent of normal, and a chest x-ray examination was negative.

The right ureter had been catheterized a second time 3 days after the first cystoscopic examination, and the original findings confirmed. On the 14th day after the onset of the illness the right kidney was exposed through a flank incision. The organ appeared pale and a little bluer than usual. It

*Assistant urologist, Hartford Hospital.

trophe Two of these (Case 21 and 31) had not had any roentgenologic studies at the time of the fire.

Films during inspiration and expiration as well as lateral films were obtained. Fluoroscopy was performed whenever it was thought to be indicated. The observation concentrated on the presence or absence of scars, areas of atelectasis, emphysema.

*Percentages of values theoretically regarded as normal.

and the position of the diaphragm in inspiration and expiration.

Of the 16 cases, 13 showed no variations from normal in any respect. Two of the remaining cases (Case 4 and 13) showed each a single vertical line in the lower-lung field, representing either a linear scar or a very thin area of plate-like atelectasis. One patient (Case 4) had had seven roentgenologic examinations between the second day and the seventh week of the fire, none of the examinations had shown any abnormality. It is unlikely that the present minimal variation from normal is connected with the disaster. Clinically, the patient is perfectly well. The patient in Case 13, in contrast, had had evidence of atelectasis when seen seventeen weeks after the fire. A third case (Case 21) showed a few similar lines in a basal segment of the right lower lobe. This patient had had no roentgenologic examination at the time of the fire. She had had a virus pneumonia in the spring of 1943. She showed at the time of examination no clinical evidence of disease. The only residual abnormal findings then that might conceivably be attributed to the disaster are the minimal areas of scarring or atelectasis present in Case 13 and 21. Both patients are symptom free.

At the end of the original observation period six years ago, only 2 cases showed residual roentgenologic changes (Case 13 and 19). Case 13 still shows a linear scar or area of atelectasis. We were not able to trace the patient in Case 19, who when

last seen eighteen weeks after the fire still had evidence of air trapping.

DISCUSSION

Analysis of Abnormal or Questionable Findings

Two patients (Case 9, a twenty-seven-year-old woman and Case 14, a thirty-four-year-old man) report occasional dyspnea on effort. The former raises fairly large quantities of thick mucus in the morning, and the latter also raises mucus at the same time. A twenty-nine-year-old man (Case 11) raises a little white or yellow sputum in the morning; he smokes about a package of cigarettes a day. These two complaints are not uncommon in unselected groups of the general population in this climate. The one person (Case 21, a thirty-one-year-old woman) who reports a chronically sore throat dates it from her second delivery in 1946. This is the patient discussed under the section on roentgenology who had a virus pneumonia in 1943.

Vital-capacity estimations show variations from 85 to 117 per cent of the theoretical normal. By this method (McKesson and Scott) 85 per cent of theoretical normal is considered within normal limits, 5 of our patients fell just below the accepted normal level.

Status of Cases Described in Detail in First Report

In our original report we described certain case records as illustrating the characteristics of the different degrees of severity of lung complications.

CASE 16 was used to illustrate Group 2 (rales and emphysema). This man later served overseas as a war correspondent. He is clinically well. His vital capacity, which was 58 per cent of theoretical normal soon after the fire, is now 114 per cent.

CASE 6 was used to illustrate Group 3 of lung complications (rales, emphysema and persistent atelectasis attributed to edema of the air passage). She is now 20, a student in college. She is clinically well. Her vital capacity, which was initially reduced to 25 per cent, is now 98 per cent of theoretical normal.

CASE 20, which we described to illustrate Group 4, has since died, presumably from carcinoma of the breast. Unfortunately, she died outside the hospital so that there was no opportunity to examine the lungs anatomically.

CASE 13. This patient is now clinically well so far as her lungs are concerned and is about to be married. She has some degree of nasal obstruction after plastic operations to her burned nose. Her initial vital capacity was 29 per cent, it is now 82 per cent.

CONCLUSION

From the data on the 16 patients whom we have recently examined clinically and roentgenologically and the 3 additional patients reporting by mail, persistent cough is not reported by any patient and only 3 of the 19 raise any sputum. It seems probable that there is no persisting or secondary pulmonary disease resulting from the fire damage.

PULMONARY EFFECTS OF THE COCOANUT GROVE FIRE

A Five-Year Follow-Up Study

HELEN S. PITTMAN, M.D.,* AND RICHARD SCHATZKI, M.D.†

BOSTON

THE Coconut Grove fire took place on November 28, 1942. In a previous report¹ we described the initial pulmonary complications in the group of 39 patients admitted to the Massachusetts General Hospital. Finland² has already published the follow-up findings in his series of 92 patients discharged from the Boston City Hospital. He found that symptoms of respiratory disease at four, nine and twenty-six months after the fire were neither frequent nor severe. Persistent cough was the most common symptom at each time period. An occasional patient later began to raise copious amounts of mucopurulent sputum (12 of the 38 patients reporting at twenty-six months). This he regarded as suggesting the development of bronchiectasis.

This study concerns the status of the Massachusetts General Hospital patients five or more years after the fire. The interval seemed sufficient to have permitted the development of any late pulmonary complications that were going to occur.

PLAN OF STUDY

We have written to 29 of the 32 patients discharged from the Massachusetts General Hospital. The other 3 were service men who remained in the hospital only until transfer to Army or Navy installations was arranged. We had no permanent addresses for these 3 patients. We know that 2 of them were returned to full duty by December 12, 1942.

The study was based on questionnaire, physical examination, vital-capacity estimation and roentgenographic examination.

RESULTS OF STUDY

Sixteen patients returned for examination, 6 reports were received by mail, and 7 persons could not be traced. Three of the 6 mailed reports included completed questionnaires (Case 9, 10 and 14). Two patients had died (Case 15 and 20). One is apparently psychotic (Case 35).

Of the 3 patients from whom we have current information but whom we have not seen, 1 is well and 2 have slight dyspnea on exertion. Answers to their questionnaires are indicated in Table 1.

CASE 9 The patient has occasional dyspnea on effort and raises fairly large quantities of thick mucus in the mornings. This case was classified as Grade I severity of lung

*Instructor in medicine, Harvard Medical School, associate physician, Massachusetts General Hospital.

†Instructor in radiology, Harvard Medical School, radiologist, Mount Auburn Hospital, Cambridge, assistant radiologist, Massachusetts General Hospital.

complications, and the patient was discharged a few hours after the fire without having chest x-ray films taken.

CASE 10 The patient, a physician, reports himself as well except for occasional asthma, which he had before the fire.

CASE 14 The patient reports that he has some shortness of breath on walking uphill and that he has some wheeze. He has no other symptoms referable to the respiratory tract.

TABLE 1 Replies to Questionnaire (19 Cases)

QUESTION No	QUESTION	YES	NO
1	Have you any chronic cough?		16+3*
2	Are you short of breath?	2*	16+1*
	If so, do you notice it at rest?		16+3*
	Do you notice it when walking on the level?		16+3*
	Do you notice it when walking uphill?	2*	16+1*
3	Have you any wheeze?	1*	16+2*
4	Are you hoarse?		16+3*
5	Do you raise any sputum?	1+2*	15+1*
6	Do you ever spit blood?		16+3*
7	Do you have pain in your chest?		16+3*
8	Do you have discharge from your nose?	2	14+3*
9	Do you have a chronically sore throat?	1	15+3*

*Replicas so designated refer to patients answering by mail and not interviewed.

Immediately after the fire he had a transient inspiratory wheeze over the front of the left side of the chest and in the left axilla. There was never any abnormal finding in his x-ray film, and examination of his chest was negative at the time of discharge from the hospital on December 10.

CASE 15 This patient committed suicide on January 9, 1943, by jumping through a window.

CASE 20 This patient died on February 3, 1945. In December, 1943, she was operated on for an adenocarcinoma (Grade III) of the left breast, with axillary metastases, in the Baker Memorial Hospital. X-ray films of the lungs were clear at that time.

CASE 35 The patient is reported as being a "psychologic case." She "will not permit a doctor to see her."

PHYSICAL EXAMINATION

Of the 16 patients who have been examined 15 are clinically well so far as their lungs are concerned. One patient (Case 16), a man now sixty-three years old, is symptom free, on examination there were persistent rales in the right axilla.

The results of vital-capacity determination are shown in Table 2.

ROENTGENOLOGICAL FINDINGS†

Sixteen of the original group of survivors had roentgenologic examinations for this follow-up study, varying from five to six years after the catas-

†We are indebted to Dr. Stanley Wyman, of the Massachusetts General Hospital, for the performance of a number of the roentgenologic examinations.

NUTRITIONAL SURVEYS AND SUBCLINICAL VITAMIN DEFICIENCY

With the exception of one report,⁶⁵ nutritionists in general note that frank deficiency diseases especially vitamin-deficiency diseases, have almost disappeared during the last decade in the United States.^{12, 7, 74} The majority of cases of clinical vitamin deficiency now seen are in association with chronic alcoholism or some debilitating disease,⁷² and a moderate number of cases of scurvy occur in infants because mothers boil the orange juice or cater to dietary dislikes.⁷⁵ The cause of this reduced incidence of gross vitamin deficiency in the United States is unexplained. Blankenhorn⁷² observes that deficiency began to disappear before the enrichment of flour was practiced generally and has continued to wane in spite of the high cost of food, indicating that improvement is probably not due to gain in economic status.

On the other hand, a survey of the many studies of the nutritional state of prisoners of war and of the populations of occupied countries during World War II showed that vitamin deficiency becomes prevalent under adverse conditions. Only a few of these reports are reviewed here. Cartwright and Wintrobe⁷⁶ elicited a history of pellagra in 50 to 70 per cent, wet beriberi in 77 per cent and dry beriberi in 50 per cent of war prisoners from the Philippines and from Japan. Similar findings in the Pacific Theater were reported by others.^{77, 78} In general, the deficiencies were multiple, but two other outstanding symptoms attributed to inadequacy of components of the vitamin B complex were the "burning-feet" syndrome and retrobulbar neuritis.^{24, 49, 79, 82} The syndrome of "burning feet" at night was observed previously in the Spanish Civil War.⁸³ The important information about these two newer syndromes of vitamin deficiency is their failure to respond to crystalline thiamine or nicotinic acid supplements alone, but they improve after ingestion of brewers' yeast or a luxurious diet.^{74, 49, 80, 83} It was mentioned above that the "burning-feet" syndrome might be due to pantothenic acid deficiency.⁴⁹

In contrast with these reports from the Pacific area, the results of nutritional surveys among

European civilians and prisoners of war showed a minimum of vitamin-deficiency signs, although they were very much undernourished with respect to calories.⁸¹⁻⁸⁷ The difference between the European and Pacific types of starvation is probably due to the fact that the diet in the Pacific Theater was primarily carbohydrate, secondary diseases such as dysentery adding to the burden of maintaining adequate vitamin intake. In Europe, however, the dietary intake was generally restricted but more nearly balanced with almost adequate protein and borderline vitamin intake. It should be noted that the vitamin requirements were somewhat reduced by the decrease in metabolic rate that occurs in semistarvation.^{85, 87}

To return to the problem of vitamin deficiency in the United States, in addition to the reports of the rarity of clinical vitamin deficiency today, the proponents of widespread avitaminosis have been dealt a further blow through recent critical surveys, which have demonstrated that many of the so-called specific signs of vitamin deficiency are not caused by a lack of vitamins but by other factors, which are often nonnutritional. The thickening of bulbar conjunctivas, which was formerly attributed to vitamin A deficiency, remained unchanged after two years of therapy with 50,000 I.U. of vitamin A per day.¹³ Similar, but not quite as definitely negative, results of therapy were obtained by Borsook et al.⁸⁸ Darby and Milam⁷⁴ found no correlation between the skin lesions supposedly caused by vitamin A deficiency and low plasma vitamin A levels or a low daily intake of vitamin A. Others have stated that keratosis pilaris is more often due to a deficiency of soap and water than to a lack of vitamin A.^{89, 90} These facts are strong evidence that the so-called signs of vitamin A deficiency are not specific.

Abnormal reflexes, calf-muscle tenderness, plantar dysesthesia and loss of vibratory sense have been considered specific signs of inadequate thiamine intake. Borsook et al.⁸⁸ failed to observe any therapeutic effect of large doses of thiamine, administered over a long period to a group of young aircraft workers, some of whom manifested these symptoms. Likewise, Darby and Milam⁷⁴ found no relation between a low level of thiamine intake and abnormalities of vibration sense, which were found in adults only. These observations suggest both that the specificity of such symptoms of athi-

ODDITY OF PREGNANCY

LOUIS LEVINE, M.D.,* AND ROBERT H. GOODWIN, M.D.†

NEW BEDFORD, MASSACHUSETTS

CURIOUS alterations of appetite of the most bizarre nature occur in some pregnant women

CASE REPORT

A well developed and well nourished 39-year-old woman came to the office in her 37th week of pregnancy. She had had eight normal pregnancies, and 7 of the children were living and well. The heart and lungs were essentially normal. The blood pressure was 120/80. There was a vertex presentation, in the left occipitoanterior position, and the fetal heart tones were normal. The teeth were in poor condition, gray and completely eroded or abraded (Fig 1). These flat, table-shaped teeth led to further questioning, which brought to light her strange diet. When she was about 16 weeks pregnant, she suddenly experienced an urge to eat coal. Since her home was heated with oil, she made her husband purchase a 100-pound bag of pea coal. She chewed and ate two or three pieces of coal daily, carefully washing it with water before eating it. She continued to indulge in this strange diet, chewing the coal until the 37th week, when her teeth became eroded and soft and when she began to break up the lumps into small pieces before eating.

She was never constipated and stated that she saw the small pieces of coal in her feces after each bowel movement. She took a normal diet otherwise, and had had no desire to eat coal or any other special foods during her previous pregnancies. She had had no medical or prenatal care previous to being seen by one of us (L. L.) during the 37th week of pregnancy.

She was given dicalcium phosphate with vitamin D, 2 tablets four times daily, and told to refrain from continuing her coal diet. The calcium seemed to satisfy her, and she stopped eating coal. Three weeks later she delivered a normal female infant in the hospital. She had an uneventful puerperium, and now requires extensive dental care.

SUMMARY

A case of a craving for coal, which developed during pregnancy, is presented. This craving was relieved by a prescription of dicalcium phosphate. Permanent damage to the teeth resulted from the coal diet. So far as is known, no similar cases have been reported.

NUTRITIONAL SURVEYS AND SUBCLINICAL VITAMIN DEFICIENCY

With the exception of one report⁶⁵ nutritionists in general note that frank deficiency diseases especially vitamin-deficiency diseases have almost disappeared during the last decade in the United States.^{12, 72-74} The majority of cases of clinical vitamin deficiency now seen are in association with chronic alcoholism or some debilitating disease,⁷² and a moderate number of cases of scurvy occur in infants because mothers boil the orange juice or cater to dietary dislikes.⁷⁵ The cause of this reduced incidence of gross vitamin deficiency in the United States is unexplained. Blankenhorn⁷² observes that deficiency began to disappear before the enrichment of flour was practiced generally and has continued to wane in spite of the high cost of food, indicating that improvement is probably not due to gain in economic status.

On the other hand, a survey of the many studies of the nutritional state of prisoners of war and of the populations of occupied countries during World War II showed that vitamin deficiency becomes prevalent under adverse conditions. Only a few of these reports are reviewed here. Cartwright and Wintrobe⁷⁶ elicited a history of pellagra in 50 to 70 per cent, wet beriberi in 77 per cent and dry beriberi in 50 per cent of war prisoners from the Philippines and from Japan. Similar findings in the Pacific Theater were reported by others.^{77, 78} In general, the deficiencies were multiple, but two other outstanding symptoms attributed to inadequacy of components of the vitamin B complex were the "burning-feet" syndrome and retrobulbar neuritis.^{24, 49, 79, 82} The syndrome of "burning feet" at night was observed previously in the Spanish Civil War.⁸² The important information about these two newer syndromes of vitamin deficiency is their failure to respond to crystalline thiamine or nicotinic acid supplements alone, but they improve after ingestion of brewers' yeast or a luxurious diet.^{24, 49, 80, 83} It was mentioned above that the "burning-feet" syndrome might be due to pantothenic acid deficiency.⁴⁹

In contrast with these reports from the Pacific area, the results of nutritional surveys among

European civilians and prisoners of war showed a minimum of vitamin-deficiency signs although they were very much undernourished with respect to calories.⁴⁴⁻⁵⁷ The difference between the European and Pacific types of starvation is probably due to the fact that the diet in the Pacific Theater was primarily carbohydrate secondary diseases such as dysentery adding to the burden of maintaining adequate vitamin intake. In Europe however the dietary intake was generally restricted but more nearly balanced with almost adequate protein and borderline vitamin intake. It should be noted that the vitamin requirements were somewhat reduced by the decrease in metabolic rate that occurs in semistarvation.^{53, 57}

To return to the problem of vitamin deficiency in the United States, in addition to the reports of the rarity of clinical vitamin deficiency today the proponents of widespread avitaminosis have been dealt a further blow through recent critical surveys which have demonstrated that many of the so-called specific signs of vitamin deficiency are not caused by a lack of vitamins but by other factors, which are often nonnutritional. The thickening of bulbar conjunctivas, which was formerly attributed to vitamin A deficiency remained unchanged after two years of therapy with 50,000 I.U. of vitamin A per day.¹² Similar, but not quite as definitely negative, results of therapy were obtained by Borsook et al.⁸⁵ Darby and Milam⁷⁴ found no correlation between the skin lesions supposedly caused by vitamin A deficiency and low plasma vitamin A levels or a low daily intake of vitamin A. Others have stated that keratosis pilaris is more often due to a deficiency of soap and water than to a lack of vitamin A.^{89, 90} These facts are strong evidence that the so-called signs of vitamin A deficiency are not specific.

Abnormal reflexes, calf-muscle tenderness, plantar dysesthesia and loss of vibratory sense have been considered specific signs of inadequate thiamine intake. Borsook et al.⁸⁵ failed to observe any therapeutic effect of large doses of thiamine, administered over a long period to a group of young aircraft workers some of whom manifested these symptoms. Likewise, Darby and Milam⁷⁴ found no relation between a low level of thiamine intake and abnormalities of vibration sense, which were found in adults only. These observations suggest both that the specificity of such symptoms of athi-

†Associate in Medicine, Harvard Medical School; assistant in Medicine, Massachusetts General Hospital.

aminosis is untrue and that the concept of thiamine-deficiency incidence based upon these signs should be revised downward

The signs most often associated with riboflavin deficiency — namely, corneal vascularization, angular fissures and changes in the buccal mucosa and tongue — have been found without relation to a low intake of riboflavin⁷⁴⁻⁹¹ The corneal vascularization may just as often be associated with physical trauma such as sun, wind or dust,⁹² whereas Darby⁹³ states that at the Vanderbilt Hospital Nutrition Clinic stomatitis due to iron deficiency is seen more frequently than cheilosis and glossitis caused by lack of riboflavin or niacin

Another example of nonspecificity of a supposedly characteristic sign of vitamin inadequacy — in this case, vitamin C — is gingivitis or swelling and blueness of the gums There are several reports of gingivitis in 50 per cent or more of adults examined, but the gingivitis is associated with poor oral hygiene rather than with low plasma ascorbic acid levels⁷⁴ and does not decrease after administration of 100 to 200 mg of vitamin C for three months or longer⁹⁴⁻⁹⁵ Although oral hygiene plays a major role in prevention of gingivitis, vitamin C may contribute, as shown in a well controlled study by Linghorne et al⁹⁶ They found that ascorbic acid therapy alone would not improve gingivitis but that, once local therapy had alleviated involvement of the gums, daily intakes of more than 22 mg of vitamin C would deter the recurrence of gingivitis

Inasmuch as many estimates of the incidence of vitamin deficiency in the United States have been based upon the presence of signs that are now shown to be nonspecific, I believe that the problem of vitamin deficiency is minimal Therefore, it becomes apparent that, with few exceptions, food intake supplies the minimal requirement of essential vitamins, and the widespread use of vitamin supplements does not seem indicated for treatment of an almost nonexistent vitamin-deficiency state

There still remains the possibility that vitamins in addition to those in the general diet are of value for improving health or well-being and for promoting recovery from disease Information obtained from review of the following studies of this problem will indicate whether or not the average American diet contains optimal quantities of vitamins

To quote from Keys,⁹⁷ who appreciated the necessity of restricting his interpretation to the small number of studies on vitamin-fitness relations that were acceptable and well controlled, "the great bulk of the evidence indicates no gain in fitness of adults from vitamin supplementation added to a good American diet" There is no improvement in tolerance to hot or cold environments from the use of vitamin supplements and no good evidence that vitamin requirements are increased during

extremes of temperature⁹⁸⁻⁹⁹ Contrary to the statement that "biochemical avitaminosis" has been found to exist in the majority of aged persons,¹⁰⁰ Vernon and McKinlay¹⁰¹ found no beneficial effect over a twelve-month period from vitamin supplementation in senile patients In two well controlled studies involving more than 500 employees of an aircraft plant⁹¹ and 241 steel workers,¹⁰² daily supplements of a multivitamin capsule showed no more beneficial effect on sense of well-being, absenteeism, appetite, sleep and increased output of work than did placebo capsules Comparison with a control group receiving neither placebos nor vitamin capsules leaves no doubt about the psychologic and morale-improving effect of any sort of medication It is the psychologic effect of vitamin supplements that opens to question the many reports of beneficial effects It has already been mentioned that added vitamins failed to alter the biomicroscopic lesions observed among the aircraft workers⁹¹ These two reports have an increased value in an attempt to determine whether there is need for supplementing the average American diet with vitamins because dietary surveys among these workers showed that intakes of vitamins were below the recommended dietary allowances of the National Research Council in a large number of the subjects⁸⁸ As additional evidence, it was found that vitamin supplements had no effect on the growth, strength, nutrition, fatigue potential, incidence or severity of clinical conditions, hearing and absenteeism among 1620 British schoolchildren observed over a one-year period of controlled study¹⁰³ Dietary surveys made in conjunction with this investigation showed that the average vitamin intakes were well below recommended standards and cast doubt upon the validity of the American "recommended dietary allowances"¹⁰³

In another three-year study of 315 workers in trinitrotoluene, multivitamin capsules did not decrease the occurrence of toxic symptoms in the treated group as compared with controls¹⁰⁴ In this study there was an interesting but probably not significant observation of 14 cases of hepatitis among the treated group in contrast to only 2 cases among the controls

In addition to these reports of the general ineffectiveness of vitamin supplements, several investigations show lack of benefit from the administration of specific vitamins in certain pathologic states These findings undermine opinion widely accepted previously that the specific vitamins were indicated in these conditions, 50,000 to 150,000 I U of vitamin A per day did not decrease color blindness¹⁰⁵ or reduce thickening of the bulbar conjunctivas¹⁰⁶ Diabetic neuropathy is not relieved by large doses of thiamine and other components of the vitamin B complex, but only by adequate insulin and diet therapy¹⁰⁵⁻¹⁰⁷ Moreover, diabetic neuropathy has developed in patients who

have been taking excessively large doses of vitamins¹⁰⁶ There was no evidence that large doses of crystalline components of the vitamin B complex had any significant effect upon rate of healing or survival after severe burns³⁶ A study of the effectiveness of various types of therapy in hepatic cirrhosis by means of serial liver biopsies raises doubt whether supplements of vitamin B complex have any beneficial effect beyond that of a high-carbohydrate, high-protein diet alone,¹⁰⁸ and excess quantities of vitamins had no protective effect on liver function as measured by urobilinogen excretion and bromsulfalein clearance during postoperative convalescence¹⁰⁹ Although one investigation showed a slight beneficial effect of added thiamine over placebo tablets in the mental responses of children in an orphanage as measured by results of 15 out of 30 aptitude tests,¹¹⁰ the results are probably not significant Moreover, negative results for improvement in growth, vision and learning after administration of 2-mg supplements of thiamine to 1 of each of 25 pairs of identical twins for nine months were observed in a carefully planned study by Robertson et al¹¹¹ These negative findings are even more impressive when it is noted that 50 per cent of the experimental subjects were eating 20 to 40 per cent less vitamins than the optimal levels of the "Recommended Dietary Allowances"

The conclusion to be drawn from these investigations is that the American diet, even though it may contain a smaller quantity of vitamins than the generous recommendations of the National Research Council suggest, generally supplies optimal amounts of vitamins and that the indiscriminate use of vitamin supplements does not benefit public health or promote recovery from diseases Such a conclusion does not deny the existence of an occasional case of vitamin deficiency that requires short-term vitamin supplementation, nor does it deny that the use of large doses of specific vitamins may not be of benefit in certain diseases in which the vitamin has a pharmacologic rather than a nutritive action Reports of the specific therapeutic uses of vitamins are reviewed below

SPECIFIC THERAPEUTIC USES OF VITAMINS

Reports of the curative or beneficial effect of large doses of a specific vitamin in a given disease are legion, and such reports, along with advertisement of supposed malnutrition, have acted as stimulants to vitamin sales In many cases reports of therapeutic success with a vitamin are the result of uncontrolled clinical investigations that do not consider either the natural history of the disease or the possible psychologic effect of vitamin pills At the risk of omitting many valuable references, only a few investigations can be reviewed

Massive doses of vitamin A have been a therapeutic favorite of dermatologists, 100,000 to 240,000 I U of vitamin A are said to bring about slow

improvement in some cases of Darier's disease^{112 113} Similar doses of vitamin A were believed to cause regression in both seborrheic and senile keratoses in all 50 cases treated for three or four months, whereas 30 control cases remained unchanged¹¹⁴ Thirty-seven per cent of 42 cases of plantar warts were cured by 100,000 I U of vitamin A daily for five weeks to nine months¹¹⁵ Although the results with vitamin A were not nearly as effective as x-ray therapy, the investigators recommend vitamin A treatment because of its safety Massive doses of vitamin A also are reported to improve pityriasis rubra pilaris¹¹⁶ A striking clinical and pathological improvement was shown by 14 of 18 cases of leukoplakia vulvae treated with 250,000 to 500,000 units of vitamin A per day by mouth, in addition to 50,000 units twice a week by injection¹¹⁷ If confirmed, this observation has considerable significance in view of the difficulties associated with the treatment of leukoplakia vulvae

I agree with many conservative dermatologists who are skeptical about reports of therapeutic benefits from vitamin A Consequently, negative reports from well controlled investigations are important for keeping therapeutic enthusiasm in balance Such a report is that of Lynch and Cook,¹¹⁸ who found that vitamin A had no special beneficial effects in the treatment of acne vulgaris

In 2 cases reported by Simkins,¹¹⁹ "cures" of thyrotoxicosis were effected by the administration of 200,000 to 400,000 I U of vitamin A per day for a year Most clinicians have discounted earlier reports of the effectiveness of vitamin A therapy in hyperthyroidism, but there has been enough suggestive evidence that vitamin A may depress thyroid function to warrant a complete investigation of this problem

The intravenous use of large doses of crystalline components of the vitamin B complex as an agent for determining arm to tongue circulation time has been reported by Swenson¹²⁰ Although it is not exactly a pharmacologic use of B vitamins, the safety of this method merits consideration Massive doses of thiamine to decrease the possibility of arsenic toxicity are suggested by Sexton and Gowdey,¹²¹ but as yet this use for thiamine has not had much of a clinical trial Mention is made of the beneficial effect of very large doses of nicotinamide for all pruriginous states,¹²² and of 25 to 300 mg of nicotinic acid for chilblains¹²³

There has been considerable enthusiasm for the use of pyridoxine in the treatment of radiation sickness during the last five years Representative reports^{124 125} stress the good results in 60 to 65 per cent of cases treated with oral or intravenous doses of 100 to 400 mg per day In view of the constantly changing fashions in the treatment of radiation sickness and of the favorable effects formerly attributed to the use of other components of the vitamin B complex, I believe that there should be

some reservation in accepting pyridoxine as the specific for radiation sickness

Lewy and Fox¹²⁶ report success in the treatment of cases of resistant Ménière's syndrome and of vertigo of undetermined origin with 100 mg of pyridoxine per day. Intravenous injections of 200 mg were said to have a remarkable effect on raising the white-cell counts of patients who had been made agranulocytic by thiouracil,¹²⁷ but pyridoxine was ineffective in the granulocytopenia of chronic benzene poisoning.¹²⁸ The possibility of spontaneous remissions must be considered when the effect of pyridoxine on the granulocytopenia due to thiouracil is evaluated. Other negative reports of value are the failure of pyridoxine in the treatment of epilepsy¹²⁹ and in the treatment of nausea and vomiting of pregnancy.¹³⁰

Promise of benefit from the use of daily doses of 400 mg of calcium pantothenate in 14 cases of discoid lupus erythematosus is reported by Goldman,¹³¹ who is aware of the capriciousness of response of this disease to therapy.

To judge from numerous reports of success, para-aminobenzoic acid seems well established as a specific therapeutic agent in the rickettsial diseases. Flinn et al¹³² compared 10 patients with Rocky Mountain spotted fever who received para-aminobenzoic acid with 13 untreated patients who recovered from the disease. As a result of the drug, the average duration of fever was reduced from seventeen and a half days to ten and a half days, and the treated patients made a more rapid clinical recovery.¹³² Ravenel¹³³ recommended dosages of 0.5 to 1.0 gm per pound of body weight per day. Because the kidneys excrete para-aminobenzoic acid rapidly, oral administration every two hours is necessary to maintain therapeutic blood levels of 30 to 60 mg per 100 cc.¹³² The drug is buffered in 10 cc of chilled 5 per cent sodium bicarbonate solution to decrease nausea and acidosis.¹³³ Administration should be continued for several days after the patient has become afebrile.¹³³ Greeley¹³⁴ suggests using pressed tablets of the sodium salt of para-aminobenzoic acid for slower absorption. If parenteral therapy is necessary, a 25 per cent solution of the sodium salt adjusted to pH 7 may be given by continuous intramuscular or intravenous drip.¹³⁴ Since the drug does not kill rickettsias but inhibits their growth, it is most effective early in the disease.¹³⁵ Para-aminobenzoic acid has also been effective in scrub typhus¹³⁶ and murine typhus.¹³⁷

Further therapeutic possibilities of para-aminobenzoic acid have been enthusiastically but critically described by Zarafonitis.¹³⁸ On the assumption that large doses of the drug might inhibit neoplastic cells with disordered metabolic function, daily doses of 48 gm of the drug were given to patients with leukemia.¹³⁸ A marked drop in white-cell count took place, but there was no essential change in

the clinical condition of the patients.^{138, 139} There is not sufficient space to discuss the rationale for therapy in each type of disease but para-aminobenzoic acid in doses of 15 to 24 gm per day was found to be beneficial in lymphoblastoma cutis, lupus erythematosus, dermatomyositis, scleroderma and sulfonamide-resistant dermatitis herpetiformis.¹³⁸

Another effect of para-aminobenzoic acid that may be of value clinically is its power to cause a great increase in the blood salicylate level when both drugs are given together.¹⁴⁰ The mechanism of this effect has been shown to be reduced detoxication and decreased urinary excretion of salicylates.¹⁴¹ Para-aminobenzoic acid may also reduce the metabolic rate of the body. In an unconfirmed report, Berman¹⁴² stated that daily intravenous doses of 1.0 to 1.5 gm of the sodium salt of para-aminobenzoic acid for three to nine months resulted in a permanent fall of the basal metabolic rate and clinical improvement in all 6 cases of thyrotoxicosis in which this therapy was used.

Several pharmacologic uses for vitamin C have been mentioned, but none of these have confirmation or stem from well controlled studies. Most promising of the group is the report that vitamin C in doses of 500 to 1000 mg per day caused a great reduction of methemoglobinemia in 2 cases.¹⁴³ Chapman and Shaffer¹⁴⁴ found that 250 mg of ascorbic acid increased the minimum lethal dose of Mercurhydrin for dogs by 50 per cent and suggest that 500 mg of vitamin C be mixed with 2 cc of Mercurhydrin in the treatment of congestive failure. Although Klasson¹⁴⁵ reports that 150 to 600 mg of vitamin C per day seemed to decrease the severity of poison-oak dermatitis and prevented the development of dermatitis in 23 out of 24 poison-oak-sensitive persons after exposure, most dermatologists have been disappointed with the use of ascorbic acid in the therapy of poison-ivy dermatitis. Finally, Charpy¹⁴⁶ has the clinical impression that a daily dose of 100 mg of vitamin C eliminated heat prostration in a group of 31 men working at temperatures of 100 to 120°F, but this observation is not in keeping with carefully controlled studies, which showed no increase in resistance to hot environments from the use of large amounts of vitamin C and other water-soluble vitamins.⁹⁸

The cure of lupus vulgaris (tuberculosis of the skin) by massive doses of vitamin D, averaging 100,000 to 150,000 units per day for three months or longer, was first reported by Charpy¹⁴⁶ and Dowing¹⁴⁷ and was subsequently confirmed by numerous other investigations. The only adverse report is that of Ingram and Anning,¹⁴⁸ who observed cures in only 4 patients and improvement in 23 others out of 158 cases treated with massive doses of calciferol. There is no explanation for this divergence of results. In general, 60 to 75 per cent cure can be expected from this type of treatment.¹⁴⁹

Charpy¹⁴⁶ believes that oral administration of the drug is superior to parenteral and that an alcoholic solution of vitamin D is more satisfactory than the oil solution but others found that the route of administration and the type of vehicle for solution of the vitamin D made little difference in the results of therapy. Doses of 150,000 units per day were usually more effective than 100,000-unit doses, and an ineffective dose remained ineffective no matter how long it was continued.¹⁴⁷ There has been no correlation between clinical results and serum calcium levels.¹⁵⁰ During the first few weeks of treatment nearly every patient has a Herxheimer-like reaction, with increase in activity of the skin lesions, a more positive tuberculin test and an increase in erythrocyte sedimentation rate.^{150, 151} Local treatment of the lesion at this time is important for good results.¹⁵¹ The greatest clearing of the lesions occurs within four to eight months.¹⁵⁰ but Charpy¹⁴⁶ believes that treatment should be prolonged for a year or two because histologic cure is considerably slower than clinical remission. Toxic symptoms (to be discussed in a later section of this review) from such large doses of vitamin D were noted in 16 to 50 per cent of the cases treated.^{147, 148, 150, 151} but Dowling¹⁵² points out that often clinical improvement is most striking just when the patient is beginning to look and feel ill from the cumulative effect of treatment. Nephritis and arteriosclerosis contraindicate the use of vitamin D. The mode of action of vitamin D in lupus vulgaris has been much debated but is not understood.

The use of massive doses (100,000 to 900,000 units per day) of vitamin D in sarcoidosis has been tried on a limited scale^{153, 154} with improvement or even clearing of the skin lesions but with marked toxic reactions. As a result the benefit to be derived is questionable. Likewise it has been recommended after critical evaluation of the results of therapy that the use of massive doses of vitamin D in rheumatoid arthritis is neither beneficial nor justified.¹⁵⁵

The pharmacologic use of vitamin E has been the subject of much heated controversy largely owing to the numerous enthusiastic reports from Shute and his co-workers. Other investigators have been unable to confirm Shute's observations. Vogelsang, Shute and Shute^{156, 157} claim to have treated 1500 patients with angina, rheumatic heart disease, hypertensive heart disease, congestive failure and other types of heart disease with 200 to 900 mg of vitamin E per day. They state that vitamin E is the most effective known drug in heart disease and that 80 per cent of the patients treated improve to such an extent that they return to activity even after great disability. Vitamin E is said to decrease capillary permeability, produce

capillary dilatation, reduce anoxia of the cardiac muscle, prevent and resolve thrombi and promote vascularization of scar tissue.¹⁵⁷ I do not believe that these actions of vitamin E have been proved, although Shute et al¹⁵⁵ present an almost convincing review of the function of vitamin E based on biochemical and animal studies.

In a carefully controlled study that avoided both subjective impressions of the patients and natural variations in disease, Levy and Boas¹⁵⁸ found that daily doses of 200 to 800 mg of vitamin E given for three to eleven weeks to 13 patients with angina pectoris were completely ineffective. Baer et al¹⁶⁰ investigated the effect of 300 to 400 mg of vitamin E per day for three to six months in 22 patients with various cardiac conditions and likewise observed no unequivocal evidence of improvement. Similar negative results were obtained by Donegan et al¹⁶¹ when they treated 21 cases of cardiovascular disease with vitamin E for five to twenty months. The consensus of medical opinion in the United States is on the side of the negative results from the use of vitamin E in heart disease, and it questions the validity of Shute's observations. On the other hand, the British opinion, as reflected by an editorial¹⁶² that completely reviews all the therapeutic uses of vitamin E, holds that Shute's claims are plausible and that further controlled clinical tests are indicated.

Additional unconfirmed reports state that vitamin E is beneficial in the treatment of nephritis,¹⁶³ toxemias of pregnancy,¹⁶⁴ purpura,¹⁶⁵ the menopausal syndrome,¹⁶⁶ Dupuytren's contracture,⁶⁹ fibrositis,¹⁶⁷ various skin diseases of the degenerative collagenous group¹⁶⁸ and a host of peripheral vascular diseases.¹⁶²

Aside from the treatment of prothrombin deficiency there has been very little pharmacologic use of vitamin K. One report of the beneficial effect of 20 mg twice a day in 8 cases of chilblains was made by Wheatley.¹⁶⁹ No prothrombin levels were obtained and improvement was measured by clinical response. The rationale for using vitamin K in this condition was based upon the assumption that in chilblains there may be increased permeability of the blood vessels and diminished coagulability of the blood. Another possible effect of vitamin K to be briefly noted is the observation that half of 15 cases with chronic essential hypertension had a significant reduction in blood pressure after oral or intravenous administration of Synkavite.¹⁷⁰

In contrast with the lack of indications for wholesale vitamin supplementation on the basis of deficiency disease the pharmacologic uses discussed above constitute a definite need for specific vitamins in certain diseases.

(To be concluded)

CASE 35511

PRESENTATION OF CASE

First admission A sixty-seven-year-old man was admitted to the hospital complaining of three episodes of terminal hematuria within the past two years, the last episode occurring four months prior to admission.

For four months, the patient had noted slightly increased frequency and occasional dribbling, but had no nocturia, pain, or retention. Physical examination at the time of admission was negative. The urine had a specific gravity of 1.022 and gave a + test for albumin, with occasional red and white cells in the sediment. The nonprotein nitrogen was 27 mg per 100 cc. An intravenous pyelogram showed good kidney function bilaterally. The

ureters were normal, but a slight deformity was noted at the base of the bladder.

On cystoscopy a 1.5-cm papillary tumor was seen just above the left ureteral orifice, and there were scattered small tumor implants elsewhere. Colon bacilli were grown from the catheterized urine. The primary tumor and implants were fulgurated and 8 l-millicurie-radon seeds were implanted above the left ureteral orifice. The patient was discharged much improved. The pathological report of the bladder tumor was carcinoma, Grade III.

Second admission (one month later) Three weeks prior to readmission external radiation therapy was begun at another hospital, following which the patient noted frequency and dysuria. For two days before admission he was nauseated and vomited. On the day of admission he had two shaking chills, a temperature of 102°F, right-flank pain and costovertbral-angle tenderness.

Physical examination was unchanged. The urine had a specific gravity of 1.014 and gave a +++ test for albumin, and the sediment was loaded with red cells and pus. *Staphylococcus aureus* was recovered on culture. The nonprotein nitrogen was 34 mg per 100 cc. An intravenous pyelogram showed good kidney function, a smooth bladder outline and some dilatation of the lower end of the left ureter. Following treatment with sulfathiazole the symptoms subsided, and the patient was discharged to continue sulfonamides at home.

Third admission (five years later) After two uneventful years the patient again began to have intermittent hematuria, either primary or total, occurring in widely spaced episodes lasting up to two days. There were also nocturia and slight dysuria. On admission the urine had a specific

gravity of 1.014 and gave a ++ test for albumin, the sediment contained many red and white cells, and yielded *Staph albus* on culture. Three grams of prostatic chips obtained by transurethral resection showed stromal hyperplasia. The bladder outlet was noted to be irregularly contracted at the time of operation, but no recurrence of tumor was seen.

Fourth admission (six weeks later) The patient was then well except for one bout of hematuria. The night before this admission he felt chilly, had left-flank pain, passed liquid and then clotted blood and went into acute retention. On admission the white-cell count was 14,000. The urine had a specific gravity of 1.012, gave a +++ test for albumin, was loaded with pus and yielded *Staph aureus* and *Staph albus* on culture. Intravenous pyelograms showed good function on the right, impaired excretion on the left, and dilatation of the lower left ureter. The patient responded to catheterization and sulfonamide therapy and was discharged improved after twelve days.

Fifth admission (one year later) After about six months there was still another recurrence of episodic hematuria every two or three weeks and the onset of hesitancy and a weak stream. On several occasions, clots in the bladder necessitated catheterization. On this admission the urine had a specific gravity of 1.016, gave a + test for albumin and contained *Staph albus* and many red cells. The temperature was normal, and the white-cell count 10,800. Following spontaneous passage of a large clot the urine cleared, and the patient was discharged.

Sixth admission (three months later) Following discharge there were two short episodes of hematuria. On the day before admission the urine became scanty and grossly bloody, with large clots. On physical examination the bladder was percussed half way to the umbilicus. The urine had a specific gravity of 1.022 and contained much albumin and red cells. Immediately following admission the temperature rose to 101°F and for the next week spiked to between 100 and 102°F daily. The white-cell count was 14,400. Two 500-cc whole-blood transfusions were given following hemoglobin determinations of 10.5 and 9.7 gm. The nonprotein nitrogen of 56 mg per 100 cc on admission rose steadily to a high of 135 mg and then subsided gradually to 84 mg on discharge. Fluoroscopy showed elevation of the left leaf of the diaphragm and some atelectasis of the left lower lobe of the lung. There was also aching left-flank pain. Cystoscopy demonstrated multiple small areas of hemorrhage in the bladder mucosa but no recurrence of the tumor. The right ureteral orifice was crescentic, and the left could not be visualized. The patient was maintained on intravenous feedings, penicillin and streptomycin. The urine

cleared, and output was good. The patient left improved after six weeks of hospitalization.

Final admission (one month later, about seven years since the first admission) The patient was then well for three weeks, when hematuria and passage of clots recurred. On admission the urine had a specific gravity of 1.012 and contained much albumin, red cells, pus and bacteria. The nonprotein nitrogen was 45 mg per 100 cc. The white-cell count was 7000, and the hemoglobin 9.2 gm, and the patient was given 500 cc of whole blood. The intravenous pyelogram showed good function of the right kidney, the cortex of which was noted to be thin. No excretion could be detected on the left.

On the ninth hospital day a bilateral ureterocutaneous anastomosis was done, following which the patient passed moderate amounts of urine from the right kidney and small amounts from the left. The nonprotein nitrogen began to climb, reaching 98 mg per 100 cc. There was onset of diarrhea, guaiac-positive stools were noted. The white-cell count began to rise, and the hemoglobin remained low. On the sixteenth hospital day the patient had a shaking chill and began vomiting. Urinary output declined markedly. Returns from bladder irrigation consisted of foul-smelling, semisolid material.

During the last week of the hospital stay, the temperature spiked to 103°F and then declined to normal. The patient died on the twenty-third hospital day.

DIFFERENTIAL DIAGNOSIS

DR GEORGE G SMITH* This patient's complaint on admission was three episodes of terminal hematuria. I want to speak of the significance of terminal hematuria. With initial hematuria in a man over fifty, within the prostatic age, the chances are that the blood is coming from the prostatic urethra, if it is terminal hematuria, it probably is from the bladder, whereas renal hematuria usually gives total discoloration of the urine.

Nothing is said here about a rectal examination or about the amount of residual urine.

The frequency and dysuria on the second admission might have been due to x-ray treatment if he had had enough to cause congestion of the bladder mucosa. The costovertebral-angle tenderness sounds as if he had an attack of acute pyelonephritis on the right side.

At the third admission we are again kept in the dark about what the prostate felt like and how much residuum the patient had, but it is evident that he had prostatic obstruction since a transurethral resection was performed.

About six years after the tumor of the bladder was treated, the bladder apparently was free of tumor. It would make the diagnosis easier if we

*Member Board of Consultation (formerly chief of Urology Service), Massachusetts General Hospital.

were told where the blood was coming from and if the patient was cystoscoped

Again, on the fourth admission, we have no information of the cause of the hematuria. Among other things, it might have come from the remnant of the prostate left behind at transurethral resection. It is not unusual to have episodes of hematuria occasionally, even for several years after transurethral resection.

A marked elevation of nonprotein nitrogen points definitely to bilateral renal involvement. At first sight it seems as if the cause of death in this patient would be easy to put one's finger on. I think he died chiefly from pyelonephritis.

He had had one previous attack of infection on the right side and now showed evidence of marked infection, with pain, elevation of the left leaf of the diaphragm and entire destruction of the function of the left kidney. I believe that probably was the result of implantation of the radium near the ureteral orifice. One can postulate swelling of the radium-affected tissue and infection traveling up the lymphatics of the ureter bringing about the combination of infection and obstruction, which led to pyelonephritis with a gradual destruction of the kidney on the affected side. There is nothing in the history to explain obstruction of the lower right ureter, and yet one of the late intravenous pyelograms showed that the right kidney had a thin cortex, this probably was the result of repeated attacks of pyelonephritis.

Let us look at one or two of the intravenous pyelograms.

DR JAMES J MCCORT. An intravenous pyelogram made on the first admission shows the kidneys to be within normal limits in size and shape, both are satisfactorily outlined. After intravenous administration Diodrast was excreted in good concentration within five minutes. The pelvis and calyces are not dilated. The films taken at fifteen minutes confirm this impression, but the film of the bladder at thirty minutes shows a slight irregularity on the left inferior margin of the bladder. A film of the bladder after evacuation again shows this slight irregularity.

DR SMITH. It is rather difficult to explain why the patient was not definitely improved by his skin ureterostomies. I do not know whether he had catheters put up to the kidneys or drainage without catheters, which we sometimes do. We can often clear up or alleviate the effects of marked pyelonephritis by adequate drainage of the kidney pelvis by means of nephrostomy, pyelostomy or ureterostomy. But in this case the drainage did not accomplish this. It makes me think that there was another factor involved besides obstruction of the lower ureter. The pyelonephritis may have been too far advanced to be relieved by drainage alone.

Another thing that ought to be explained is the repeated attacks of hematuria. In fact, this was really the chief item in the past history. At the sixth admission, cystoscopy showed multiple small areas of hemorrhage in the bladder mucosa. Whether the blood came down the left ureter and indicated a carcinoma of the left renal pelvis or ureter, I do not know, but it would explain the bleeding. No tumor was found in the bladder. However, the wall of a bladder that has been chronically inflamed for a long time will sometimes bleed so that one has to do a cystostomy. I remember 2 cases in which it was necessary to do a total cystectomy to stop bleeding.

An item that I think is important is that the tumor was classified as Grade III. That is significant and means that it was an unusually malignant tumor even though it did not recur in a period of seven years. It is perfectly possible, and I think probable, that the lesion extended from the largest tumor here into the bladder wall, which may account for the fact that when the bladder was examined cystoscopically bleeding areas were seen in the bladder mucosa.

The picture that Dr McCort showed us is suggestive of a mass behind the bladder and more or less around the bladder neck. The dilatation of the right kidney, which was due, perhaps, to pyelonephritis, may also have been due to obstruction of the lower end of the ureter by a malignant lesion involving the bladder wall or coming up behind the bladder. The elevation of the left leaf of the diaphragm and the aching pain around the left kidney may indicate perinephritic abscess secondary to the severe left renal infection. I believe that if this man had been cured of his cancer the first time it was treated, as he appeared to be, and even if his left kidney had been destroyed by the effect of radium at the lower end of the ureter or from some other reason, the right kidney would have carried on adequately. But the right kidney evidently was seriously damaged. Later on, after a number of years, if this patient did have carcinoma that extended into the bladder wall and around the base of the bladder, it is more than likely that he had metastases to the aortic lymph nodes, and possibly in the lung—a disseminated carcinomatosis. My impression is that death was primarily due to pyelonephritis, but he probably had extensive carcinoma and certainly obstruction to the lower ureters.

DR FLETCHER H COLBY. This patient is very interesting from certain points of view. It is not quite clear in the protocol that he had a great deal of external radiation. He was one of the early patients given external radiation on the 1200-kilovolt machine at the Huntington Memorial Hospital. In addition he had a large amount of interstitial radiation in the bladder tumor. This man, as I remember, had about 12,000r of external radiation at

the time, or soon after the radium was implanted, so that he was given an unusual dose of both external and internal radiation. I do not think Dr Smith appreciated the fact that he had had so much radiation to his bladder, that might have made a difference in the way he thought about the bleeding.

DR SMITH Yes.

DR COLBY The patient was followed carefully in the seven or eight years after the initial tumor was treated in this way. I may add also that when he was first seen a sufficient amount of induration was felt on bimanual examination so that it was believed that this tumor probably involved the whole thickness of the bladder wall. It was subsequently shown that that was not true. At any rate, the patient was cystoscoped on many occasions following that, and at no time was the slightest evidence of recurrence of the primary bladder neoplasm seen. He had a sufficient amount of difficulty in voiding so that a transurethral resection was done on the prostate. I think the difficulty was due to contraction of the bladder neck rather than real prostatic hypertrophy. At no time did the prostate feel very large, and the bleeding subsequently was definitely not from the area of resection. It was a diffuse bleeding from all over the bladder, and at no time, even when he was actively bleeding, was any blood seen by cystoscope coming from either one of the ureteral orifices. It was again perfectly obvious on clinical examination that this man had progressive fibrosis of the bladder involving both ureteral orifices, more on the left, which had radium planted nearby, than on the right, but both orifices were involved in disease.

DR McCORT Did you specify the tumor dose as 12,000 r?

DR COLBY That was the dose measured in air.

DR McCORT The actual tumor dose was therefore about 6000 or 7000 r.

DR COLBY The external radiation was so extensive that this man was practically incontinent of urine for months.

DR SMITH I think it is worth saying that I have seen some patients who have been treated with extensive radiation, both internal and external, and after some years the ureters became fibrosed into a spindle-shaped canal, which gradually became obstructed. They usually go on all right after that. I suppose that happened to this patient's ureters. I think it would have made a little difference in my consideration of the case if I had realized that he had had more than the conventional dosage of x-ray because that would have explained the ureteral obstruction.

CLINICAL DIAGNOSES

Carcinoma of bladder
Radiation fibrosis of bladder
Uremia

DR SMITH'S DIAGNOSES

Pyelonephritis, bilateral
Obstruction of lower ureters by tumor

ANATOMICAL DIAGNOSES

(Carcinoma of bladder cured by radiation)
Radiation fibrosis of bladder and ureters
Papillary carcinoma, Grade III, left renal pelvis
Pyelonephritis, acute and chronic, bilateral
Pelvic abscess, small

PATHOLOGICAL DISCUSSION

DR TRACY B MALLORY At post-mortem examination we found no evidence of metastatic or recurrent tumor in the bladder. The bladder wall was fibrotic. Both ureters were bound in a heavy mass of scarred tissue, and it was very difficult to trace the right one more than about 3 cm from the ureteral orifice. The left ureter ended in an abscess cavity, 3 cm in diameter. The surprise of the autopsy was that a large part of the left kidney was replaced with tumor. It was a papillary carcinoma of the renal pelvis, filling the pelvis and extensively invading the renal tissue. The remainder of that kidney was virtually destroyed by pyelonephritis. The right kidney was free from tumor but showed almost as extensive infection. We could find no evidence that the bladder tumor had extended or recurred, and I believe that this tumor of the renal pelvis was an entirely independent separate tumor.

DR SMITH That did not show in the early intravenous pyelograms.

DR COLBY I do not believe that the tumor of the left kidney was an essential factor in the production of symptoms. The essential feature was the fact that here was a man whose bladder cancer was definitely cured by radiation. But it is the exception, and, not to mince words, the cure was as lethal as his original disease. We had always believed in treating these patients with cancer by external radiation that it was an agent to be used cautiously not with the idea that it would be curative, simply palliative. Although this patient was cured of the cancer, we wonder if the effects of radiation resulted in his death.

CASE 35512

PRESENTATION OF CASE

A sixty-two-year-old man entered the hospital for study.

About six years before admission, the patient began having recurrent attacks of five to ten minutes' duration in which there were involuntary jerking movements on the right, beginning in the face and spreading to the right arm and then to the leg. The patient was unable to speak during the attacks but did not lose consciousness between

attacks he felt entirely well. However, as time went on, the attacks slowly increased in frequency. Two years before admission, he entered a community hospital, where no abnormalities were found on examination. He was discharged on anticonvulsive medication, which he took irregularly. About six months before admission, the patient began to be confused. Two months before admission his wife noticed that he tended to drag the right leg slightly in walking. The seizures meanwhile became progressively more frequent, occurring two or three times a day in the two months before admission. There was no change in the character of these attacks. Throughout the illness, the patient had no headaches and had not felt ill. About a month before admission, he re-entered the same community hospital. His general physical condition was good, and there were no abnormalities on routine physical examination. Neurologic examination disclosed impaired ability to understand commands, recent poor memory and confusion as to the chronology of his life and his illness, although he was oriented as to date and place. He was able to read, write and name objects. The right fundus was normal except for moderate arteriosclerosis, the left fundus could not be seen because of cataract. Visual acuity was normal in the right eye. Confrontation fields were full. The right pupil was slightly larger than the left, both reacted normally to light and on convergence. Ocular movements were normal. There was slight right lower facial weakness on both volitional and emotional movement. The other cranial nerves were intact. There was falling away of the right arm and leg when outstretched, and on walking the right leg moved stiffly and over a smaller range than the left. The tendon reflexes were more active on the right, the plantar reflexes were normal. There were no sensory changes, although the patient was not sufficiently co-operative for refined testing.

X-ray films of the skull were normal. The spinal-fluid pressure was equivalent to 130 mm. of water, with no cells, and the protein was 44 mg. per 100 cc. The Wassermann reaction was negative. An electroencephalogram showed a "definite slow-wave focus" in the left posterior frontoparietal region. Admission to the Massachusetts General Hospital for further study was recommended.

On physical examination the findings were essentially as before. At this time, however, he was

disoriented in time and place. He tended to perseverate on commands. The right pupil measured 3 mm. and the left 2.5 mm. Right lower facial weakness and the falling away of the outstretched right arm and leg were again observed. The tendon reflexes were slightly more active on the right, the abdominal reflexes present and equal, and the plantar reflexes fewer. There was some loss of position sense.

FIGURE 1. *Pneumoencephalogram. Arrows point to abnormal operation of the bodies of the lateral ventricles (note the slight ventricular shift to the right).*

in the toes, more on the right. The general physical examination again was negative.

The routine laboratory studies were negative. Arteriography showed a normal vascular pattern. Pneumoencephalography revealed some shift downward of the left lateral ventricle and displacement of the third ventricle to the right (Fig. 1 and 2).

On the fifteenth hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. JAMES B. AYER* This sixty-two-year-old man gave a consecutive history over a period of six years of Jacksonian epilepsy on the right side, increasing in frequency to two or three times daily and presumably not influenced by medication.

*Member Board of Consultation (formerly chief of Neurology Service) Massachusetts General Hospital.

For six months he had been confused in thought, and latterly had shown memory loss, difficulty in comprehension, disorientation and perseveration. No note is made of motor aphasia or of agnosia. Recently, there was evidence of right hemiparesis, as shown by lagging of the right side of the face, drifting of the hand (not due to sensory loss) and stiffness of the leg, with active tendon reflexes of this side. So far the evidence indicates a progressive lesion involving the left frontal lobe, invading or

lateral ventricles. There is an abnormal separation between the superior portions of the bodies of the lateral ventricles. The inner surface of the left lateral ventricle in the region of the separation is concave. There is a definite shift of the ventricle systems to the right side. The third ventricle is displaced only slightly to the right. The lateral films (Fig. 2) corroborate essentially what has been said about the anteroposterior view, and show an indentation superiorly upon the bodies of the lateral ventricles. The arteriograms were not very helpful in this case. There was no obvious midline shift of the cerebral vessels, and I cannot be sure of a localized deformity.

DR. AYER: On seeing these films I think it is fair to say that the changes in the encephalogram could not have been brought about by any lesion except an expanding one. Although the exact location is not too evident, there is some evidence that the lesion separated the ventricles and further evidence that there was a dislocation to the right and that the ventricle on the affected side was smaller, at least in the anteroposterior view. We must now admit that, in spite of absence of symptoms of increased intracranial pressure, we have definite evidence of an expanding lesion involving the frontal and parietal regions. Against its origin in the parietal area, suggested by early Jacksonian seizures, is the tardy advent of paralysis. Against its origin at the brain base is absence of signs of pressure on optic nerves or visual pathways.

That brings us to the pathologic possibilities. The commonest causes of tumor with a focus in the frontal lobe or frontoparietal region are two: a slowly growing glioma (I think we would have to say six years is fairly long) and meningioma. Of the meningioma group about half probably arise from the sphenoidal ridge and therefore cause early symptoms referable to the base of the brain. Meningiomas may arise from the region of the falx and grow down, displacing the brain on one side or both sides, which is perhaps indicated a little by this widening of the lateral ventricle although it was not mentioned in the protocol. One of these two tumors would be by far the most likely cause of an expanding lesion in this region.

Of the other possibilities that have to be considered, we may exclude embolism, thrombosis and hemorrhage, even when encapsulated, and also subdural hematoma, always a bugbear to the neurologist.

FIGURE 2. *Pneumoencephalogram. Arrow points to pressure defect on the lateral ventricles.*

compressing the motor strip. The electroencephalogram corroborates this.

Although there was no headache, no choked disk and a normal spinal-fluid pressure, the shift of the left lateral ventricle and third ventricle proves that the lesion was an expanding one. In slowly growing tumors of the frontal lobe especially, we not infrequently fail to have the clinical evidence of pressure.

May I see the x-ray films? I hate to let a single laboratory procedure influence me too much, but with a pneumoencephalogram as definite as this, we must pay heed to it.

DR. JOSEPH HANELIN: I do not believe the encephalograms have been fully described. This is an anteroposterior film (Fig. 1), showing air within the anterior portions of the bodies of the

ogist or the neurosurgeon, for these could hardly have led to such long-standing progressive symptoms

An abscess could have grown like a tumor. We have no history of underlying infection. We have no evidence for septic embolism and no sinus infection is recorded. Fever is not necessary but cells in the spinal fluid are characteristically found in abscess, nor is abscess likely to give this continuous picture.

I suppose we ought to mention a few rare things because if I make a diagnosis of something common I am often wrong at these clinics. Gumma should be considered, although it is usually close to the surface, yet it can grow inward. The serologic reaction may or may not be positive, none is given here. I should put a gumma very far down the list. Cysticercus in the frontal lobe occurs but is a surprise finding in this part of the world. Hemangioma must be considered as a possibility, but seemingly it is ruled out or made most unlikely by the angiogram which should show large and abnormal blood channels.

I am forced to say, therefore, that my choice rests between one of the two common glial tumors — probably astrocytoma which is more slowly growing than glioblastoma — and meningioma. If this was a glioma it must have grown from an intracerebral location and extended toward the vertex to separate the ventricles, it probably extended into the corpus callosum to explain some of the mental symptoms. If it was meningioma it should have originated in the meninges over the vertex and grown downward or taken origin from the falx.

The operation was probably a bone flap to remove tumor if possible, but the tumor should have been a large one, and probably not removable in toto.

DR J. C. WHITE: I am sorry that Dr. Ballantine is not here, he was the surgeon who operated. There are a few points that I would like to bring out. We thought, as Dr. Ayer pointed out, that the long history meant that this probably was an expanding tumor. Tumors, if they grow slowly enough, may become large without raising intracranial pressure. If this were an astrocytoma, we believed the chances of helping him were rather remote. If it were a meningioma, operation had a good chance of helping the seizure greatly. The astrocytomas have not responded well to operative intervention as far as seizures are concerned.

If subject to seizures, over half the patients with meningiomas are relieved of them following removal of the tumor. We discussed the problem with the family, and in view of the desperate condition they said that we should take any chance. That is why operation was done. Dr. Ballantine operated, and Dr. Bidwell assisted him.

CLINICAL DIAGNOSIS

Brain tumor ? astrocytoma, ? meningioma

DR. AYER'S DIAGNOSIS

Brain tumor left frontal, probably glioma, possibly meningioma

ANATOMICAL DIAGNOSIS

Glioblastoma multiforme of corpus callosum probably arising from astrocytoma

PATHOLOGICAL DISCUSSION

DR. ROBINSON L. BIDWELL, II: We did a bone flap on the left side, crossing the midline slightly to the right. Upon the reflexion of the dura, tumor in the left precentral region next to the midline body was immediately evident, and that was biopsied for frozen section. While we were awaiting the report, the operation was continued. As we went down, tumor outcropping on the surface was evident almost all the way down to the corpus callosum. The tumor was soft and not sharply defined at the margins. Because it was an obvious glioma and could not be excised the operation was stopped. The report that came back to the operating room was glioma, probably astrocytoma. Post-operatively, the patient did poorly, developed pulmonary symptoms and died three days later.

DR. CHARLES S. KUBIK: At post-mortem examination there were indications of greatly elevated intracranial pressure consisting of flattening of the convolutions, and temporal and cerebellar pressure cones. Coronal section at the level of the mammillary bodies disclosed a pinkish-gray tumor of the corpus callosum of rather firm, rubbery consistence involving chiefly the left side, but extending across the midline to the other side, and this accounted for the spreading apart and flattening of the lateral ventricle visualized in the ventriculogram. The tumor extended for a considerable distance laterally into the white matter of the left hemisphere and also anteriorly and posteriorly.

(Fig 3) There was no line of demarcation between tumor and brain tissue. The gross appearance was fairly typical of astrocytoma. There were numerous hemorrhages in the midbrain, these are found in most cases of increased intracranial

FIGURE 3 *Gross Specimen*
Arrows point to gross limitations of tumor

pressure with large herniations of the temporal lobe through the tentorial notch.

Histologically, the tumor was interesting. Parts of it, composed of fairly well differentiated astrocytes, would ordinarily be classified as astrocytoma,

other parts were typical of glioblastoma multiforme. The history was much longer than is usually the case in glioblastoma multiforme, and I should suppose that this was a case in which an astrocytoma had recently undergone a change to a more malignant type of tumor. We have had two or three other examples of the same kind. In a case with a twelve-year history, an astrocytoma of the cerebellum was found at operation. There was rapid recurrence of symptoms, and a second operation disclosed glioblastoma multiforme. We have had a number of cases of glioma of the corpus callosum. They have usually been associated with convulsive seizures, not infrequently Jacksonian in type, presumably because the tumor involved one hemisphere more than the other, as in this case. Another symptom, not invariably present, has been impairment of memory and confusion, one patient, however, a young man attending the Harvard Business School a good many years ago, made a very good showing in a stiff examination just before entering the hospital. In that case there was a glioblastoma multiforme of the corpus callosum much larger than this.

DR STANLEY COBB: How do you explain the original low spinal-fluid pressure?

DR KUBIK: The tumor was situated anteriorly and may have been slowly growing, and there were probably factors that we do not know about. One may also ask in a case like this whether the reading obtained at lumbar puncture represented the true pressure.

NOBEL PRIZE IN MEDICINE

THE Nobel Prize for 1949 in medicine has been awarded jointly to two scientists, both investigating the function of the brain. Dr. Egas Moniz, a former professor of neurology in the University of Lisbon, developed cerebral angiography and made the procedure one of practical value in the diagnosis of brain tumor and blood-vessel abnormalities, and in addition devised the revolutionary brain operation of prefrontal leukotomy, later known as lobotomy, now widely used in the treatment of certain forms of mental disease. Dr. W. R. Hess, director of the Physiological Institute of Zurich University, has shown by animal experimentation the regulatory effect of the brain stem, through its peripheral projections by way of the autonomic nervous system, on such bodily processes as circulation, respiration, digestion, muscular action and psychic response. In the field of mental activity,

Hess was able to produce artificial sleep by electrical stimulation of the diencephalon, thus indicating that some psychic processes, at least, are under brain-stem control and not entirely dominated, as previously postulated, by the cerebral cortex. Although the work of Hess is less spectacular than that of Moniz, with less immediate clinical application, the research emanating from the Zurich laboratory has greatly affected the physiologic and psychiatric thinking throughout the world.

The revolutionary contribution of Moniz was announced quietly to an unsuspecting world. Lisbon was not a "center of research," such as London, Paris, Stockholm or one of a dozen other cities in Europe, where advances were being made constantly and the news quickly spread by students and visiting colleagues. Few scholars from other laboratories went to Lisbon for advanced studies, and before 1927 the name of a modest neurologist, Moniz, was virtually unknown outside his own city. So small was his audience in Portugal that he decided to present his initial paper in Paris. He journeyed to that city in the summer of 1927 and, before the Société de Neurologie on July 7, he gave his first account of cerebral angiography, showing roentgenograms of the cerebral vessels, outlined with sodium iodide, from cadavers, dogs and from a living man with a pituitary tumor.¹ The audience was astounded by the beauty of the plates and the skill of the operator in obtaining them almost instantaneously after intracarotid injection. Babinski and others, who heard Moniz's striking report, pronounced the pictures remarkable. Moniz was soon deluged with requests for information on the technic of cerebral angiography, and he responded with a second paper, outlining his experiences, which soon led to the adoption of the method in all neurosurgical and roentgenographic centers.² So carefully made were Moniz's preliminary experiments that the method devised by him prior to 1927 remains unchanged today, except for modification in the contrast mediums and the injection of the artery without previous dissection. Moniz, however, went into an even more important field than cerebral angiography and in less than a decade was able to announce his radical operation, severing the frontal lobes from the rest of the

brain, by cutting the pathways between them. Again, he went to Paris to report the results in the first 20 cases before the Académie de Médecine, on March 3, 1936.³ The idea had occurred to him about 1934, but he was encouraged to go through with the operation after a meeting of the Second International Neurological Congress, held in London in the summer of 1935. There reports were presented regarding the behavior of patients who had undergone total removal of the frontal lobes and of animals subjected to similar experimental investigations. Some of the concepts developed at this Congress, particularly those based upon the animal experiments reported from America, so impressed Moniz that, on returning to Lisbon, he devised a method of cutting the connecting pathways between the frontal lobes and the rest of the brain and had the operation carried out by his surgical colleague, Almeida Lima, as early as November 12, 1935. In less than four months, 20 case records were ready for the Paris report. In the last thirteen years, since his report in 1936, thousands of such operations, now modified into various patterns, have been carried out in many parts of the world, greatly to the betterment of patients with the more serious and prolonged types of mental aberration. A new psychiatry may be said to have been born in 1935, when Moniz took his first bold step in the field of psychosurgery.

Hess, on the other hand, has worked steadily in his physiologic laboratory, for more than twenty years, developing animal experiments on the functional organization of the diencephalic nuclei, with the particular aim of elucidating the complex functions of the autonomic nervous system, the coordinator that ensures the harmonious interplay of all vegetative organs.⁴ Taking into consideration the analyses that had accumulated throughout the years, as well as his own work on circulation and respiration, Hess⁵ attempted a resynthesis based on a view of the body organs as a system of efficiently co-ordinated functions. Of the two divisions of the autonomic system, the sympathetic section he believes plays a decisive part in preparing the subject for activity, whereas the parasympathetic system affects economy and repair. Both may exert their characteristic influences in the

psychic field, as well as on the soma. In his studies on artificial disturbance of the equilibrium between the central influences of the sympathetic and parasympathetic systems, he found a method of dampening the sympathetic control, without interfering with the activity of the parasympathetic centers. The stimulus, instead of preparing the animal for activity, induced artificial sleep, thus allowing for the possibility of better economy and repair through release of the parasympathetic forces.⁶

To psychiatry, this indication, on a sound experimental basis, that somatic influence might play a role in psychic function, gave impetus to a broadening viewpoint of cerebral action. Hess made a fundamental contribution in developing the idea that sleep was a vegetative process by which the autonomic nervous system regulated the activity of the higher cerebral functions. For this, and the rest of his great pioneering work on the physiology of the diencephalon, he, too, earned a right to the Nobel Prize.

LET'S TALK IT OVER

BASIC agreement among professional groups on many points in the over-all problem of the nation's health has been overshadowed by controversies based on differences of opinion over certain aspects of the problem. There is real hope that give-and-take discussion across a table could rather promptly determine areas of agreement and clarify disagreements on current issues of health and medical care. The National Health Assembly in May, 1948, and the Massachusetts Health Conference in 1949 illustrate the possibilities of tangible accomplishment.

Therefore, the recent announcement of the formation of the Inter-Association Committee on Health is ground for real optimism. Participating organizations are the American Dental Association,

the American Hospital Association, the American Medical Association, the American Nursing Association, the American Public Health Association and the American Public Welfare Association, all with membership including professional workers in the health field. Each organization has as voting members three of its officers or others who carry important policy-making responsibilities. The stated objectives are to "study and discuss various phases of health care in the interest of improving the health of the nation" and to "serve as a means for the exchange of information on the programs and interests of the participating organizations to the end, that, in so far as possible, a common understanding may be reached toward the solution of health problems of mutual interest."

The principles upon which the Committee will operate are now being passed upon by the parent associations, and there is every reason to expect complete and prompt approval.

Not even the executive secretaries of these professional organizations have met together previously to discuss mutual problems. One wonders why something of this sort was not undertaken long ago. As soon as the professionals have learned to work together effectively, there will be great value in bringing in representatives of the public to give the consumer point of view. Advice from the combined group would be invaluable to Congress and other bodies now struggling to find the right answers to the nation's health problems.

THE SOUTHARD CLINIC

IN THE annals of few of the diseases of man are early diagnosis and treatment more imperative than they are in the realm of mental disorders, for in few is the possible penalty of delay more disastrous. It is for the general purposes of prevention and of early diagnosis and treatment that the federal grants outlined on a succeeding page of the *Journal* were awarded, it was for the purposes of early diagnosis and treatment that the Boston Psychopathic Hospital was created and has met with such success.

Since many of the patients who came early to the Psychopathic Hospital for diagnosis and treat-

ment were found not to require hospitalization, the outpatient department, now operating as the Southard Clinic, was established and has steadily increased its activities. Like many worthy and successful agencies, however, the Southard Clinic has found its usefulness so great that it is outgrowing its resources.

Its needs have consequently been made the subject of study by a committee of the trustees of the Hospital, and a report has been submitted that was unanimously approved by the whole board in July. The needs of the Clinic, according to this report, are not ones that should be met by still greater private benefaction as has been the case in the past. The Clinic's achievements have been instrumental in saving the Commonwealth great sums of money that would have been expended on custodial care, the Commonwealth itself is now confronted with the plain duty not only of supporting the Clinic as it at present functions but of providing for its expanded activities.

HEALTH LEAGUE PASSES

ON November 21, 1949, the Boston Health League, Incorporated, passed out of mortal being. This unusual organization, originally incorporated on June 15, 1922, has had a unique and extraordinarily useful existence. Made up of practically all the social organizations that have contributed to the preservation of health and the treatment of sickness in the city of Boston, its functions for these years have been to study the problems that have arisen, to help in their solution, and to coordinate the activities of the various groups that have composed it.

It is not because its functions are finished, however, that the Health League has shaken off its corporate bonds and passed beyond the veil. Rather is it that it might emerge, after this ordeal of dissolution, into fields of still greater usefulness as the Health Council of United Community Services. With a stream-lined program the former Health League, too, is off on the new course with the rest of the stream-lined organizations of Greater Boston.

At Pittsfield, Massachusetts, a medical student shot at a man with a revolver, with whom he had a dispute. He was immediately arrested, but liberated on bail, and then soon disappeared.

Boston M & S J, December 19, 1849

MASSACHUSETTS MEDICAL SOCIETY

COMMITTEE ON MENTAL HEALTH

The Committee on Mental Health, as part of its report to the Council next February, has included a statement on the use of federal funds for mental health in Massachusetts for the fiscal year July 1, 1949, to June 30, 1950. The sum of \$100,300 is the grant made to the Commonwealth for the current year, to be administered through the Department of Mental Health with the assistance of an Advisory Committee on Mental Hygiene and Community Activities.

The funds have been allocated as follows for training of personnel for work in mental health, \$26,140, for community mental health clinics, \$17,600, for the Catholic Boys Guidance Center of Boston, \$3750, for the Habit Clinic of Boston, \$8000, for the Child Psychiatric Clinic of Massachusetts Memorial Hospitals, \$5474, for the new community clinic in Dedham, operated in connection with the Dedham Visiting Nurse Association, \$2340, for the Massachusetts Society for Mental Hygiene, \$5000, for the Beth Israel Hospital, \$3000, for the Salem and Newton public schools, \$5000, for the Boston Floating Hospital, \$3000, and for the Massachusetts Postgraduate Training Program in Psychiatry, \$21,000.

In recognition of the short supply of psychiatrists, the last-named program has been developed as a new and special project to increase the number of psychiatrists who can be trained in the Boston area. It consists of a co-operative arrangement between teaching institutions and mental hospitals within the Commonwealth, providing for an educational director to supervise and co-ordinate the training activities and insure maximal use of facilities.

DEATHS

GOFF — Almon P. Goff, M.D., formerly of Hyannis, Massachusetts, died recently. He was in his seventy-seventh year.

Dr. Goff received his degree from University of Buffalo School of Medicine in 1897. He was formerly health officer of Barnstable County and was a fellow of the American Medical Association.

A son, a daughter and two grandsons survive.

HAWES — Alfred T. Hawes, M.D., of Lynn, died on December 2. He was in his seventy-sixth year.

Dr. Hawes received his degree from University of Vermont College of Medicine in 1901. He was an honorary member of the staff of Lynn Hospital.

A daughter, a son and two brothers survive.

MCCARTHY — Eugene A. McCarthy, M.D., of Fall River, died on December 1. He was in his sixty-ninth year.

Dr. McCarthy received his degree from Harvard Medical School in 1908. He was a fellow of the American Academy of Orthopaedic Surgeons, American College of Surgeons and American Medical Association.

His widow survives.

PHIPPS — Cadis Phipps, M.D., of Brookline, died on December 5. He was in his sixty-ninth year.

Dr. Phipps received his degree from Harvard Medical School in 1907. He was professor of medicine and head of the Department of Medicine at Tufts College Medical School and was formerly physician-in-chief of the Third Medical Service and director of the First and Third Medical Services at Boston City Hospital. He was a fellow of the American Medical Association.

His widow and a daughter survive.

WILLIAMS — Edward D. Williams, M.D., of Easthampton, died on June 25. He was in his eighty-first year.

Dr. Williams received his degree from Harvard Medical School in 1894. He was a member of the staff of the Cooley Dickinson Hospital, Northampton.

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

CONSULTATION CLINICS FOR CRIPPLED CHILDREN IN MASSACHUSETTS

The January schedule for Consultation Clinics for Crippled Children in Massachusetts under the provisions of the Social Security Act follows:

ORTHOPEDIC CLINICS	DATE	CLINIC CONSULTANT
Haverhill	January 4	William T. Green
Greenfield	January 5	Charles L. Sturdevant
Lowell	January 6	Albert H. Brewster
Salem	January 9	Paul W. Hugenberger
Gardner	January 10	Carter R. Rowe
Brockton	January 11	George W. Van Gorder
Springfield	January 17	Garry deN. Hough, Jr.
Pittsfield	January 18	Frank A. Slawick
Worcester	January 20	John W. O'Meara
Fall River	January 23	David S. Grice
Hyannis	January 26	Paul L. Norton

RHEUMATIC FEVER CLINICS	DATES
North Reading	January 3, 10, 17, 24, 31
Fitchburg	January 4, 11, 18, 25

Physicians referring new patients to clinics should get in touch with the district health officer to make appointments. Patients are seen by appointment only.

MISCELLANY

ARMY INTERNSHIP APPOINTMENTS

One hundred and ninety senior medical students have been appointed to Army internships beginning July 1, 1950, representing the Army's selections out of the 1014 candidates who applied for both Army and Air Force internships. Sixty-four of the 71 approved medical schools in the country are represented in the group of students selected, 96 per cent of whom are former servicemen. Upon graduation from

medical school each of them will be commissioned a first lieutenant in the Army Medical Corps Reserve called to extended active duty and assigned for internship to one of the ten Army General Hospitals that are approved for intern training: Brooke General Hospital San Antonio Texas Fitzsimons General Hospital Denver Colorado Gorgas Hospital Ancon Canal Zone Letterman General Hospital San Francisco California Madigan General Hospital Tacoma Washington Oliver General Hospital Augusta Georgia Percy Jones General Hospital Battle Creek Michigan Tripler General Hospital Honolulu Hawaii Valler Forge General Hospital Phoenixville Pennsylvania and Walter Reed General Hospital Washington, D. C.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Report of a Six-Months Nationwide Study of Public Knowledge about and Attitudes Toward Medical Science. By the National Opinion Research Center on a grant from the Rockefeller Foundation. 4^o, paper 25 pp. Chicago: National Society for Medical Research, 1949.

This pamphlet embodies an abbreviated report of a six-month nationwide survey of public knowledge about and attitudes toward animal experimentation.

Neuroradiology. By Alexander Orlev, M.D., F.F.R., D.M.R. &E., hon. consulting radiologist, West End Hospital for Nervous Diseases, London. 4^o, cloth, 421 pp. with 572 illustrations. Springfield, Illinois: Charles C. Thomas, 1949. \$11.50.

The author of this atlas published, in collaboration with Dr. Wakeley in 1938, a *Textbook of Neuroradiology*. Dr. Orlev states that except for the general layout, the present book has little in common with the original publication. The material covers the head, brain, spinal cord and neuropathic disturbances and is well arranged and well written. The text is concluded with a bibliography of twenty-eight pages arranged by subjects. There are good author and subject indexes. It is pleasing to note that although the book is by a British author, the printing was done in the United States and not imported. The book is recommended for all medical libraries and to all neurologists.

Care of the Surgical Patient, Including Pathologic Physiology and Principles of Diagnosis and Treatment. By Jacob Fine, M.D., surgeon-in-chief, Beth Israel Hospital, and professor of surgery at Beth Israel Hospital and Harvard Medical School. 8^o, cloth, 544 pp., with 40 illustrations and 9 tables. Philadelphia: W. B. Saunders Company, 1949. \$8.00.

This book is intended to serve the special purpose of providing a ready guide for the over-all care of the surgical patient. Dr. Fine has been aided by twenty-two specialists in the compilation of the text. The material is divided into six main divisions: general considerations, regional and special surgery, endocrine diseases and hormone therapy, coincidental medical illnesses in surgical patients, clinical and laboratory methodology, and general preoperative and postoperative care. There is a good index. The type and printing are excellent, but the use of a heavy coated paper is not justified by the few illustrations.

Coronary Artery Disease. By Ernst P. Boas, M.D., associate physician, Mt. Sinai Hospital, New York City, and Norman F. Boas, M.D. 8^o, cloth, 399 pp., with 88 illustrations. Chicago: Year Book Publishers, Incorporated, 1949. \$6.00.

This manual is one of the *General Practice Manuals*, designed for the practicing physician. The subject is well covered from the anatomy and physiology of the coronary vessels to treatment. The text is well arranged and well written.

There is a good index, and the publishing is excellent. The book should prove valuable as a ready reference source to the general practitioner. The series should be in all medical libraries.

Posttraumatic Epilepsy. By A. Earl Walker, M.D., professor of neurologic surgery, Johns Hopkins University School of Medicine, Baltimore. 8^o, cloth, 86 pp., with 20 illustrations and 6 tables. Springfield, Illinois: Charles C. Thomas, 1949. \$2.75. (*American Lecture Series*).

This monograph No. 20 in the *American Lecture Series*, discusses the condition thoroughly from pathogenesis to medical and surgical treatment. There is a bibliography of eighty titles and a good index. All the monographs are excellent, and the series should be in all medical libraries.

Care of the Infant and Child with Congenital Heart Disease: A Clinical and Physiological Study of Infants and Children. By André Courmand, M.D., associate professor, Department of Medicine, College of Physicians and Surgeons, Columbia University; Janet S. Baldwin, M.D., assistant professor, Department of Pediatrics, New York University College of Medicine; and Aaron Himmelstein, M.D., instructor, Department of Surgery, College of Physicians and Surgeons, Columbia University. 4^o, cloth, 108 pp., with illustrations. New York: Commonwealth Fund, 1949. \$4.00.

This special atlas-type monograph is divided into two parts: the physiologic methods and illustrative cases with approximate hemodynamic data. Seventeen cases are discussed in detail and illustrated with diagrams, electrocardiograms, x-ray and fluoroscopic pictures and simple schematic drawings of the circulation. A bibliography is appended to the text. There is no index. The book should be in all collections on cardiology.

Fetal and Neonatal Death: A Survey of the Incidence, Etiology, and Anatomic Manifestations of the Conditions Producing Death of the Fetus in Utero and the Infant in the Early Days of Life. By Edith L. Potter, M.D., Ph.D., associate professor in the Department of Obstetrics and Gynecology, University of Chicago School of Medicine, and pathologist at The Chicago Lying-in Hospital and Fred L. Adair, M.D. 8^o, cloth, 175 pp., with 38 illustrations and 19 tables. Chicago: University of Chicago Press, 1949. \$5.75.

This second edition of a monograph first published in 1940 has been revised, the results of the most recent research being included. Material on the Rh factor, its influence on the fetus and newborn child, and on the effects of German measles on the fetus has been added. The charts and tables also have been revised and brought up to date. The publishing is excellent in every way. The monograph should be in all large medical-reference collections.

Human Embryology and Morphology. By Sir Arthur Keith. Sixth edition. 8^o, cloth, 690 pp., with 578 illustrations. Baltimore: Williams and Wilkins Company, 1948. \$10.00.

This standard book was first published in 1901 and has gone through six editions—good evidence of its soundness and authority. This edition has been thoroughly revised in the light of present-day knowledge of the subject. The notes and references to the various chapters have been amplified. There is a good index. The text is well printed with a good type on a light, soft, non-glare paper. The sheets were printed in Great Britain. The book should be in all medical libraries.

Neoplasms of Bone and Related Conditions: Their Etiology, Pathogenesis, Diagnosis and Treatment. By Bradley L. Coley, M.D., attending surgeon, Bone Tumor Department, Memorial Hospital for Cancer and Allied Diseases, and assistant professor of clinical surgery, Cornell University Medical College. 4^o, cloth, 765 pp., with 622 illustrations and 53 tables. New York: Paul B. Hoeber, Incorporated, 1949. \$17.50.

This large special treatise endeavors to present the current knowledge of not only true neoplasms of bone, both benign and malignant, but also the diverse group of conditions affecting the skeletal system, with which true bone tumors are often confused. The work is based on the author's experience.

of twenty-five years spent in the Bone Tumor Department of Memorial Hospital and on a survey of the literature. The text is divided into ten main sections and one miscellaneous section. The sections discuss, in order, classification, etiology and diagnosis, benign tumors and tumorlike lesions of bone, primary malignant tumors, tumors involving bone by extension, metastatic tumors involving bone, tumors of bone in special localities, surgical, radiation and constitutional therapy, and lesions of the skeletal system that may simulate neoplasms of bone. The last section discusses pathologic fracture, the medicolegal aspects of trauma in tumors of bone and the experimental production of bone sarcoma. Extensive bibliographies are appended to the various sections. There are indexes of personal names and subjects. The type, printing and illustrations are excellent. The price is not out of line for this type of book with so many expensive illustrations. The treatise should be in every medical library and available to all surgeons interested in bone tumors.

Current Therapy 1949. Latest approved methods of treatment for the practicing physician. Howard F. Conn, M.D., editor, 4° cloth, 672 pp. Philadelphia: W. B. Saunders Company, 1949. \$10.00.

In the fifteenth century the first medical books published were treatises on treatment, considered the most likely to sell. Today, if the physician can diagnose and treat successfully, he is on the way to fortune. This new book on therapy is the joint work of nearly 250 specialists, supervised by 12 consulting editors, specialists in different fields of medicine, who were responsible for obtaining contributors in their particular fields. The list of contributors looks like a "Who's Who in Medicine." The text is divided into fourteen sections, covering the whole field of medicine, including the diseases of the skin, obstetric and gynecologic conditions and diseases due to physical and chemical agents. In this book for the first time an attempt has been made to furnish the latest approved and currently used method of treatment of a particular condition. There are indexes of authors and subjects. The text is well printed in a two-column format, with a good type. The book should prove invaluable to the practicing physician and should be in all medical libraries.

Atlas of Peripheral Nerve Injuries. By William R. Lyons, Ph.D., associate professor of anatomy, University of California Medical School, and Barnes Woodhall, M.D., professor of neurosurgery, Duke University School of Medicine. F° cloth, 335 pp., with 135 plates. Philadelphia: W. B. Saunders Company, 1949. \$16.00.

This atlas is a beautiful book and should be in all medical libraries and available to all neurosurgeons. It should prove the standard work on the subject and should remain so for many years. The authors are well equipped by training and experience. Dr. Lyons is a neurohistologist, with a full appreciation of clinical values, and Dr. Woodhall is an experienced clinician with a sound training in neuropathology. They both had a large experience in neurosurgery in World War II, and the advantage of teaching of many years. It is interesting to note that the project was carried on without an elaborate budget, but with help and encouragement of many individuals and institutions, including the Army Institute of Pathology, without whose facilities the atlas could not have been completed. The material is well organized and divided into six chapters. The first section is an introduction and discusses methods of taking tissue and the clinical material used. The following parts deal with the peripheral nerve, its terminology and anatomy, completely severed nerves, traumatic nerve lesions in continuity, nerve sutures, and nerve grafts. A bibliography of 190 titles concludes the text. There is a good index. The text is sufficient only to introduce the parts and describe the plates. The plates are excellent, and the publisher is to be congratulated for producing a fine example of good bookmaking.

Your Child's Mind and Body. A practical guide for parents. By Flanders Dunbar, M.D., 8° cloth, 324 pp. New York: Random House, 1949. \$2.95.

This book constitutes a popular manual on child hygiene in all its aspects. The volume is concluded with a special table of references to the text, covering the emotional prob-

lems occurring between the ages of one month and seven years. The other subjects and older periods are listed in a comprehensive index. There also is a short bibliography for further reading. The book is well published and should prove useful to parents.

Skin Diseases in General Practice. By F. Ray Bettley, T.D., M.D., F.R.C.P., physician for diseases of the skin, Middlesex Hospital, London, and physician, St. John's Hospital for Diseases of the Skin, London. 8° cloth, 260 pp., with 96 illustrations. London: Eyre and Spottiswoode (Publishers) Ltd., 1949. 21s net. (*The Practitioner Handbooks*.)

In this manual the author has limited the number of skin diseases to thirteen of the most common. Eczema is considered in four chapters. There is an extensive appendix on patch testing. The text is well written, and the material well arranged. The type, printing and illustrations are excellent. There is a good index. The book should prove valuable to the general practitioner.

American Red Cross First aid textbook for juniors. 8° cloth, 132 pp. Philadelphia: Blakiston Company, 1949. \$1.00.

This manual, intended for junior-high-school pupils, was written by Dr. Carl J. Potthoff, national director of first aid and associate medical director of the American Red Cross. The text covers the whole field of recognized first aid and is well written. The type, printing and illustrations, drawn especially for teen-agers, are excellent. The volume should be in all public and school libraries.

Mycoses and Practical Mycology. A handbook for students and practitioners. By N. Gohar, M.R.C.S. (Eng.), L.R.C.P. (Lond.), assistant professor, parasitology and mycology, Department of Clinical Pathology, Kasr el Ainy Faculty of Medicine, Fouad I University, Cairo, Egypt. With a foreword by Sir Philip Manson-Bahr, C.M.G., D.S.O., M.A., M.D., D.T.M., & H. (Cantab.), F.R.C.P. (Lond.). 8° cloth, 234 pp., with 134 illustrations. Baltimore: Williams & Wilkins Company, 1948. \$6.00.

This manual is well written, and the material well arranged. The botany, physiology and classification of fungi are first discussed, followed by chapters on the mycoses in general, and on the various classes of mycotic diseases. Treatment is emphasized throughout the text. The last chapter is devoted to fungicides, fungistatics, prescriptions, mediums and poisonous fungi. There is a good index, and the publishing is excellent, including the illustrations. The printing was done in Great Britain. The price seems excessive. A similar volume, published in England, is priced at 21 shillings. However, the manual should prove a valuable addition to the subject.

How to Become a Doctor. A complete guide to the study of medicine, dentistry, pharmacy, veterinarian medicine, occupational therapy, chiropody and foot surgery, optometry, hospital administration, medical illustration, and the sciences. By George R. Moon, M.A., examiner and recorder, University of Illinois Colleges of Medicine, Dentistry and Pharmacy. 8° cloth, 131 pp. Philadelphia: Blakiston Company, 1949. \$2.00.

In this small volume the author provides the necessary information for the prospective student in medicine and its allied fields. The various chapters discuss the requirements for admission, selection of a school, the methods of admission, women and the study of medicine, success and failure and special problems, such as fees and expenses, and outline of the courses. There are special chapters on dentistry and pharmacy. Lists of accredited schools are included in these chapters. In the chapter on allied fields brief consideration is given to veterinary medicine, osteopathy, optometry, chiropody and foot surgery, nursing, medical illustration, occupational therapy and hospital administration. The text is concluded with a list of schools and colleges in all the fields. There is a good index. The book should be in all medical and public libraries.

GENERALIZED INTESTINAL POLYPOSIS AND MELANIN SPOTS OF THE ORAL MUCOSA, LIPS AND DIGITS (Concluded)*

A Syndrome of Diagnostic Significance

HAROLD JEGHERS, M.D.,† VICTOR A. MCKUSICK, M.D.,‡ AND KERMIT H. KATZ, M.D.§

WASHINGTON, D. C., BALTIMORE, MARYLAND, AND BOSTON, MASSACHUSETTS

DISCUSSION

Table 2 and 3 summarize data concerning our 10 proved cases of intestinal polyposis that manifested a distinctive variety of melanin spots of the oral mucosa, lips and digits.

The ages of these 10 patients ranged from nine to thirty-nine at the time of death or first study by us. In each case, however, symptomatology referable to the intestinal polyposis had been present before, usually beginning in the teens. The pa-

Seven of our 10 patients were females, Peutz^{7, 10} had 5 cases in males and 2 in females. The patient of Touraine and Couder^{17, 18} was a male. For those with the entire syndrome the sexes were equally distributed. The sex was given for 24 cases of the pigment part of the syndrome as 11 males and 13 females¹⁸. Apparently, then, the same sex distribution holds also for the patients with the pigment picture alone.

A rather wide ethnologic spread is evidenced by its occurrence in persons of American, French-

TABLE 2 Characteristics of the Pigmentation in Proved Cases of Polyposis

CASE No.	RELATIVE INTENSITY OF PIGMENT SPOTS					PIGMENTATION ELSEWHERE ON SKIN	COLOR OF HAIR	COLOR OF IRIS	AGE AT WHICH PIGMENTATION WAS FIRST NOTED
	MOUTH	LIPS	FINGERS	TOES	FACE				
1	+++	+++	++	+	++	0	Dark brown	Brown	Early childhood
2	+++	+++	++	+	+++	0	Black	Dark brown	Early childhood
3	+++	+++	++	+	+	0	?	?	?
4	+++	+++	+	+	+	0	Dark brown	Dark brown	Early in life
5	+++	+++	+	+	+	0	Dark brown	Dark brown	From infancy
6	+++	+++	++	0*	+	Light generalized negroid pigmentation	Black	Dark brown	From birth
7	++	++	++	+	+	0	Dark brown	Dark brown	From birth
8	++	++	++	0	+	0	Dark brown	Dark brown	From infancy
9	++	++	+	0	+	0	Dark brown	Dark brown	From infancy
10	++	++	+	0	0	0	Dark brown	Dark blue	From infancy

*Pigmentation present on sole of left foot.

tients of Peutz^{7, 10} and the one of Touraine and Couder^{17, 18} were in an age range similar to that in our series. Apparently, the type of intestinal polyposis present in this condition becomes clinically manifest early in life.

*From the Fifth and Sixth (Boston University) Medical Services, Boston City Hospital and the Department of Medicine, Boston University School of Medicine, the Medical Clinic, Johns Hopkins University and Hospital and the Department of Medicine, Georgetown University School of Medicine.

†Director and professor, Department of Medicine, Georgetown University School of Medicine, physician in chief, Georgetown University Hospital, consulting physician, Boston City Hospital.

‡Assistant in medicine, Johns Hopkins University School of Medicine.
§Assistant director, Fifth and Sixth (Boston University) Medical Services, Boston City Hospital, assistant professor of medicine, Boston University School of Medicine.

Italian, French, Welsh, Italian, Indo-European, Dutch and Negro family background. There are also suspected cases in English and German persons.

All our patients were of dark complexion as evidenced by brown, dark-brown or black hair and brown irides. Two had dark-blue irides. One was a lightly pigmented Negro boy. This type of complexion occurred also in the cases of Peutz^{7, 10} and Touraine and Couder,^{17, 18} as evidenced by either their statement or by the photographs they published.

The consistency of this in all subjects may be of significance, particularly since the pigmentary

of twenty-five years spent in the Bone Tumor Department of Memorial Hospital and on a survey of the literature. The text is divided into ten main sections and one miscellaneous section. The sections discuss, in order, classification, etiology and diagnosis, benign tumors and tumorlike lesions of bone, primary malignant tumors, tumors involving bone by extension, metastatic tumors involving bone, tumors of bone in special localities, surgical, radiation and constitutional therapy, and lesions of the skeletal system that may simulate neoplasms of bone. The last section discusses pathologic fracture, the medicolegal aspects of trauma in tumors of bone and the experimental production of bone sarcoma. Extensive bibliographies are appended to the various sections. There are indexes of personal names and subjects. The type, printing and illustrations are excellent. The price is not out of line for this type of book with so many expensive illustrations. The treatise should be in every medical library and available to all surgeons interested in bone tumors.

Current Therapy 1949. Latest approved methods of treatment for the practicing physician. Howard F. Conn, M.D., editor, 4th, cloth, 672 pp. Philadelphia: W. B. Saunders Company, 1949. \$10.00.

In the fifteenth century the first medical books published were treatises on treatment, considered the most likely to sell. Today, if the physician can diagnose and treat successfully, he is on the way to fortune. This new book on therapy is the joint work of nearly 250 specialists, supervised by 12 consulting editors, specialists in different fields of medicine, who were responsible for obtaining contributors in their particular fields. The list of contributors looks like a "Who's Who in Medicine." The text is divided into fourteen sections, covering the whole field of medicine, including the diseases of the skin, obstetric and gynecologic conditions and diseases due to physical and chemical agents. In this book for the first time an attempt has been made to furnish the latest approved and currently used method of treatment of a particular condition. There are indexes of authors and subjects. The text is well printed in a two-column format, with a good type. The book should prove invaluable to the practicing physician and should be in all medical libraries.

Atlas of Peripheral Nerve Injuries. By William R. Lyons, Ph.D., associate professor of anatomy, University of California Medical School, and Barnes Woodhall, M.D., professor of neurosurgery, Duke University School of Medicine. 8th, cloth, 335 pp., with 135 plates. Philadelphia: W. B. Saunders Company, 1949. \$16.00.

This atlas is a beautiful book and should be in all medical libraries and available to all neurosurgeons. It should prove the standard work on the subject and should remain so for many years. The authors are well equipped by training and experience. Dr. Lyons is a neurohistologist, with a full appreciation of clinical values, and Dr. Woodhall is an experienced clinician with a sound training in neuropathology. They both had a large experience in neurosurgery in World War II, and the advantage of teaching of many years. It is interesting to note that the project was carried on without an elaborate budget, but with help and encouragement of many individuals and institutions, including the Army Institute of Pathology, without whose facilities the atlas could not have been completed. The material is well organized and divided into six chapters. The first section is an introduction and discusses methods of taking tissue and the clinical material used. The following parts deal with the peripheral nerve, its terminology and anatomy, completely severed nerves, traumatic nerve lesions in continuity, nerve sutures, and nerve grafts. The plates are excellent, and the publisher is to be congratulated for producing a fine example of good bookmaking.

Your Child's Mind and Body. A practical guide for parents. By Flanders Dunbar, M.D., 8th, cloth, 324 pp. New York: Random House, 1949. \$2.95.

This book constitutes a popular manual on child hygiene in all its aspects. The volume is concluded with a special table of references to the text, covering the emotional prob-

lems occurring between the ages of one month and seven years. The other subjects and older periods are listed in a comprehensive index. There also is a short bibliography for further reading. The book is well published and should prove useful to parents.

Skin Diseases in General Practice. By F. Ray Bettley, T.D., M.D., F.R.C.P., physician for diseases of the skin, Middlesex Hospital, London, and physician, St. John's Hospital for Diseases of the Skin, London. 8th, cloth, 260 pp., with 96 illustrations. London: Eyre and Spottiswoode (Publishers) Ltd., 1949. 21s. net. (*The Practitioner Handbooks*).

In this manual the author has limited the number of skin diseases to thirteen of the most common. Eczema is considered in four chapters. There is an extensive appendix on patch testing. The text is well written, and the material well arranged. The type, printing and illustrations are excellent. There is a good index. The book should prove valuable to the general practitioner.

American Red Cross. First aid textbook for juniors. 8th, cloth, 132 pp. Philadelphia: Blakiston Company, 1949. \$1.00.

This manual, intended for junior-high-school pupils, was written by Dr. Carl J. Potthoff, national director of first aid and associate medical director of the American Red Cross. The text covers the whole field of recognized first aid and is well written. The type, printing and illustrations, drawn especially for teen-agers, are excellent. The volume should be in all public and school libraries.

Mycoses and Practical Mycology. A handbook for students and practitioners. By N. Gohar, M.R.C.S. (Eng.), L.R.C.P. (Lond.), assistant professor, parasitology and mycology, Department of Clinical Pathology, Kasr el Ainy Faculty of Medicine, Fouad I University, Cairo, Egypt. With a foreword by Sir Philip Manson-Bahr, C.M.G., D.S.O., M.A., M.D., D.T.M., & H. (Cantab.), F.R.C.P. (Lond.). 8th, cloth, 234 pp., with 134 illustrations. Baltimore: Williams & Wilkins Company, 1948. \$6.00.

This manual is well written, and the material well arranged. The botany, physiology and classification of fungi are first discussed, followed by chapters on the mycoses in general and on the various classes of mycotic diseases. Treatment is emphasized throughout the text. The last chapter is devoted to fungicides, fungistatics, prescriptions, mediums and poisonous fungi. There is a good index, and the publishing is excellent, including the illustrations. The printing was done in Great Britain. The price seems excessive. A similar volume, published in England, is priced at 21 shillings. However, the manual should prove a valuable addition to the subject.

How to Become a Doctor. A complete guide to the study of medicine, dentistry, pharmacy, veterinarian medicine, occupational therapy, chiropody and foot surgery, optometry, hospital administration, medical illustration, and the sciences. By George R. Moon, M.A., examiner and recorder, University of Illinois Colleges of Medicine, Dentistry and Pharmacy. 8th, cloth, 131 pp. Philadelphia: Blakiston Company, 1949. \$2.00.

In this small volume the author provides the necessary information for the prospective student in medicine and its allied fields. The various chapters discuss the requirements for admission, selection of a school, the methods of admission, women and the study of medicine, success and failure and special problems, such as fees and expenses, and outline of the courses. There are special chapters on dentistry and pharmacy. Lists of accredited schools are included in these chapters. In the chapter on allied fields brief consideration is given to veterinary medicine, osteopathy, optometry, chiropody and foot surgery, nursing, medical illustration, occupational therapy and hospital administration. The text is concluded with a list of schools and colleges in all the fields. There is a good index. The book should be in all medical and public libraries.

GENERALIZED INTESTINAL POLYPOSIS AND MELANIN SPOTS OF THE ORAL MUCOSA, LIPS AND DIGITS (Concluded)*

A Syndrome of Diagnostic Significance

HAROLD JEGHERS, M.D.,† VICTOR A. McKUSICK, M.D.,‡ AND KERMIT H. KATZ, M.D.§

WASHINGTON, D. C., BALTIMORE, MARYLAND, AND BOSTON, MASSACHUSETTS

DISCUSSION

Table 2 and 3 summarize data concerning our 10 proved cases of intestinal polyposis that manifested a distinctive variety of melanin spots of the oral mucosa, lips and digits.

The ages of these 10 patients ranged from nine to thirty-nine at the time of death or first study by us. In each case, however, symptomatology referable to the intestinal polyposis had been present before, usually beginning in the teens. The pa-

Seven of our 10 patients were females, Peutz^{7 10} had 5 cases in males and 2 in females. The patient of Touraine and Couder^{17 18} was a male. For those with the entire syndrome the sexes were equally distributed. The sex was given for 24 cases of the pigment part of the syndrome as 11 males and 13 females.¹⁵ Apparently, then, the same sex distribution holds also for the patients with the pigment picture alone.

A rather wide ethnologic spread is evidenced by its occurrence in persons of American, French-

tients of Peutz^{7 10} and the one of Touraine and Couder^{17 18} were in an age range similar to that in our series. Apparently, the type of intestinal polyposis present in this condition becomes clinically manifest early in life.

*From the Fifth and Sixth (Boston University) Medical Services, Boston City Hospital and the Department of Medicine, Boston University School of Medicine, the Medical Clinic, Johns Hopkins University and Hospital and the Department of Medicine, Georgetown University School of Medicine.

†Director and professor, Department of Medicine, Georgetown University School of Medicine, physician-in-chief, Georgetown University Hospital, consulting physician, Boston City Hospital.

‡Assistant in medicine, Johns Hopkins University School of Medicine.
§Assistant director, Fifth and Sixth (Boston University) Medical Services, Boston City Hospital, assistant professor of medicine, Boston University School of Medicine.

Italian, French, Welsh, Italian, Indo-European, Dutch and Negro family background. There are also suspected cases in English and German persons.

All our patients were of dark complexion as evidenced by brown, dark-brown or black hair and brown irides. Two had dark-blue irides. One was a lightly pigmented Negro boy. This type of complexion occurred also in the cases of Peutz^{7 10} and Touraine and Couder,^{17 18} as evidenced by either their statement or by the photographs they published.

The consistency of this in all subjects may be of significance, particularly since the pigmentary

of twenty-five years spent in the Bone Tumor Department of Memorial Hospital and on a survey of the literature. The text is divided into ten main sections and one miscellaneous section. The sections discuss, in order, classification, etiology and diagnosis, benign tumors and tumorlike lesions of bone, primary malignant tumors, tumors involving bone by extension, metastatic tumors involving bone, tumors of bone in special localities, surgical, radiation and constitutional therapy, and lesions of the skeletal system that may simulate neoplasms of bone. The last section discusses pathologic fracture, the medicolegal aspects of trauma in tumors of bone and the experimental production of bone sarcoma. Extensive bibliographies are appended to the various sections. There are indexes of personal names and subjects. The type, printing and illustrations are excellent. The price is not out of line for this type of book with so many expensive illustrations. The treatise should be in every medical library and available to all surgeons interested in bone tumors.

Current Therapy 1949. Latest approved methods of treatment for the practicing physician. Howard F. Conn, M.D., editor, 4th, cloth, 672 pp. Philadelphia: W. B. Saunders Company, 1949. \$10.00.

In the fifteenth century the first medical books published were treatises on treatment, considered the most likely to sell. Today, if the physician can diagnose and treat successfully, he is on the way to fortune. This new book on therapy is the joint work of nearly 250 specialists, supervised by 12 consulting editors, specialists in different fields of medicine, who were responsible for obtaining contributors in their particular fields. The list of contributors looks like a "Who's Who in Medicine." The text is divided into fourteen sections, covering the whole field of medicine, including the diseases of the skin, obstetric and gynecologic conditions and diseases due to physical and chemical agents. In this book for the first time an attempt has been made to furnish the latest approved and currently used method of treatment of a particular condition. There are indexes of authors and subjects. The text is well printed in a two-column format, with a good type. The book should prove invaluable to the practicing physician and should be in all medical libraries.

Atlas of Peripheral Nerve Injuries. By William R. Lyons, Ph.D., associate professor of anatomy, University of California Medical School, and Barnes Woodhall, M.D., professor of neurosurgery, Duke University School of Medicine. 8th, cloth, 335 pp., with 135 plates. Philadelphia: W. B. Saunders Company, 1949. \$16.00.

This atlas is a beautiful book and should be in all medical libraries and available to all neurosurgeons. It should prove the standard work on the subject and should remain so for many years. The authors are well equipped by training and experience. Dr. Lyons is a neurobiologist, with a full appreciation of clinical values, and Dr. Woodhall is an experienced clinician with a sound training in neuropathology. They both had a large experience in neurosurgery in World War II, and the advantage of teaching of many years. It is interesting to note that the project was carried on without an elaborate budget, but with help and encouragement of many individuals and institutions, including the Army Institute of Pathology, without whose facilities the atlas could not have been completed. The material is well organized and divided into six chapters. The first section is an introduction and discusses methods of taking tissue and the clinical material used. The following parts deal with the peripheral nerve, its terminology and anatomy, completely severed nerves, traumatic nerve lesions in continuity, nerve sutures, and nerve grafts. A bibliography of 190 titles concludes the text. There is a good index. The text is sufficient only to introduce the parts and describe the plates. The plates are excellent, and the publisher is to be congratulated for producing a fine example of good bookmaking.

Your Child's Mind and Body. A practical guide for parents. By Flanders Dunbar, M.D., 8th, cloth, 324 pp. New York: Random House, 1949. \$2.95.

This book constitutes a popular manual on child hygiene in all its aspects. The volume is concluded with a special table of references to the text, covering the emotional prob-

lems occurring between the ages of one month and seven years. The other subjects and older periods are listed in a comprehensive index. There also is a short bibliography for further reading. The book is well published and should prove useful to parents.

Skin Diseases in General Practice. By F. Ray Bettley, T.D., M.D., F.R.C.P., physician for diseases of the skin, Middlesex Hospital, London, and physician, St. John's Hospital for Diseases of the Skin, London. 8th, cloth, 260 pp., with 96 illustrations. London: Eyre and Spottiswoode (Publishers) Ltd., 1949. 21s net. (*The Practitioner Handbooks*.)

In this manual the author has limited the number of skin diseases to thirteen of the most common. Eczema is considered in four chapters. There is an extensive appendix on patch testing. The text is well written, and the material well arranged. The type, printing and illustrations are excellent. There is a good index. The book should prove valuable to the general practitioner.

American Red Cross First aid textbook for juniors. 8th, cloth, 132 pp. Philadelphia: Blakiston Company, 1949. \$1.00.

This manual, intended for junior-high-school pupils, was written by Dr. Carl J. Pottboff, national director of first aid and associate medical director of the American Red Cross. The text covers the whole field of recognized first aid and is well written. The type, printing and illustrations, drawn especially for teen-agers, are excellent. The volume should be in all public and school libraries.

Mycoses and Practical Mycology. A handbook for students and practitioners. By N. Gohar, M.R.C.S. (Eng.), L.R.C.P. (Lond.), assistant professor, parasitology and mycology, Department of Clinical Pathology, Kasr el Ainy Faculty of Medicine, Fouad I University, Cairo, Egypt. With a foreword by Sir Philip Manson-Bahr, C.M.G., D.S.O., M.A., M.D., D.T.M., & H. (Cantab.), F.R.C.P. (Lond.). 8th, cloth, 234 pp., with 134 illustrations. Baltimore: Williams & Wilkins Company, 1948. \$6.00.

This manual is well written, and the material well arranged. The botany, physiology and classification of fungi are first discussed, followed by chapters on the mycoses in general and on the various classes of mycotic diseases. Treatment is emphasized throughout the text. The last chapter is devoted to fungicides, fungistatics, prescriptions, mediums and poisonous fungi. There is a good index, and the publishing is excellent, including the illustrations. The printing was done in Great Britain. The price seems excessive. A similar volume, published in England, is priced at 21 shillings. However, the manual should prove a valuable addition to the subject.

How to Become a Doctor. A complete guide to the study of medicine, dentistry, pharmacy, veterinarian medicine, occupational therapy, chiropody and foot surgery, optometry, hospital administration, medical illustration, and the sciences. By George R. Moon, M.A., examiner and recorder, University of Illinois Colleges of Medicine, Dentistry and Pharmacy. 8th, cloth, 131 pp. Philadelphia: Blakiston Company, 1949. \$2.00.

In this small volume the author provides the necessary information for the prospective student in medicine and its allied fields. The various chapters discuss the requirements for admission, selection of a school, the methods of admission, women and the study of medicine, success and failure and special problems, such as fees and expenses, and outline of the courses. There are special chapters on dentistry and pharmacy. Lists of accredited schools are included in these chapters. In the chapter on allied fields brief consideration is given to veterinary medicine, osteopathy, optometry, chiropody and foot surgery, nursing, medical illustration, occupational therapy and hospital administration. The text is concluded with a list of schools and colleges in all the fields. There is a good index. The book should be in all medical and public libraries.

Italian, French, Welsh, Italian, Indo-European, Dutch and Negro family background. There are also suspected cases in English and German persons.

All our patients were of dark complexion as evidenced by brown, dark-brown or black hair and brown irides. Two had dark-blue irides. One was a lightly pigmented Negro boy. This type of complexion occurred also in the cases of Peutz^{7 10} and Touraine and Couder^{17 18} as evidenced by either their statement or by the photographs they published.

The consistency of this in all subjects may be of significance, particularly since the pigmentary

anomaly of freckles (ephelides) is common in persons of light complexion with blond, light-brown or red hair and lighter-colored irides

Pigmentation

In each case in which data were available pigmentation had been present from early in childhood to the age of twenty or more, with little or no change over the years and no very striking tendency to fade prior to that time. In Case 6 the mother noted the pigment at birth, and in Case 7

larger. Patches in the mouth were most prominent on the buccal mucosa, occasionally on the gums or hard palate and only rarely on the tongue. Those on the lips were more noticeable on the dental than outer aspect and more numerous on the lower than upper lip (Fig 1, 2, 5, 6, 7, 9, 11 and 16).

Some of the spots had a somewhat stippled appearance when examined by means of a high-power magnifying glass. This phenomenon was present in all cases when looked for (that is, Case 7, 8, 9 and 10). It is of interest that the histologic study

†Patient living

it was noted in a picture taken at the age of three months. Peutz¹⁰ observed it in the second year of life. He believes that the mouth pigmentation persists but that some fading of the portion on the face may occur after the age of twenty-five. If only the mucosal portion of the pigmentation remains in the later years of life, it appears that the mucosal pattern is the *sine qua non* of the pigmentary part of the syndrome. Diminution of the facial portion of the pigmentation with the years may account for the difficulty that some patients had in recalling whether or not their ancestors had shown the pigmentary syndrome. Mucosal and even labial pigmentation is readily overlooked by the layman and, for that matter, in the average medical examination.

The most impressive feature in these cases was the consistent and peculiar distribution of their pigmentation. It was most striking on the lips and buccal mucosa, presenting as round, oval or irregular patches of brown or occasionally almost black pigment. A few patches may appear blue and probably represent the scattering phenomenon described by Edwards and Duntley²⁴ as being due to reflection of blue rays and absorption of red rays of the spectrum when white light is reflected from pigment particles in the dermis or corium. The patches on the lips and buccal mucosa varied from 1 mm in diameter up to 5 mm or slightly

of the lesion revealed the pigment deposit to be distributed in vertical bands through the epidermis.

Biopsy of a typical pigmented spot in Case 6 was studied histologically by Dr Lloyd W. Ketron,²⁵ who made the following remarks on the sections*:

A biopsy has been taken of a pigmented macule on the hypothenar portion of the right palm. The tissue was fixed in formalin and sections stained with hematoxylin and eosin, polychrome and methylene blue and by Giemsa's method. The patient would not permit the removal of adequate tissue to make it possible to perform silver nitrate stains.

Although clinically the pigmentation seems to have a uniform and diffuse distribution, the sections reveal that the changes occur mainly in vertical bands (see Fig 18). In these segments the following alterations are seen in the various layers in the stratum corneum there are masses of melanin conforming in size and shape with those of cells in most instances, in the basal layer there is an increased number of "clear cells" of Masson and perhaps also of the melanoblasts although none of the stains used demonstrate well the branching processes of these cells. Occasionally, one of the rete cells shows melanin granules, and a few cells in the granular layer have yellowish-brown granules. In the cutis there are a moderate number of chromatophores and occasional extracellular accumulations of melanin. One gains the impression that there is slight proliferation of the fixed tissue cells around the superficial blood vessels, which also appear to be dilated. However, because of regional differences this cannot be said with absolute certainty. These changes are similar pathologically to those seen in lentiginos. However, because of the age incidence and anatomic distribution, I should hesitate to place them in that group.

*Published here with Dr. Ketron's permission.

The above description is essentially what was noted by Touraine and Couder¹⁵ and by Siemens¹² in the study of biopsies of pigment spots in their cases. However, the vertical bands of pigment noted in our cases were not mentioned in their reports.

One patient (Case 7) had a few small pigment spots on the mucous membrane inside the nose. None of our cases had melanosis coli as evidenced by negative examination by sigmoidoscopy or inspection of the colonic mucosa in operative or autopsy specimens. However one of Peutz's patients had pigmentation of the rectal mucosa, first noted at the age of four.

To some degree pigment spots were noticed on the face in nine subjects. There are certain distinctive features. In contrast to the mucosal spots those on the face are usually quite small (1 mm in diameter or less) and are round and flat with the surface of the skin. The spots are distributed so as to be most numerous about the mouth, in some cases below the nose, about the eyes and more rarely in a butterfly pattern over the bridge of the nose. In other words they are most numerous near the orifices of the face (that is, the eyes, the nostrils and especially the lips). The spots become progressively more sparse on the forehead, temples, glabella and angles of the jaw and in the front of the ears, or, in other words, in the areas removed from the oral and nasal orifices. The facial spots usually have a darker color than freckles, and are more distinctly outlined with no tendency to coalesce as a rule. Peutz¹⁰ has been able to follow one family for thirty years and noted a tendency for the facial spots to fade progressively after the age of twenty-five, although the mucosal spots were found to persist unchanged. Facial spots in our cases varied from minimal (Case 7, Fig 9) to moderate involvement (Case 2, Fig 1). None showed the marked involvement noted in the cases of Peutz¹⁰ (Fig 14) and Touraine and Couder¹⁵ (Fig 16). Apparently, the facial distribution of the pigmentary portion of the syndrome is most varied, is not the essential portion, and may be absent or disappear as the person gets older.

When the spots were carefully looked for, each patient showed some pigmented areas on the fingers and in some cases on the toes also. To a lesser degree a few patients had spots on the hands and feet as well. On the hands the pigment spots were most numerous on the fingers, varying from a few to many, involving both the plantar and the dorsal surface. They varied in size from 1 mm to several millimeters in diameter, and were sometimes round and sometimes irregular in shape. As on the face and mucous membranes they were flat. In color they were light to very dark brown. The spots are particularly well depicted in the left hand of Case 2 (Fig 2). On clinical inspection they were much more evident than is apparent in the

photographs being obscured by high lights in some pictures.

In no case was any pigment spot elevated, vascular or hairy. In addition an important observation is that no patient showed pigmentation on any part of the body in addition to the areas noted. There was no diffuse skin pigmentation, and no accentuation of pigment in the body folds or about the nipples.

The possibility that the pigment portion of this syndrome represents ephelides (freckles) must be considered. There is much against this idea. Freckles are due to inherited aggregates of melanoblasts in the skin producing sharply demarcated

FIGURE 18 *Histologic Appearance of Melanin Spot in the Skin Obtained by Biopsy in Case 6*

Study of this section revealed that pigment particles in the epidermis occur mainly in vertical bands. Clinically, some of the spots had a somewhat stippled appearance under magnification, which could be explained by this curious histologic pattern.

yellowish-brown areas, of varying size, and often zigzag in outline. They are more obvious in spring and summer, appear early in life but not in infancy, never occur on the palms and soles, are prominent on the exposed portion of the body and are most likely to occur in persons of light complexion.

On the face, freckles are most numerous over the nose and cheeks and most sparse near the mouth and nostrils. In other words, the distribution pattern of freckles on the face is the reverse of the pattern we have described. In fact, Siemens¹² characterized the spots of the syndrome under consideration as "ephelides inversae" because of this contrast in distribution when compared with ephelides.

The most important point against ephelides is the striking and constant occurrence on the lips and buccal mucosa even when the spots are minimal on the face. During the past few years we have examined the lips and oral mucosa of several dozen heavily freckled persons of both sexes and various age groups from childhood up through the third

decade. One was a boy who had won a "freckle contest." Although heavily freckled persons may show a few lesions on the lips, in no case did we see pigment spots on the buccal mucosa, hard palate or gums.

Lentigo is essentially a localized macular area of hyperpigmentation²⁶ containing a normal number of melanoblasts. They are usually multiple, dark brown, of varying size and up to 1 cm. in diameter, occurring on the covered parts of the body as well as on the face and hands and appearing later in life than freckles do. They have no characteristic or fixed pattern of distribution. There is no known hereditary predisposition. Mucous-membrane lesions do not occur. The usually accepted description and definition of lentigo seems to exclude the idea that the pigmentary portion of the syndrome falls into this category in spite of the fact that Touraine and Couder¹⁸ refer to them as such.

Chloasma, xeroderma pigmentosa, von Recklinghausen's disease and melanosis of external origin are readily excluded from consideration.

The pigment of this syndrome is undoubtedly melanin. It may well fit into the group of melanin pigments classified by Becker and Obermayer²⁷ as "melanosis associated with increased number of melanoblasts." Its hereditary tendency (See Fig 10, 12, 13 and 15) is best explained on this basis. Is the pigment syndrome a variant of ephelides or a separate and distinct form of melanosis? The latter possibility appears most likely to us, but we have been unable to prove or disprove this thesis. In essence, the nature of the pigmentary anomaly remains obscure. Apparently, it is limited to, or most common in, persons of dark complexion.

A summary of the data concerning the pigmentation is given in Table 2.

Intestinal Polyposis

The other portion of the syndrome consists of intestinal polyposis. Apparently, in each case the polyps are distributed throughout the entire intestinal tract with their most striking clinical manifestations in the small intestine.

The features referable to the polyposis in our 10 cases are given in Table 3. The presence and nature of the polyps in each subject were definitely established by means of one or more operations on the small bowel in all cases, and in addition by post-mortem examination in 3 cases.

The symptomatology of these patients was referable chiefly to the small intestine with numerous episodes of abdominal pain and signs of minor obstruction terminating in one or more attacks of small-bowel intussusception. Surgery of the small intestine was performed on these 10 patients, varying from one to four operations each. Several patients had melena of varying degree. In Case 1 a sprue-like syndrome developed after resection

of portions of the small intestine, the procedure led to inanition and contributed to her death.

By contrast, rectal and large-bowel symptoms and signs were minimal or absent. One patient (Case 6) had significant trouble with rectal polyps, but this disappeared after the age of four, several local operations for removal of the lesions having been performed.

Just as the symptomatology pointed to the small intestine principally, operation and autopsy revealed the majority of the polyps to be located in the small intestine in all 10 cases. Furthermore, of the small intestine, it was principally the jejunum that was involved. Peutz^{7, 10} had a similar experience with polyposis involving predominantly, but not exclusively, the small intestine in his 7 cases. Four of Peutz's patients had nasal polyposis, and 1 bladder polyposis. Touraine and Couder's¹⁸ patient was said to have only rectal polyps, but adequate small-bowel studies were apparently not done.

Although predominant in the small intestine, polyposis was also present in the stomach and colon in the 3 autopsied cases in our series. Polyps were demonstrated in the colon of 3 of the living patients and in the stomach of 1. Their presence or absence in the colon and stomach of the other patients was not demonstrated. It appears that the polyposis is present throughout the entire intestinal tract but most prominent in the small intestine.

The intestinal lesions were the usual adenomatous polyps as evidenced by histologic study of resected or autopsy specimens, or both, in all 10 of our cases. This was true also of the cases of Peutz,^{7, 10} Foster^{15, 16} and van Dijk and Oudendal¹⁴ and of the rectal polyp described by Touraine and Couder.^{17, 18} A representative gross lesion of the small intestine from one of our patients (Case 7) is shown elsewhere.²⁸ In summary, then, the intestinal polyposis in these patients appears grossly and microscopically similar to generalized intestinal polyposis in persons not having the associated pigmentary syndrome.

The well known tendency for multiple polyposis of the colon to develop malignancy apparently holds to some degree for the small-bowel polyps in cases of this syndrome. In 1 patient (Case 3) in this series, 2 of Peutz's 7 patients and possibly 3 of Foster's the small-bowel lesion became malignant. The incidence of cancer here is not so great as that in the hereditary large-bowel polyposis but is distinctive enough nevertheless.

Most of the cases of multiple intestinal polyposis described in the literature^{29, 33} appear to have been limited to the colon or rectum, or both. Symptomatology in these cases is rectal or colonic. It is quite rare to find any mention at all of lesions in the small intestine in these reports. Since exploratory procedures were commonly performed, any

small-bowel polyps present would probably have been found and comment made about them

Ladd and Gross³⁴ studied the records of 92 cases of intestinal polyposis at Children's Hospital in Boston. In only 2 of these were polyps noted in the small intestine. At the Mayo Clinic, Coffey,³⁵ in a study of 29 cases of multiple intestinal polyposis noted their localization to the colon in all but 2, in which the polyps were disseminated throughout the stomach and entire intestinal tract. Apparently, multiple polyps of the small intestine are quite rare as contrasted with multiple polyposis of the large intestine. On the basis of 7000 consecutive autopsies at the Cook County Hospital, Lawrence³⁶ concluded that polyps are approximately twelve times more common in the colon than in the small intestine.

In contrast to the numerous papers dealing with polyposis of the colon and rectum is the distinct paucity of studies referable to multiple polyposis of the small intestine,³⁷⁻⁴⁰ especially cases with a heredofamilial pattern similar to that in colonic polyposis.^{14 15 41} The recent review by Ravitch⁴² on polyposis of the small intestine and polyposis of the entire gastrointestinal tract further confirms the rarity of these two varieties.

Our 10 cases, most of which were heredofamilial, seem a large number in view of the rarity with which such cases are described in the literature. Peutz's^{7 10 7} similar cases makes the number even more impressive. The additional fact that each member of this relatively large group with this unusual intestinal lesion showed a peculiar and distinctive type of pigmentation seems to us to indicate that the association is not fortuitous but of real diagnostic significance.

We have not found any report with adequate bowel studies in which the pigmentation portion of the syndrome was associated solely with large-bowel polyposis. A number of surgeons with extensive experience with large-bowel polyposis, with whom this subject was discussed, were unable to recall a personally recognized example.

*Heredity**

It is well established that multiple polyposis of the large intestine is frequently hereditary. Dukes,⁴² in an exhaustive review of the subject, concludes that it "is an inheritable disease which is transmitted by both males and females, that both males and females suffer from the disease and that the inheritance can be traced through several generations." Gates⁴³ reviewed the genetic aspects of polyposis of the large intestine and was able to discover the pedigree of a total of forty families in the literature. He concluded that the condition is a simple mendelian dominant with an occasional skip in some families.

*We are indebted to Dr. Bentley Glass of the Department of Biology, Johns Hopkins University for his assistance in the preparation of this portion of the manuscript.

As pointed out above, multiple polyposis of the small intestine or of the entire gastrointestinal tract, as seen in the syndrome discussed in this paper, appears to be an entity distinct from the more common colonic polyposis, yet our data indicate that it follows a similar genetic pattern. That this type of polyposis is likewise often hereditary there can be little question. Among our 10 cases, two families are represented by 3 cases each. In the literature there are no genealogic charts large enough to permit any conclusion regarding genetics. There are, however, reports of several families in which more than one member suffered from polyposis of the small intestine.^{7 14 15 41 44 45}

That the pigmentary portion of this syndrome is likewise hereditary is inescapable from the two family groups among our 10 cases, and from the fact that Touraine and Couder,¹⁵ in reviewing the literature on the pigmentary anomaly alone, found 31 cases, of which 22 were familial. These authors presented several genealogic charts of the pigmentary anomaly indicating inheritance as a simple mendelian dominant.

Our genealogic tables of the Dutch family (Fig 13), the Welsh family (Fig 15), the Boston family (Fig 12) and the Harrisburg family (Fig 10) not only offer proof of the hereditary nature of the complete syndrome but also permit certain other conclusions.

In the first place the syndrome appears to be inherited as a simple mendelian dominant. The involvement rate of approximately 50 per cent in the second and third generations of the Dutch family, and in the second generation of the Harrisburg family, is consistent with, although not absolute proof of, such an inheritance through the mating of persons heterozygotic for this characteristic with persons not carrying this trait. In favor of inheritance of the syndrome as a dominant is the fact that, although rare, it occurs in a large percentage of members of tainted families.

Secondly, from these four charts the characteristics constituting the syndrome appear to have a high degree of penetrance, occurring probably in the majority of those who carry the necessary factors.

Thirdly, there are no generation skips. Both males and females carry the factor, and both are affected about equally.

Further study of the genealogic tables (Fig 12 and 13) impresses one with the fact that whenever patients were actually examined and subjected to complete studies the full syndrome, polyposis and spots, occurred together in the same person. "Gene linkage" (that is, the presence on the same chromosome of a separate gene for each characteristic) will not explain the association. Snyder⁴⁶ states it thus:

The occurrence of genetic linkage between the genes for two traits does not change the association for these traits in the population from what it would be if they were not linked. Stated inversely, a correlation between two traits in a free-breeding population does not indicate genetic linkage between the genes for these traits.

The correct explanation for this syndrome as for the majority of the other hereditary syndromes must be the presence of a single pleiotropic gene responsible for both characteristics, the polyps and the spots.⁴⁷

We still await the autopsy report of a patient with the characteristic pigmentation that shows absolutely no polyps of the intestine on careful search. That the converse situation occurs seems probable. There may be several reasons for the occurrence of generalized intestinal polyposis or of polyps of the small intestine without spots. First, it must be appreciated that clinical identity does not necessarily mean genetic identity, 2 cases of polyposis clinically identical may have quite different genetic backgrounds. Secondly, in other inherited syndromes, such as Marfan's arachnodactylia, essential familial xanthomatosis and von Recklinghausen's disease, there may be in the same family great variability in the completeness or degree of expression of the individual characteristics, because of factors not well understood. That variability may, at times, be present in this syndrome, although we have no definite evidence of it. It might be subsequently demonstrated that in the same family some members show only polyposis, and some only spots.

SUMMARY

On the basis of 10 cases studied, an attempt is made to establish a syndrome that previously was not clearly identified in the English medical literature and recognized to only a very limited extent elsewhere. By supplementing our own cases with those discovered in a search of the literature and with data from personal communications, it has been possible to assemble a total of 22 proved, 5 probable and 4 possible cases.

This syndrome consists of two features distinctive melanin spots of the buccal mucosa and lips — the face and digits may be involved to a variable extent, but the mouth pigmentation is the *sine qua non* of this portion of the syndrome, and polyposis (synonyms are adenomatosis and papillomatosis) of the small intestine. The stomach, colon and rectum may be involved, but the presence of polyps in the small intestine is the constant feature of this portion of the syndrome.

Our group of 10 cases included 6 in which more

than one member of the same family was involved. Sufficient genealogic data are reported to demonstrate the hereditary nature of the syndrome, which appears to be inherited as a simple mendelian dominant. Sporadic cases also occur.

The syndrome appears to have important diagnostic significance in that the external manifestations may be of considerable value in the recognition of the intestinal condition.

As a result of several lectures on this subject, 3 additional cases have been called to our attention since the preparation of the manuscript. Two were examined in detail by one of us — 1 through the courtesy of Dr. C. Stuart Welch of the Joseph H. Pratt Diagnostic Hospital, Boston, and the other through the courtesy of the staff of the United States Naval Hospital, N. N. M. C., Bethesda, Maryland. (A colored illustration of the latter case was reproduced with the first section of this report.) All 3 patients had small-bowel polyposis, one or more operations for intussusception of the small intestine and the typically distinctive melanin spots. The last 2 cases will be reported separately by the institutions mentioned above. These additional cases provide further evidence that the syndrome is a distinct entity.

AUREOMYCIN TREATMENT OF HERPES ZOSTER*

MAXWELL FINLAND, M.D.,† EDMUND F. FINNERTY, JR., M.D.,‡ HARVEY S. COLLINS, M.D.,§

BOSTON

AUREOMYCIN and Chloromycetin are generally referred to as agents that are effective against "viral" infections. Their demonstrated therapeutic action in this field, however, has been limited to nickettsial diseases¹⁻¹⁷ and to infections with the psittacosis-lymphogranuloma venereum group.^{1-4, 17-21} Aureomycin has also proved efficacious in cases of the so-called viral or primary atypical pneumonias.²²⁻²⁵ The etiology of the latter is still unknown beyond the demonstration that some of them may be transmissible by filtrates of materials from human cases.²⁶⁻²⁷ Neither of these agents has yet been proved to be effective against what might be called true viruses, such as those which cause yellow fever, influenza, poliomyelitis or the encephalitides.

Recently, some beneficial effects have been claimed for these antibiotics in certain skin diseases that are thought to be due to viral agents,²⁸⁻³² among which is herpes zoster.³¹⁻³² As regards the etiology of the latter, grafts of human skin onto the chorioallantois of chick embryos have been successfully infected with vesicle fluid from a patient with herpes zoster,³³ and elementary bodies have been demonstrated by electron microscopy in the vesicle fluid from various clinical types of herpes-zoster lesions.³⁴⁻³⁵ The demonstration of a therapeutic effect in this disease is therefore of considerable interest as well as of practical importance.

In this paper are presented the results of aureomycin treatment in 24 cases of herpes zoster. Although a specific therapeutic effect has not been demonstrated beyond any reasonable doubt the results are sufficiently encouraging to warrant this report.

MATERIALS AND METHODS

Cases Treated

The 24 patients included in this report were all treated during the first nine months of 1949. All had lesions that were clinically characteristic of herpes zoster. With 4 exceptions they were consecutive cases seen on the wards or in the Out Patient Skin Clinic of the Boston City Hospital. However, mild cases or those in which there was any doubt of the diagnosis or the activity of the disease were omitted. Of the 4 patients who were not treated at this hospital, 1 was a physician, another was the wife of a physician, and a third was a patient treated in another hospital by a dermatologic colleague. Detailed reports of these 3 cases were made by the physicians concerned.

Aureomycin. The aureomycin was supplied in the form of capsules each containing 250 mg. of the hydrochloride and was given by mouth, generally in doses of 1 gm. four times a day (after each meal and before retiring), and the individual doses were reduced to 0.5 gm. each after definite improvement occurred or if there was significant nausea or vomiting. Crystalline aureomycin hydrochloride was also supplied in sterile vials containing 100 mg. for intravenous use. This was given to 2 patients who refused oral therapy; individual doses of 500 mg. in 500 or 1000 cc. of 5 per cent dextrose were given by slow intravenous drip taking about an hour for each dose. (The recommended alkaline buffers were not used in these cases.)

CASE REPORTS

CASE 1. The patient was a retired physician whose herpetic lesions began in the right side of the back near the midline and extended within 7 to 10 days around the lower axillary region and reached almost to the midline. The eruption was very extensive posteriorly but tapered off as it spread to the front of the thorax. The patient paid little attention to his lesions until the middle of the 3rd week, when they became much worse and caused him considerable pain and discomfort. A month after the first appearance of the lesions and after failing to obtain relief from various remedies, he took aureomycin by mouth, a total of 7 gm. in 3 days, without any effect. He then took a course of x-ray therapy to the lesions over a period of 1 week. This gave slight relief from the pain, and the lesions began to improve but within a few days "the whole thing flared up again."

Because of the failure of the first course of x-ray treatment to terminate the disease, the patient was given a second course of x-ray treatments over a period of 2 weeks during which he also took aureomycin, 1 gm. daily, in divided doses. He improved steadily, and by the end of the 2 weeks the lesions had healed, the pain had subsided and he was able to lead a normal life again. In the course of the next 4 or 5 months, however, he had occasional recurrence of sudden, sharp pains or burning sensations, each lasting about 1 or 2 minutes and limited to the region of the eruption.

*From the Thorndike Memorial Laboratory, Second and Fourth Medical Services (Harvard) and Skin Service, Boston City Hospital, and from the Department of Medicine, Harvard Medical School and the Department of Dermatology, Tufts College Medical School.

This investigation was aided in part by a research grant from the Division of Research Grants and Fellowships of the National Institutes of Health, United States Public Health Service.

The aureomycin used in this study was kindly supplied by the Lederle Laboratories Division, American Cyanamid Company, New York City.

In this case a short course of aureomycin given during the fifth week failed to alleviate the symptoms or prevent a relapse. The lesions and acute symptoms finally yielded by the end of the second month and after a second course of x-ray therapy together with small doses of aureomycin given over a period of two weeks. The role of aureomycin in this case cannot really be assessed. There were no untoward effects from the antibiotic.

CASE 2 One day after a "light" treatment at his barber's the patient began to have a burning sensation over his right eye. This continued for 3 days, after which herpes zoster appeared, first as patches of erythematous lesions over the right side of the forehead and then over the scalp. During the next 24 hours the lesions became deeply vesiculated in 2 patches, one over the right eyebrow and the other at the hairline, and these caused a constant, dull aching and marked itching. Aureomycin hydrochloride was started at this time, 1 gm orally 4 times a day for a total of 12 gm, and this produced no untoward effects. No local therapy was used. On the day after this therapy was started, 12 discrete and widely scattered vesicles, each on an erythematous base, appeared over the chest and abdomen. The right upper eyelid became swollen on this day, but no new lesions appeared in this area. The cornea and bulbar conjunctiva were spared. The pain and itching stopped, and the edema subsided on the 2nd day. The original lesions became hemorrhagic and necrotic and then dried up rapidly. All lesions were completely healed within 1 week of the first dose. There was no relapse and no post-herpetic pain.

CASE 3 This patient's first symptom was prickling pain over the left eye, which was soon followed by the appearance of groups of vesicles, one on the left side of the bridge of the nose, 2 over the eyelid and another on the forehead. Erythematous macules were also scattered over the scalp. Aureomycin hydrochloride was started 48 hours after the onset of symptoms, 1 gm was given by mouth 4 times daily for a total of 24 gm and without untoward symptoms. No local therapy was used. On the day after the aureomycin was started the left eye was swollen shut by edema of the lids, but the cornea and conjunctiva were spared, no other new lesions appeared, and vesicles did not develop in the macular lesions over the scalp. Thereafter, improvement was rapid. The edema of the lids and the pain subsided in 2 days, and within 5 days all the lesions had cleared and there was only slight itching of the scalp during this time. There were no relapses, sequelae or pain thereafter. In this case many lesions were apparently aborted by the aureomycin.

CASE 4 The first symptom was itching, and after 1 day a group of vesicles appeared on the back of the right shoulder. During the next 7 days 5 more groups of closely packed vesicles appeared around the original lesions, and severe itching persisted. Aureomycin orally was started on the 10th day, 1 gm 4 times daily. Because of nausea, the individual doses were reduced on the second day to 0.5 gm, and treatment was continued for a total of 5 days. No local therapy was used. Within 72 hours, most of the lesions had dried and were healing, and the itching had almost entirely subsided. When the patient was next seen 4 days later, all the lesions had completely cleared, and there had been no further itching. There were no relapses, nor did the patient later experience any pain. The dermatologist who followed this patient in the clinic noted in his record that he had never seen such a case clear so rapidly.

CASE 5 The patient first experienced marked itching, and within a few days an extensive vesicular eruption appeared over the right middle portion of the thorax from the spine around to the midline anteriorly. The lesions rapidly became gangrenous, and there was slight pain during the 3rd week. At that time the patient was admitted to the hospital, and aureomycin was started, 1 gm being given orally 4 times a day for a total of 25 gm. There were no untoward effects. There was remarkably rapid improvement, with considerable clearing of the lesions and subsidence of

pain within the first 2 days and almost complete clearing with minimal scarring within 6 days. Four days later, however, the patient began to have slight pain referred to the affected area. This pain increased in severity at first and then persisted with diminishing intensity for about 6 weeks without the appearance of any further lesions. It was difficult to evaluate the pain in this patient since he had no home and no resources and was obviously anxious to remain in the hospital as long as possible. In this case treatment with aureomycin was started late and appeared to have a strikingly beneficial effect on the skin lesion, but did not seem to prevent the appearance of postherpetic pain.

CASE 6 This patient first experienced discomfort in the left ear and cheek. On the following day she had general malaise and noted the appearance of a herpetiform eruption over the same area and also some enlarged cervical lymph nodes on that side. The symptoms and some shooting pains over the mandibular region increased, and the lesions advanced during the next 2 days until aureomycin was started and for about 16 hours longer. Thereafter there was steady improvement; the lesions cleared almost completely within 3 days, and the shooting pains rapidly diminished in intensity and then subsided entirely within 9 days. Neither of these recurred. The aureomycin was given by mouth, 1 gm every 6 hours for 10 doses and then 0.5 gm every 6 hours for 5 more doses. During the first 3 days, there was marked nausea for about 10 minutes after each dose, particularly when the drug was taken on an empty stomach, and during the next 2 days the nausea was continuous and there was also some diarrhea. This patient was nursing an infant during this episode, and the baby remained well.

CASE 7 The first symptom in this patient, a dental student, was a severe itching over the left flank, which caused him to scratch a good deal. On the following day the area was painful "like a boil," and during the succeeding 3 days groups of vesicles appeared lateral to the original lesions and a large patch of vesicles appeared over the upper outer quadrant of the buttock. The patient applied tincture of iodine to the initial lesion and various lotions to the entire area and also took some analgesic pills, all without preventing the progress of the lesions or of the symptoms. Aureomycin by mouth was begun on the 7th day, 1 gm 4 times a day for 2 days, and then, because of increasing nausea and frequent loose bowel movements, the dosage was reduced to 0.5 gm 4 times a day and continued until a total of 12.5 gm had been given. The untoward symptoms subsided completely on the smaller dosage. The pain and itching increased during the first 24 hours, at the end of which the lesions had already begun to improve. Within 48 hours, the vesicles had almost completely dried, and the pain had subsided. On the 4th day the lesions were almost completely healed, and only slight itching persisted for another day. There were no further lesions and no recurrence of the pain.

CASE 8 The patient first noticed a "dead feeling" and some prickling in the left flank. During the next few days groups of vesicles appeared over this area and were soon followed by sharp, knife-like pain. When the patient was first seen, at the end of the 2nd week, the lesions involved an extensive area from the spine at the level of the twelfth thoracic and first lumbar segments, around the flank and to the midline anteriorly from just above the umbilicus to the groin. There were some old lesions that were beginning to dry up and many new groups of vesicles with deep surrounding erythema that had appeared during the previous 2 days. There was severe superficial prickling and some sharp pain and paresthesias over the involved areas, and also a "clutching" feeling in the abdomen. Aureomycin was begun at this time. The patient took 750 mg by mouth 4 times a day for 3 days. No other therapy was used. No further lesions appeared after this treatment was started, and there was almost complete healing of the lesions by the end of the 3rd day. There was still slight pain at this time, but this soon subsided and there was no recurrence of pain or lesions.

CASE 9 The patient awoke one morning with a marked burning sensation over a band of the left upper portion of the chest corresponding to the cutaneous distribution of the third and fourth thoracic segments. Only after this sensation

had continued for about 5 days did he become aware of an extensive outbreak of shingles over this area. He was first seen 2 days later, when there were many groups of fresh vesicles with surrounding bright erythema. Aureomycin was started at this time, and the patient took 1 gm 4 times daily for 3 days. On the 3rd day he felt nauseated and vomited after the last 2 doses. The pain and burning cleared rapidly, and the lesions began to dry up promptly and were entirely healed within 5 days. There were no sequelae.

CASE 10 This patient first noticed some itching and a burning sensation around the left upper eyelid, which soon became red, hot and swollen. Two days later, herpetic vesicle appeared above the eyelid and spread back over the left side of the scalp. The redness and swelling of the eyelids, especially the upper lid, increased, and some of the lesions became pustular. At that time he consulted a physician, who treated him with procaine penicillin, 2 daily injections of 500,000 units each for 2 days and 1 a day for 4 more days and then sent him into the hospital. At that time the lesions involved the left side of the nose, forehead and scalp. The eye was swollen shut and the patient's temperature was 101°F. Most of the vesicles had become pustular, some of them had become encrusted, and pus oozed from the inner canthus of the eye. The left eye was swollen shut, there were blepharitis and keratoconjunctivitis with marked clouding of the cornea and 2 distinct herpetic lesions of the cornea were visualized with fluorescein. The white-cell count was 5600, with 84 per cent neutrophils. The blood nonprotein nitrogen was 107 mg per 100 cc, and the urine was loaded with pus cells. Culture of the pus from the forehead yielded a predominance of hemolytic *Staphylococcus aureus* and some *Staph. albus* alpha-hemolytic streptococci, *Proteus vulgaris* (*Bacillus proteus*) and *Clostridium perfringens* (*Cl. welchii*). A culture of pus from the left eye yielded *Escherichia coli*, *P. vulgaris* and a few staphylococci. The blood culture was negative.

The patient was treated with an aqueous solution of sodium penicillin G, 100,000 units intramuscularly every 4 hours and sulfadiazine by mouth, 1 gm every 4 hours. The latter was stopped after 3 days when he began to vomit and the sulfadiazine level was found to be 21.5 mg per 100 cc free and 26.3 mg total. The penicillin was discontinued on the next day. During these 4 days new vesicles kept appearing and there was no improvement. The blood nonprotein nitrogen was 85 mg per 100 cc. Aureomycin therapy was then started 1 gm of the hydrochloride being given orally every 4 hours and 2 drops of fresh 1 per cent aqueous solution of aureomycin borate (50 mg in 5 cc.) being instilled into the left conjunctival sac every 1 or 2 hours. The oral dose was reduced to 0.5 gm every 6 hours after 5 days because of nausea and some vomiting.

Within 24 hours of the beginning of aureomycin therapy the involved areas began to look definitely less inflamed, and no new lesions appeared thereafter. The edema of the lids began to subside on the 2nd day. By the 3rd day all redness of the skin had gone, the purulent discharge had decreased markedly and most of the lesions had become encrusted. By the 4th day healing of the skin had definitely begun, but at this time the patient complained of pain in the eye for the first time. The cornea still looked cloudy but much less inflamed, and the 2 herpetic lesions were smaller. All the swelling of the eye had subsided after 9 days, when the aureomycin was stopped. Some pain persisted and 2 days later there was a recurrence of the conjunctival infection and of a small amount of purulent discharge, but the corneal lesion continued to improve. A culture of the pus from the conjunctiva at this time showed *Staph. aureus* and *P. vulgaris*, the former sensitive to 50 microgm and the latter resistant to 200 microgm of aureomycin per cubic centimeter. The blood nonprotein nitrogen was 114 mg per 100 cc. at this time, but there were only a few pus cells in the urinary sediment.

The patient began to vomit again after the course of aureomycin therapy, and his tongue became fiery red, smooth and shiny. This cleared promptly after treatment was stopped. He was digitalized, and fluids were given parenterally, with a careful check on electrolytes. During the following 4 weeks without further antibiotic or chemotherapy, the eye gradually improved, and the nonprotein nitrogen dropped to near normal levels. At the same time the corneal opacity had cleared

almost completely and the ulcers were barely demonstrable. When the patient was last seen there was no further trace of any skin or ocular lesions. Vision was apparently unimpaired, and the conjunctivas were clear. There was no post-herpetic pain and no recurrence of lesions.

The result in this case, though not spectacular, was considered to be moderately good because of the poor prognosis that usually accompanied this type of lesion in patients of this age group.

CASE 11 The onset in this case was with pain and smarting, which was followed on the next day by the appearance of erythema and groups of vesicles scattered about the left side of the chin, jaw and temporal area. By the 3rd day, when the patient entered the hospital, some of the lesions had become hollous, and there were lesions on the left buccal mucous membrane and soft palate. Aureomycin was started on that day but was stopped because of nausea and vomiting after only 3 doses of 1 gm each had been given. Two days later there was no improvement, and several crops of new lesions had appeared, including a few on the side of the tongue. The patient was then given 500 mg of aureomycin hydrochloride in 500 cc. of 5 per cent dextrose solution by slow intravenous drip. On the following day the erythema was much less intense, and many of the vesicles had begun to dry. A second and similar injection was then given, and this was followed by oral doses of 0.5 gm 4 times a day for about 7 days. Except for occasional vomiting she tolerated this dosage well, and marked improvement followed. The lesions on the tongue improved rapidly, and the skin lesions became dry and encrusted after 2 days. The lesions had all dried up and the pain subsided after 4 days. All the lesions had completely healed within 1 week. The burning sensation in the face and the tenderness of the tongue regressed slowly during this period. After discharge from the hospital however, she began to have periodic, lancinating pains in the face, which gradually decreased in frequency and severity and finally stopped after about 2 months. After that time the site of the skin lesions was no longer discernible, but there were 2 pale, circumscribed pinkish-gray plaques without surrounding erythema on the side of the tongue.

In this case the lesions cleared, but post-herpetic pain was not prevented by the treatment.

CASE 12 Aureomycin was started in this patient as soon as she was admitted to the hospital in the middle of the 3rd week after the first appearance of her shingles. At this time there were extensive gangrenous herpetic lesions involving the right upper portion of the thorax anteriorly and posteriorly and the lower axillary region, and the patient was complaining of severe pain and burning sensations. She received 1 gm orally 4 times a day, and because of moderate nausea and some vomiting after the second day, the individual doses were reduced to 0.5 gm and continued for another 4 days. By the end of the 2nd day of this treatment there was remarkable drying of the lesions, no new ones had appeared, and there was only slight residual pain. Healing proceeded rapidly, the superficial ones were almost completely healed in 4 days, and the deeper ones healed during the next few days. After the patient left the hospital however she again had considerable burning and some intermittent shooting pains over the involved areas. For this she was given codeine and local applications of collodion by her physician. The pains gradually subsided but the burning persisted for about 3 months. After that time there was still some faint erythema at the site of the lesions, probably maintained by the local applications and irritation.

CASE 13 The herpetic lesion first appeared in this patient on the left side of the forehead 1 week after she sustained a bump on her head. During the next few days, groups of vesicles appeared on the cheek, below the eye and on the hard palate — all on the left side. By the end of 1 week, when she entered the hospital, there was extensive edema over the entire area, with intense redness surrounding the

lesions and the left eyelids were swollen. Aureomycin was started by mouth at this time, but only 2 gm was given, and the patient rejected each of them and refused oral medication. She was then given an intravenous injection of 500 mg of aureomycin hydrochloride. Within 24 hours, the lesions in the mouth had almost cleared, and there was considerable improvement in the facial and palatal lesions, the erythema and edema decreased markedly, and the vesicles appeared to be drying up. A second intravenous dose of 500 mg was given at this time and the edema and pain were entirely gone by the next day, and healing of the lesions proceeded during the next 2 days. The patient refused further medication and left the hospital. New lesions then promptly began to appear and spread over the scalp and side of the face and were accompanied by severe pain and itching. The lesions of the eye also reappeared and progressed. All the lesions healed very gradually over a period of 6 weeks, leaving scars of the skin and cornea. The latter remained hazy, and the patient's vision in the affected eye remained markedly blurred after 3 months. The pain and itching also persisted, though with diminished intensity throughout this time.

In this case marked improvement followed a brief course of intravenous injection of aureomycin, and there was a prompt, severe and prolonged relapse after the aureomycin was stopped.

CASE 14* This Negro first felt a burning sensation over the right side of the forehead, scalp and temporal region and soon noted numerous small blisters over this area. By the next day the lesions had increased in size and number, and the right eye had become red and swollen. When first seen on the 3rd day he had numerous vesicles and bullae from 1 to 13 mm in diameter over the right side of the head involving the forehead, upper eyelid and parietal region of the scalp. The lids were swollen almost completely shut. In addition, about 30 small vesicles were scattered over the rest of the body. There was only slight pain over the affected area of the head. The temperature was 99.5°F, and the white-cell count 4100. Aureomycin by mouth, 4 gm daily, was promptly started, and no other therapy was used.

In the course of the next 2 days the temperature rose to 103.8°F, and the eruption extended, with vesicles appearing on the side of the nose down to the lip, a few more bullae appeared on the forehead, and the eye was swollen shut. The lesions on the trunk, however, did not progress or increase. The tarsal conjunctivas were markedly injected, and there was some seropurulent discharge but the cornea and bulbar conjunctiva remained clear. On the 3rd day the maximum temperature was 99°F, the vesicle fluid remained clear, and no new lesions appeared. By the 4th day, the lesions had definitely begun to dry up, the eyelids were much less swollen and could be opened, the conjunctival injection subsided, and the cornea had remained clear. At the end of 1 week of treatment all of the lesions were solidly encrusted, and healing had definitely begun. Aureomycin was continued for 2 more days at 2 gm a day, and healing progressed thereafter. There were no untoward effects from the aureomycin. There was no recurrence of lesions and no post-herpetic pain.

The rapid improvement in this case was considered to be quite striking considering the severity of the lesions. It was also believed that corneal involvement may have been prevented by the treatment.

CASE 15 Five days before entering the hospital this patient noticed a rash, which began as a group of reddish raised lesions on the right side of the lower abdomen and on the right flank. This was followed by the appearance of scattered papular and vesicular lesions over the trunk and extremities. The patient experienced pains down his legs, cramps and

numbness in his toes and some burning over the lesions. When he was first seen he had several groups of lesions over the right flank and abdomen, including one large area that was gangrenous and pustular. There were also numerous scattered papules, vesicles and pustules and some encrusted lesions widely scattered over the extremities, trunk, face and neck. Two days later fresh clusters of herpes lesions, one of them a cluster of vesicles, 2 by 5 cm, with surrounding deep erythema, appeared in the right flank.

Aureomycin by mouth, 0.5 gm every 4 hours, was then started and this was increased to 1 gm every 4 hours on the 3rd and 4th days, after which the original dosage was resumed for 3 more days. The only untoward effect was slight nausea after 2 of the 1-gm doses. The pain had subsided entirely within 2 days. There was rapid improvement in the lesions, and by the 3rd day they had dried, encrusted and cleared markedly. After 6 days, when treatment was stopped, there was almost complete healing, only a few faint erythematous patches remaining. There were no recurrences of the pains or the lesions. When the patient was last seen, only a few slightly pigmented superficial scars were visible at the site of the gangrenous lesions on the lower abdomen.

CASE 16 The first symptom in this case was pain in the right shoulder radiating down the ulnar aspect of the arm—dull and aching at first but soon becoming intermittently knife-like and severe enough to interfere with sleep. On the following day the pain was worse, involving the upper right anterior portion of the chest, with radiation around to the spine, and a herpetic rash appeared on the inner aspect of the arm. On the 3rd day vesicles and erythema were also noted on the chest and back, those on the arm had become extremely painful, and the lesions had spread over most of the ulnar surface of the arm and hand, including the fingers. On the 4th day marked erythema and vesiculation covered this area and also a band about 4 cm wide across the chest from the angle of Louis around the lower axilla to the fourth dorsal vertebra.

Aureomycin was started by mouth at this time. The patient took 1 gm every 4 hours, omitting only 1 night dose. After 48 hours, the pain had almost entirely subsided, and there was only a residual mild intermittent aching. There was still moderate erythema, but the vesicles had definitely begun to dry up and no new lesions appeared. Because the patient had mild diarrhea, the individual doses of aureomycin were reduced to 500 mg each. Two days later, he was entirely free of pain, only a faint erythema was barely discernible, and there were many dry, punctate crusts over the chest and arms. There were no further untoward effects from the antibiotic, which was stopped at this time. The lesions healed rapidly, and there were no recurrences of pain or lesions.

CASE 17 The patient was being treated in the Medical Clinic with digitalis and diuretic for chronic congestive heart failure when she began one day to complain of severe pain in the left side of the chest. When she returned 2 days later, she had extensive groups of herpes vesicles, many of them bullous and each on a deeply erythematous base over an area about 8 cm wide and extending from the spine at a level of the fourth to the sixth thoracic segment around and below the axilla to the middle portion of the chest anteriorly. There was intense pain referred to this area—severe enough to interfere with sleep.

Aureomycin, 1 gm 4 times a day, was promptly started, and no other local or systemic treatment was used for these lesions. In the course of the next 3 days, the pain improved considerably, no new lesions appeared, and many of the vesicles had begun to dry up, but clear bullae were still present and there was still considerable deep erythema. Within the following 2 days the pain had almost completely subsided, and there was only a mild burning sensation over the lesions, which were now all covered with clean dry crusts and surrounded by some erythema. The patient had some nausea, and the dose of aureomycin was reduced to 0.5 gm 4 times daily. After 8 days there were only a few crusted lesions with faint erythema, and all the others showed considerable healing. The patient had 2 or 3 large loose bowel movements daily and lost a considerable amount of her edema—much more than had previously been accomplished with mercurial diuretics.

*Treated on the Dermatologic Ward of the Massachusetts General Hospital and reported through the courtesy of Dr. Walter F. Lever.

Aureomycin was stopped at this time. The patient still had some slight burning sensations during the next 3 days. A week later she again began to have rather annoying twinges of pain referred to the scarred areas, but there were no new lesions or local reactions. Aureomycin treatment was resumed for 2 days, with slight reduction of the pain but without complete relief. The itching and the twinges of pain continued for 2 more weeks.

In this case there was marked and rapid improvement in the local lesion and relief from pain accompanying the aureomycin therapy during the acute phase. The late pain was not prevented, though it may have been very slightly eased by further doses of aureomycin.

CASE 18 The patient first noted a burning sensation over the lateral aspect of the right thigh, and a pale erythematous rash appeared over this area. In the course of the next 3 days, the erythema became deeper, groups of clear vesicles appeared in the erythematous area, and the burning sensation became more severe and was soon accompanied by recurrent, intense stabbing pains. By the 7th day when he was first seen, the lesions involved the lateral aspect of the upper two thirds and part of the anterior surface of the lower third of the right thigh.

Aureomycin was promptly started and given in doses of 10 gm every 4 hours, one night dose being omitted. After 2 days the pains and burning subsided almost completely and the lesions began to dry up rapidly. On the 3rd day rather severe diarrhea, with urinary frequency and dysuria developed. The dose of aureomycin was then reduced to 0.5 gm every 4 hours and continued for 4 more days. The diarrhea and urinary symptoms were promptly relieved. The lesions, meanwhile, began to heal and by the end of a week were almost completely healed, leaving only faint erythematous areas. No new lesions had appeared.

On the morning after the aureomycin was stopped, the patient on arising noted that his tongue was swollen. The swelling subsided in about 2 hours, but he then began to have tenderness, itching, stiffness and redness of his hands, and his face felt flushed. He was given 25 mg of Thephorin (an antihistaminic), and within 1 hour the lesions and swelling cleared completely and did not recur. He had no previous history of sensitivity reactions, but he had been taking codeine and barbiturates since the onset of the shingles. It is possible that these manifestations represented a sensitization reaction to the aureomycin, although a reaction to either the codeine or the barbiturates could not be excluded since the clearing of the urticaria followed the discontinuance of these drugs as well as the aureomycin.

CASE 19 The patient first noted a burning pain beginning in the middle of the back and radiating around the right axilla to the sternum, and then an erythematous rash appeared over the right breast. On the next day she had a slight headache and malaise, she felt chilly, the temperature rose to 101°F and she was sent into the hospital. By this time the erythema had become deeper, and groups of vesicles had appeared in the erythematous areas, which now extended from the midline over the breast to the posterior axillary region. There was marked hyperesthesia over this area.

Aureomycin was started at this time and given in doses of 10 gm every 4 hours for 10 days, with no untoward effect except for some nausea on the last day. Within the first 24 hours there was a decided decrease in the hyperesthesia, and by the following day there was much less erythema and the vesicles were beginning to dry up. The pain decreased in intensity over the following 2 days but a sensation of soreness and burning in the axilla persisted for a few days longer. Meanwhile, the erythema cleared and the vesicles dried up completely and began to heal. No new lesions appeared after the aureomycin was started, and there was no late recurrence of pain.

CASE 20 The patient's wife first noticed redness over the back of his chest near the spine, and this soon extended around the right over the lower ribs to the sternum. Two days later

anorexia and general malaise developed, and the temperature rose to 100°F. At this time groups of vesicles appeared in the area of erythema to which the patient applied a lotion prescribed by his physician. By the 4th day the lesions over the involved segment had increased in number, and numerous isolated lesions resembling those of chicken pox were noted over the head, trunk and extremities but the scalp, palms and soles and the mucous membranes of the mouth were spared. Accompanying the generalized eruption there was considerable itching, anorexia and a low-grade fever. The patient continued to apply lotions to the skin and took some codeine and salicylates. Pain then began insidiously and increased in intensity after the 9th day. By the end of the 2nd week the generalized rash had completely cleared and the local lesions were beginning to dry, but the pain was still severe and there were still some acute vesicular lesions.

Aureomycin was begun at this time with doses of 0.5 gm by mouth 5 times a day and continued for 7 days. There were no ill effects except for slight nausea on several occasions. The lesions had been covered with fullers' earth by a nurse, and the healing and drying was somewhat delayed, but the pain subsided entirely within 36 hours after aureomycin was started and no new lesions appeared. Healing progressed steadily, but a slight gnawing sensation persisted for several days.

CASE 21 The patient first noted a burning sensation on the left side of his chest, and on the following day a group of erythematous lesions and some small vesicles began to appear over this region. When first seen on the 3rd day he was having intense shooting pains, and the burning sensation had become more severe. There were groups of small vesicles over deeply erythematous areas extending in a band about 6 or 7 cm wide around the left side of the chest from the middle portion of the back to the sternum, sparing only the axillary region.

Aureomycin by mouth, 1 gm 4 times a day, was promptly started. No new vesicles appeared after that. Within 2 days the pain had eased considerably, but there was still some slight burning sensation and hyperesthesia over the scapular region. After a week the lesions were all encrusted and dry, and there was no further pain and only a slight itching at night over the healing lesions. There were no untoward effects from the aureomycin, and no other local and systemic treatment was used.

CASE 22 This patient first noted intermittent, sharp, stabbing pains in the right axilla. These were followed in a few days by similar pains down the medial side of the arm and across the right side of the chest. By the 5th day, after the pain had become quite severe, a rash appeared in the right axilla and spread quickly. When she was first seen 3 days later, the vesicular, herpeticiform rash involved the axilla, the posterior surface of the upper arm and also an area extending in a band across the chest at the level of the fourth thoracic segment — all on the right side. There were also numbness and hyperesthesia on the same side involving the little finger, triceps area and ulnar surface of the forearm to the wrist. The patient had been intimately exposed to chicken pox 2 weeks before her first symptoms had begun.

Treatment was started with 1 gm of aureomycin by mouth 4 times daily. On the 2nd day, however, the patient reduced the individual doses to 0.5 gm because of severe nausea. The gastric distress continued on this dosage, and she took only 0.5 gm on the 3rd day and 250 mg on the next day. Her first return visit was on the 5th day, when the pain had almost completely subsided. Although a few new vesicles appeared in the axilla during the 1st day of treatment, most of the lesions were dry and crusted over. Further aureomycin was prescribed, but the patient took only 1 dose of 0.5 gm. The lesions continued to heal, and there was no further pain or recurrence of lesions. When she was next seen 4 weeks later only a few faint scars were discernible.

CASE 23 The patient first noted sharp, shooting pains in the left buttock radiating along the posterior aspect of the thigh to the knee. The pains continued intermittently for 2 days, and then a vesicular rash appeared, first on the left thigh and then just above the left buttock. When he was first seen on the 3rd day there were small vesicles in clusters with surrounding erythema scattered along the lower half of the medial aspect of the left thigh, and there was one

cluster just above the patella. There were also clusters of vesicles to the left of the sacral cornu and a few early erythematous, nonvesicular lesions scattered along the upper half of the medial surface of the left leg along the margin of the gastrocnemius.

Treatment with aureomycin, 1 gm orally 4 times a day, was begun at that time and continued for a total of 22 gm. There were no untoward effects. After 2 days of this therapy the pains were entirely gone, there was only slight itching, and the lesions were beginning to dry. The itching had completely subsided and the lesions were almost completely healed when the therapy was stopped. There were no recurrences of pain or lesions.

CASE 24 This patient first experienced severe lancinating pains, which began at about the angle of Louis and radiated around the right side of the chest. General malaise and ano-

patient had had one episode of vomiting 3 hours after one of the doses, so she was asked to take 0.5 gm 4 times daily. On the 4th day there was minimal burning (chafing) in the axilla, and a few small dry crusts had already appeared. On the next day the dose was again dropped to 0.5 gm 3 times a day because of nausea. By the 7th day the lesions had all dried up and were almost completely encrusted. There was one tender denuded area in the axilla but no evidence of secondary infection. The patient now complained of soreness of the tongue and mouth, but these areas looked normal. Aureomycin was stopped, and the soreness of the tongue and mouth subsided promptly. There was only slight residual burning over the axillary lesions and an occasional twinge of pain over the anterior portion of the chest in the next 2 days. Thereafter the patient was completely symptom free, and the lesions healed. There was no recurrence of the lesions and no post-herpetic pain.

*G = generalized eruption in addition to the segmental lesion. C = cervical, T = thoracic, and L = lumbar the numbers indicating the segment. V₁, V₂ and V₃ indicate the cutaneous distribution of the ophthalmic, maxillary and mandibular branches, respectively, of the trigeminal nerve (V).

† + indicates 2 separate courses or 2 separate episodes.

‡ Post-herpetic pain not prevented.

§ Generalized lesions.

¶ Patient also received aureomycin borate drops in the eye.

|| Two doses of 500 mg given intravenously on successive days, in addition to oral doses.

** Patient relapsed promptly after cessation of treatment (initial response good).

†† Negro patients.

rexia accompanied the pain. After 4 days she noted an erythematous rash over the painful area, and she felt very weak. When she was first seen on the 6th day, she still complained of recurrent pains over the right upper portion of the thorax, but these were somewhat less severe. At this time, however, there was a bullous, confluent zoster eruption with intense erythema extending from the spinous processes of the second, third and fourth dorsal vertebrae around the chest and axilla over the area between the second and fourth ribs to the sternum.

The patient was given 1 gm of aureomycin by mouth 4 times a day, but she returned the next day complaining bitterly of pain and burning over the right deltoid area and in the axilla, which kept her awake throughout the night. A few new lesions had appeared along the posteromedial aspect of the right arm, over the triceps and down to the lower third of the forearm. The patient was reassured and was asked to continue taking the aureomycin, but no analgesic was prescribed. On the following day she returned, obviously happier, and stated that her pains had virtually stopped and that she had only slight burning over the vesicular area. The original lesions on the chest had now begun to dry. The

ANALYSIS OF RESULTS

Some of the relevant data in the 24 cases are listed in Table 1. The total number of patients treated was not large, but an analysis of some of the major features will serve to bring out some of the points of interest in these results.

Effect of Sex and Age

There was a preponderance of males (15) over females (9). The patients ranged in age from twenty-three to eighty-five years, but, as usual in this disease, most of them were in the older age groups; only 5 patients were under fifty, 10 were fifty to sixty-nine and the remaining 9 were over seventy years old. There did not seem to be any correla-

tion between the sex or age of the patients and their response to aureomycin

Effect of the Stage of the Disease When Aureomycin Was Started

Patients whose skin lesions were just beginning to appear when treatment was started are listed in Table 1 as treated in the "initial" stage; those whose erythematous lesions or clear vesicles were still appearing are listed as treated in the "acute" stage, and those treated after the middle of the second week as judged from the onset of symptoms

arrested, and marked improvement followed when aureomycin therapy was resumed and the antibiotic given for two days intravenously. The good effects were maintained in Case 11 by resumption of oral therapy, but in Case 13, in which no further therapy was given, there was another relapse. Post-herpetic pain was not prevented in either of these 2 patients. There was only 1 other patient in this group (Case 17) who had post-herpetic pain in spite of what seemed to be adequate treatment and a good immediate effect on both the lesions and the pain.

or the first appearance of skin lesions, are listed as "late" cases.

By these criteria 3 patients were classified as being in the initial stage and aureomycin was started in them on the second to the fourth day. 14 others were considered to be in the acute stage and were first treated between the second to the seventh day. In all but 2 of these 17 patients the lesions and the symptoms began to show definite evidence of improvement after the first twenty-four hours of therapy. In some cases new lesions appeared during the first twenty-four to thirty-six hours but not later, except in 2 patients (Case 11 and 13), in whom oral therapy had to be interrupted. In both these cases the progress of the disease was then

In 3 patients treatment was first undertaken on the tenth to the fourteenth day, but some of the lesions were fresh and new ones were appearing at the time. They are listed as "late acute." In 2 of these patients (Case 4 and 18) the response was similar to that of the early cases, whereas in the third (Case 10) the result may be considered as quite good in view of the severity of the lesion, the amount of secondary infection and damage present when aureomycin was started and the usually poor prognosis in such cases.

Four patients were treated late in their diseases. In 3 aureomycin was started between the fourteenth and twenty-first days and their lesions and pain improved promptly, in the fourth, treatment was

started with small doses during the fifth week and there was essentially no effect. Post-herpetic pain occurred in 3 of these 4 patients, the only one among them who did not have a recurrence or persistence of pain was the one whose treatment was started on the fourteenth day.

It therefore seems that the best results were obtained in the patients who were treated on or before the middle of the second week after the first appearance of symptoms or lesions. New lesions did not appear after the first day of therapy, and then the pain subsided, the lesions dried up, and healing progressed rapidly. When treatment was interrupted early, new lesions soon appeared and pain recurred, and the progress of the lesions was again arrested by resumption of therapy. In an occasional case, post-herpetic pain appeared in spite of early and adequate treatment. In the patients treated after the end of the second week, there may have been some beneficial effect on the lesions, and there was immediate alleviation of the pain, but the post-herpetic pain was not prevented.

Effect on the Lesions

Rapid evolution and clearing of the lesions usually began within or shortly after the first twenty-four hours of aureomycin therapy. The intense erythema, when present, lessened quite promptly. The vesicles then began to dry and were usually well dried up and encrusted between two and four days after the first dose. Complete healing occurred in the great majority of cases by the seventh or eighth day, when there was left either no trace of the lesions or only a faintly erythematous scar at the site.

Appearance of New Lesions

There were 3 patients (Case 2, 22 and 24) in whom new lesions continued to appear during the first day of therapy and a fourth (Case 14) in whom such lesions occurred during the first two days while full doses of aureomycin were given. In Case 2 these were generalized lesions. In these 4 patients all the lesions began to dry up shortly thereafter, and the progress of the disease was otherwise favorable. In 3 other patients (Case 1, 11 and 13) new lesions appeared only after the early interruption of therapy.

Effect of the Site of the Lesion

There were 5 patients in this series in whom the lesions involved the cutaneous distribution of the ophthalmic branch of the trigeminal nerve, and in 1 of them the area of distribution of the maxillary nerve was also affected. One of these patients (Case 10) already had severe secondary infection of the conjunctivas with a mixture of pyogenic organisms, and there was also involvement of the cornea with herpetic lesions. In addition, this

patient had marked nitrogen retention. The progress of the herpes was promptly arrested after aureomycin was started, and the secondary infection cleared but recurred shortly after the therapy was stopped. Another of these patients (Case 13) was the one who would not continue treatment, and the lesions progressed after temporary improvement, this patient was the only one in whom there was a residuum of corneal damage and impairment of vision. The 3 remaining patients with ophthalmic herpes zoster all responded favorably and have any corneal lesions.

There was also 1 patient with in the area of the mandibular branch in whom the herpes involved the 1 of the trigeminal nerve. In both treatment was begun early. The former cleared rapidly, the 1 the one whose lesion progress was interrupted but again aureomycin was resumed.

The remaining patients the trunk and extremities.

Generalized Herpes Zoster

In addition to the segmental 3 patients (Case 2, 15 and 16) lesions or small groups of parts of the body. In 2 patients at the time aureomycin third they appeared during the first dose was given promptly and complete was started.

There was no clinical system involvement in other patients in this however, were not done was any asymptomatic.

Effect on Pain

The immediate striking. Severe pain reduced after the first and were usually cleared five days. In a few continued with days longer.

Post-herpetic pain. Late pain was not including 3 in whom middle of the third; (Case 13) in whom not resumed. In 1 herpetic pain occurring inadequate response of the skin. In 17) an attempt was further aureomycin only two days, and

pain decreased slightly in intensity but the benefit derived was not considered sufficient to warrant continuing the therapy.

Dosage

The total dose used in these cases (excluding Case 13) varied from 7.5 to 54 gm and was given over periods ranging from three to seventeen days. Three fourths of the patients were treated for three to seven days and all but 4 received 25 gm or less. The average was about 19 gm given in six and a half days. From these observations the dose recommended at present is 4 gm daily until the lesions show definite signs of healing — usually about two to four days — and 2 gm daily for three to five days longer. The daily dose may be divided and given after each meal and on retiring.

Untoward Effects

The only evidence of any toxic effects from aureomycin was the occurrence of nausea in most of the patients. There was occasional vomiting in some, and a few had large, bulky bowel movements. These manifestations were usually encountered only during administration of the full doses of 4 gm or more daily, and nausea or vomiting was particularly apt to occur when individual doses of 1 gm each were taken on an empty stomach. They usually did not appear until after the second or third day and at a time when the lesions already showed signs of regressing. They were readily controlled in most of the patients by reduction of the dose, and only rarely were they severe enough to interfere with effective therapy. In such cases the drug could be given intravenously without untoward effects. There was 1 patient in whom angioneurotic edema of the tongue and mild generalized urticaria occurred after six days of oral administration of aureomycin but this patient also received other drugs (codeine and barbiturates), which might have been responsible for these manifestations, and the toxic effects cleared promptly after all medications were stopped.

Follow-up Study

Some of the patients were seen frequently after their aureomycin therapy was ended, and all but 1 were seen or heard from shortly before this report was completed. The last observation in these cases was made from six to eight months after therapy was started in 6 patients, after three to six months in 7, between five and ten weeks in 5 and after two to four weeks in the remaining 6 patients.

The occurrence of post-herpetic pain in 6 patients was mentioned above, this lasted from two weeks up to three months.

In only 2 patients was there a recurrence and extension of the skin lesions after therapy was stopped. One of these was the first patient treated,

and the aureomycin was started during the fifth week and only small doses were used, the other was the patient (Case 13) who refused further treatment after two intravenous doses and relapsed after leaving the hospital. This was the only patient who had residual corneal opacities and impairment of vision.

In most of the patients in whom treatment was started early the site of the original lesions was no longer discernible. In a few there were some superficial scars, and in others there was slight pigmentation in some of the sites of the lesions.

DISCUSSION

The cases presented above strongly suggest that aureomycin has a definite, beneficial effect on the course of herpes zoster. It should be emphasized, however, that although these results were obtained in consecutive cases, no parallel control series of cases was observed either without therapy or under other forms of therapy. The feature of these results that suggests a highly beneficial if not a specific effect is the fairly regular and characteristic response in all patients receiving adequate amounts of this antibiotic in the early or active stage of the disease.

It seems highly unlikely that this benefit is wholly the result of an effect on secondary bacterial infection. Although such an effect undoubtedly played a part in some of the cases there was no evidence of bacterial infections in most of the patients. Furthermore, other potent antibacterial agents, notably penicillin, have not had any similar effect although they may have favorably influenced the progenic component of the lesions. Perhaps more significant is the fact that new herpes-zoster lesions have not developed during aureomycin therapy except during the first day or so, although such lesions have appeared after treatment was interrupted too soon.

Mention has been made by one reliable observer¹⁶ that herpes zoster has developed during the course of aureomycin treatment for other infections that occurred after nephrectomy. In a personal communication Schoenbach has mentioned another patient who was treated for a urinary-tract infection following a left nephrectomy and in whom "herpes zoster" developed on the right lower quadrant and back on the seventh day of aureomycin treatment (2 gm daily) and 2 weeks after the nephrectomy. In view of these cases, the estimate of the specific value of aureomycin in this disease, as suggested by the experience in the present series of cases, may have to be revised.*

Results similar to those noted in these cases have been reported from Chloromycetin in 4 cases that were treated in the acute stage. Post-herpetic pain

*Schoenbach, in a personal communication, has also observed 5 patients with typical herpes zoster who showed a rapid clinical improvement similar to those described in this paper. These 5 patients had not had any operations.

started with small doses during the fifth week and there was essentially no effect. Post-herpetic pain occurred in 3 of these 4 patients, the only one among them who did not have a recurrence or persistence of pain was the one whose treatment was started on the fourteenth day.

It therefore seems that the best results were obtained in the patients who were treated on or before the middle of the second week after the first appearance of symptoms or lesions. New lesions did not appear after the first day of therapy, and then the pain subsided, the lesions dried up, and healing progressed rapidly. When treatment was interrupted early, new lesions soon appeared and pain recurred, and the progress of the lesions was again arrested by resumption of therapy. In an occasional case, post-herpetic pain appeared in spite of early and adequate treatment. In the patients treated after the end of the second week, there may have been some beneficial effect on the lesions, and there was immediate alleviation of the pain, but the post-herpetic pain was not prevented.

Effect on the Lesions

Rapid evolution and clearing of the lesions usually began within or shortly after the first twenty-four hours of aureomycin therapy. The intense erythema, when present, lessened quite promptly. The vesicles then began to dry and were usually well dried up and encrusted between two and four days after the first dose. Complete healing occurred in the great majority of cases by the seventh or eighth day, when there was left either no trace of the lesions or only a faintly erythematous scar at the site.

Appearance of New Lesions

There were 3 patients (Case 2, 22 and 24) in whom new lesions continued to appear during the first day of therapy and a fourth (Case 14) in whom such lesions occurred during the first two days while full doses of aureomycin were given. In Case 2 these were generalized lesions. In these 4 patients all the lesions began to dry up shortly thereafter, and the progress of the disease was otherwise favorable. In 3 other patients (Case 1, 11 and 13) new lesions appeared only after the early interruption of therapy.

Effect of the Site of the Lesion

There were 5 patients in this series in whom the lesions involved the cutaneous distribution of the ophthalmic branch of the trigeminal nerve, and in 1 of them the area of distribution of the maxillary nerve was also affected. One of these patients (Case 10) already had severe secondary infection of the conjunctivas with a mixture of pyogenic organisms, and there was also involvement of the cornea with herpetic lesions. In addition, this

patient had marked nitrogen retention. The progress of the herpes was promptly arrested after aureomycin was started, and the secondary infection cleared but recurred shortly after the therapy was stopped. Another of these patients (Case 13) was the one who would not continue treatment, and the lesions progressed after temporary improvement, this patient was the only one in whom there was a residuum of corneal damage and impairment of vision. The 3 remaining patients with ophthalmic herpes zoster all responded favorably and did not have any corneal lesions.

There was also 1 patient with involvement of the area of the mandibular branch and another in whom the herpes involved the maxillary branch of the trigeminal nerve. In both these patients treatment was begun early. The lesions in the former cleared rapidly, the latter (Case 11) was the one whose lesion progressed when treatment was interrupted but again improved when aureomycin was resumed.

The remaining patients all had involvement of the trunk and extremities.

Generalized Herpes Zoster

In addition to the segmental lesions there were 3 patients (Case 2, 15 and 20) who had isolated lesions or small groups of vesicles over all other parts of the body. In 2 patients they were present at the time aureomycin was started, and in the third they appeared during the first few hours after the first dose was given. These lesions all cleared promptly and completely after the aureomycin was started.

There was no clinical evidence of central-nervous-system involvement in any of these or any of the other patients in this series. Lumbar punctures, however, were not done to determine whether there was any asymptomatic involvement.

Effect on Pain

The immediate effect on the pain was quite striking. Severe pain and itching were markedly reduced after the first twenty-four hours of therapy and were usually completely relieved in four or five days. In a few patients, however, the pain continued with diminishing intensity for a few days longer.

Post-herpetic pain was mentioned above. This late pain was not prevented in 6 of the patients, including 3 in whom therapy was started after the middle of the third week of the disease and a fourth (Case 13) in whom therapy was interrupted and not resumed. In the other 2 patients the post-herpetic pain occurred in spite of early and seemingly adequate therapy and in spite of a good response of the skin lesions. In 1 of the latter (Case 17) an attempt was made to influence the pain by further aureomycin therapy. This was given for only two days, and the patient stated that the

PROSTHESIS FOLLOWING HEMIPELVECTOMY*

JOHN F. COOPER, M.D.,† AND GRANTLEY W. TAYLOR, M.D.‡

WEST ROXBURY, MASSACHUSETTS

A MAJOR problem in the rehabilitation of patients subjected to hemipelvectomy has been the adaptation of a suitable prosthetic appliance. Owing to the rarity of this type of amputation both the surgeon and the artificial-limb manufacturer have had few opportunities to clarify the problem. The purpose of this report is to present

in 1916. Later reviews of the subject with presentation of cases were recorded by Judin,³ Gordon-Taylor,^{4, 5} Leighton,⁶ Morton,⁷ Sugarbaker⁸ and Pack et al.^{9, 10} The last authors, in their comprehensive work on exarticulation of the extremities for cancer, reaffirm the idea that a useful prosthesis has never been devised for these patients subjected

FIGURE 1 Extent of Amputation

an efficient prosthetic appliance of this character and to record a case of its successful use.

In the last half century 138 cases of hind-quarter amputation have been reported in the literature. This radical surgical procedure was first performed successfully in 1895 by Girard¹ and later standardized by the methodical work of Hogarth Pringle.²

*Published with the permission of the Chief Medical Director, Department of Medicine and Surgery, Veterans Administration, who assumes no responsibility for the opinions expressed or the conclusions drawn by the authors.

to hemipelvectomy. Perforce, the patient learns to sit on the remaining ischial tuberosity and becomes adept in the use of crutches.

It is recognized that the successful adaptation of a prosthesis in these cases is difficult and wholly dependent upon the personality and physical status of the patient. A lithe, young, energetic and co-operative patient naturally possesses greater potentialities for complete rehabilitation than the apathetic, more passive subject. The case reported below represents the successful prosthetic reha-

was not affected by the Chloromycetin in 2 other cases³² Initial experiences in 3 early cases of herpes zoster treated with Chloromycetin in this clinic seem to substantiate these findings

It is to be borne in mind that many other agents have, in the past, been claimed to have striking and specific effects in this disease³⁷ These will not be reviewed here Suffice it to say that none of them have thus far gained acceptance or wide use as specific therapeutic agents for herpes zoster Further experience will be necessary to ascertain the true value and place of aureomycin (and Chloromycetin)

Brief mention may also be made of aureomycin in herpes simplex Claims have been made of beneficial effects from this antibiotic in patients with skin lesions considered to be due to the virus of herpes simplex^{29, 31} (herpes labialis and Kaposi's varicelliform eruption) We have observed several cases in which the lesions of herpes labialis healed fairly rapidly under systemic treatment with aureomycin Some of these patients believed that they were definitely benefited by the aureomycin in that their lesions healed much more rapidly than they had in previous similar episodes Most of these patients, however, had coincident impetiginous lesions or superimposed staphylococcal and streptococcal infections, and the improvement could be interpreted as a result of the effect on these secondary infections

As opposed to these apparently favorable results, at least 4 patients have now been observed in this hospital in whom characteristic herpes labialis appeared and extended during treatment with full doses of aureomycin given for acute bacterial infections³⁸ The latter observations are much more significant and render it unlikely that aureomycin has a specific action against herpes-simplex infections It is possible, of course, that multiple agents are involved in the etiology of these types of lesions or that there are strain differences in the susceptibility of the herpes virus to aureomycin This possibility must also be considered, of course, in cases of herpes zoster

SUMMARY

The relevant findings in 24 cases of herpes zoster treated with aureomycin are presented

Aureomycin appeared to halt the progress of this disease and to bring about rapid healing of the lesions Vesicles dried up and became encrusted in the first two to four days after treatment was started and proceeded to heal rapidly and completely thereafter In occasional patients new lesions appeared during the first day of treatment but not later unless the therapy was interrupted

The pain accompanying the acute lesions also subsided after the first day of therapy Post-herpetic pain rarely occurred in the patients whose treatment was begun early and was maintained in adequate dosage, but it was not prevented in the pa-

tients in whom treatment was begun more than two weeks after the first appearance of the lesions

The oral dosage found to be effective in these cases was 4 gm daily (1 gm after each meal and at bedtime) for two to four days, or until the lesions were well dried and encrusted Half this dose is given for an additional three to five days and may also be used throughout when the larger doses are not tolerated Intravenous doses of 500 mg daily likewise appear to be effective and may be used if the oral dose is not well tolerated The optimum intravenous dosage, however, was not ascertained

it was found necessary to displace the center of gravity of the artificial limb several inches laterally to force the patient to shift his weight to his sound limb after initially bearing weight on his prosthesis. In this manner any tendency to shift weight toward the prosthetic or unstable side of the body in motion was effectively minimized.

With the foregoing type of prosthesis the patient rapidly became ambulant and manifested complete satisfaction with his appliance. The extent of the amputation, the patient with the prosthesis applied and the appliance itself are shown in Figure 1 to 3. At present he is able to walk without the aid of a cane or crutch, with only a moderate limp resulting from the required shortening of the appliance. He is able to ascend and descend several flights of stairs with ease. The only apparent disadvantage is that he requires considerable aid in attaching his prosthesis, which is bulky and difficult for him to apply without assistance.

SUMMARY

Adaptation of a prosthetic appliance after hemipelvectomy has proved a difficult problem in the

past. This is apparent in a review of the current literature. A case of chondrosarcoma of the acetabulum in which the patient was subjected to hemipelvectomy, with subsequent complete rehabilitation as a result of the development of a suitable and efficient artificial limb, is presented.

MANAGEMENT OF TRIAL LABOR*

THOMAS F. FOLEY, M.D.†

MANCHESTER, NEW HAMPSHIRE

OBSTETRIC patients usually fall into three broad clinical groups. First, a fairly large number have normal pelvic measurements and satisfactory labor and deliver without difficulty. Secondly, a very small number have pelvic measurements that make normal delivery impossible, with cephalopelvic disproportion evident both clinically and by x-ray examination — it is readily apparent that elective cesarean section is indicated for these patients. Thirdly, a large number have what might be termed "border-line" pelvic measurements that place them in the mind of the examiner as suspects for cephalopelvic disproportion. The prognosis for delivery through the pelvis in the third group may be somewhat doubtful. It is this particular group that I should like to discuss, because conservative management will result in a high percentage of uncomplicated pelvic deliveries if the patients are given a trial labor.

It may be well to recall that there are five components of cephalopelvic disproportion: the size and shape of the pelvis, the size of the fetal head, the position and presentation of the fetus, the degree of molding to which the head is subjected, and the force of the labor pains. Of these, only the

first, the size and shape of the pelvis, is susceptible to accurate measurement before labor begins. Current methods of fetal cephalometry have not proved satisfactory.

The final position and presentation cannot be adequately determined until the onset of labor, because an unfavorable presentation is often converted into a more favorable one by the forces of labor. The most important factor in determining the outcome in the group under discussion is the quality of the labor pains. One has no way of pre-determining the nature of the labor. The quality of the labor pains is important, because satisfactory labor will frequently more than compensate for small pelvic diameters, and a normal pelvic delivery will result.

I do not wish to place too much emphasis on x-ray pelvimetry, but when the question of cephalopelvic disproportion arises it is very helpful toward intelligent management of the situation. X-ray examination of the pelvis is indicated if the clinical examination discloses such unfavorable signs as the ability to touch the promontory easily on vaginal examination, angulation of the sacrum, narrowing of the outlet and failure of a primipara to engage at term, to mention only a few.

*Presented at the annual meeting of the New Hampshire Medical Society, Newcastle, June 1949.

†Associate obstetrician, Elliot Hospital.

bilitation of an agile and earnest young man who made a rapid recovery after hemipelvectomy for a chondrosarcoma of the acetabulum

CASE REPORT

F R, a 24-year-old Navy veteran, was admitted to the Orthopedic Service of the Veterans Administration Hospital, West Roxbury, Massachusetts, on April 21, 1947, complaining of recurrent pain in the right hip of 4 years' duration following minor trauma. This pain had a tendency to develop while the patient was at rest, particularly in the sitting position.

The past and family histories were noncontributory.

Physical examination was entirely negative except for limited motion of the right hip. X-ray study revealed a destructive cystic process involving the right acetabulum. Pertinent laboratory studies revealed only an elevated blood cholesterol of 240, 275 and 289 mg per 100 cc, and an alkaline phosphatase of 5.3 Bodansky units. X-ray films of the chest and a bone series were normal.

Biopsy of the lesion on May 5, 1947, demonstrated numerous, free, cartilaginous bodies within the joint space. A pathological diagnosis of chondrosarcoma was made on

that time adequate shrinkage of the stump had occurred and sufficient consolidation of tissue had taken place so that weight bearing was possible. It should be realized that no true stump was actually present but only a soft-tissue mass composed of anterior and posterior abdominal parietes, which provided weight-bearing surface.

The prosthesis itself was of the conventional willow-wood type with the usual knee and ankle articulation designed in the standard fashion of all artificial-limb manufacturers. In addition to

FIGURE 2 Patient with Prosthesis in Place

examination of this material. At a later date a right sacro-iliac disarticulation was performed, and the patient made a remarkably rapid and uneventful recovery. He was soon able to be about on crutches with surprising agility. Pathological examination confirmed the original diagnosis and disclosed disease arising in the acetabulum with invasion of the ilium to within 1 or 2 mm of the pelvic surface. There was also moderate involvement of the femoral neck and joint capsule. Repeated follow-up x-ray examinations of the chest have been negative for metastasis.

DISCUSSION

The prosthetic appliance was not provided for the patient until six months had elapsed. During

FIGURE 3 Photograph of the Prosthetic Appliance

these articulations, a steel hip-joint device, which locked in extension and could be readily released for flexion of thigh in the sitting position, was developed. A preliminary cast of the amputation site enabled the manufacturer to evolve a "leather bucket" composed of molded laminated cowhide, which closely approximated the contours of the stump. This was fashioned so that weight was borne on the soft-tissue mass anteriorly, laterally and inferiorly, without direct pressure on the coccyx or opposite ischial tuberosity. To ensure union of the prosthesis and patient there was a wide abdominal belt fastening anteriorly, with the added support of a broad shoulder strap applied over the left shoulder.

The problem of stability of the patient in motion was solved in an ingenious manner by the limb maker. It was recognized that the sound limb of the subject was the keystone of stability and function, and therefore the artificial limb was so designed as to compel the subject to utilize it as a secondary aid in locomotion rather than a primary one. Thus,

observed that the hematologic response to folic acid paralleled that which followed treatment with concentrated liver extract in cases of macrocytic anemia, but the rate of regeneration was greater with a potent liver extract. Berk et al.¹⁷² reported the reticulocyte responses and initial rises in the red-cell count and hemoglobin of 12 patients with pernicious anemia treated with daily doses of 10 mg of folic acid intramuscularly to be comparable to those seen with purified liver extract. In general the evidence is against folic acid in cases of Addisonian pernicious anemia and nontropical sprue. Hall and Watkins¹⁷³ found that the maximal reticulocyte response was lower after folic acid therapy as compared with liver extract, and that in 3 cases the red-cell count did not increase above 3,500,000 despite prolonged treatment with folic acid. An unsatisfactory hematologic response to folic acid was observed in 9 of 10 patients with the sprue syndrome, but these patients had a normoblastic bone marrow, although their peripheral red blood cells were macrocytic.¹⁷⁴ A similar observation was made by Weir and Comfort.¹⁷⁵ There are even reports of hematologic relapses in Addisonian pernicious anemia during prolonged therapy with adequate doses of folic acid¹⁷⁶⁻¹⁷⁸ but with subsequent remissions after administration of liver extract. Jones et al.¹⁷⁹ also record a case of nontropical sprue in which a hematologic relapse developed after good initial response to folic acid and the patient subsequently improved with vitamin B₁₂ therapy.

In contrast to these two diseases, folic acid has proved to be effective hematopoietically in other types of megaloblastic anemia that are refractory to liver extract and vitamin B₁₂.¹⁸⁰⁻¹⁸³

The failure of folic acid to alleviate or prevent the neurologic sequelae of Addisonian pernicious anemia has been reported by so many investigators that nearly all clinicians agree with the advice of an editorial in the *Lancet*,¹⁸⁴ which states, "The practical lesson is clear and agreed: folic acid whether alone or with liver extract must not be given to patients with pernicious anaemia." The chief controversy over the use of folic acid concerns its possible toxic effect on the central nervous system. Neurologic manifestations of pernicious anemia appear with much greater frequency after treatment with folic acid than in untreated cases.¹⁸⁵ This complication after folic acid therapy is also more precipitous in nature and involves the posterior columns of the spinal cord more completely than the lateral columns.¹⁸⁶ Such observations suggest that the resultant effect of folic acid on the central nervous system is not identical with "combined-system disease."

Neurologic complications of folic acid therapy are not limited to Addisonian pernicious anemia alone. An occasional case of peripheral neuritis

after folic acid therapy for other macrocytic anemias has been reported.¹⁸⁷⁻¹⁸⁸

Some investigators have believed that folic acid was actually toxic to the central nervous system.¹⁸⁹ This seems to be a minority view, because of the small number of cases other than Addisonian pernicious anemia that have had neurologic complications after prolonged folic acid therapy.¹⁸⁹⁻¹⁹⁰ The occasional case of glossitis or other characteristic signs of vitamin deficiency that appear during the prolonged administration of folic acid is explained on the basis of vitamin imbalance. In view of these observations, it is probable that the peripheral neuritis and possibly the central-nervous-system symptoms associated with folic acid therapy actually represent another manifestation of vitamin imbalance rather than true toxicity.¹⁸⁸

The mechanism whereby folic acid produces a hematologic response is not known. In fact, there is no evidence that there is a dietary deficiency of folic acid in these diseases, but perhaps an impairment in the utilization of folic acid. On the other hand, in the nutritional deficiency disease, tropical sprue, the remarkable effectiveness of folic acid, which has been so well established by Suarez et al.,¹⁹¹ seems to indicate that tropical sprue represents a true primary folic acid deficiency. The effect of folic acid in nontropical sprue has been clinically beneficial according to some observers.¹⁷⁴⁻¹⁹² Darby and his associates¹⁹² noted the return of glucose tolerance tests toward normal in 5 out of 6 cases of nontropical sprue after folic acid therapy, and improvement in the vitamin A absorption curve in 2 cases. Other investigators have not observed any striking benefit of folic acid in cases of nontropical sprue.¹⁷⁵⁻¹⁹³ This difference in result may be due to the fact that cases of idiopathic steatorrhea that do not respond to folic acid are not nontropical sprue but represent fatty diarrhea from other causes.¹⁹² It is possible, however, that some cases of nontropical sprue do not respond to folic acid because the disease has reached an irreversible stage. The mode of action of folic acid in nontropical sprue is not replacement therapy for a deficiency state, since most of these patients have had an adequate diet, however, the therapeutic effect of folic acid may represent a pharmacologic manifestation.

As a result of the investigations that have appeared since Sargent's⁸ review, the place of folic acid in nutrition is now more clearly defined. The vitamin is effective in certain liver-refractory macrocytic anemias and is almost specific for the malnutrition state of tropical sprue. The neurologic complications, glossitis and pellagra associated with folic acid therapy seem to be best explained by vitamin imbalance rather than the toxic effects of folic acid. This member of the vitamin B complex does not have the same hematopoietic effect as liver in the treatment of Addisonian pernicious

The management of a trial labor is essentially the management of *any* labor in addition to the adherence to certain definite principles from the outset. It is important in the conduct of a trial labor to set some reasonable time limit on the length of the trial period. I believe it is fair to state that if after twelve to fifteen hours no progress has been made, the termination of labor by abdominal delivery should be considered. Many factors enter into an evaluation of whether the patient has or has not made progress. Three significant signs or symptoms indicating progress are — effacement and dilatation of the cervix, increase in the strength and frequency of the labor pains and descent of

the head. The last is positive evidence that the patient has made progress.

Lateral films taken at intervals during labor offer concrete proof of whether or not the head was descended. Progress or the lack of progress is the decision that the obstetrician must make as the end of the trial period approaches.

I should like to offer a word of caution regarding strict asepsis during labor. It should be constantly remembered throughout a trial labor that the patient is a potential candidate for cesarean section, and therefore, all examinations should be conducted aseptically. The number of rectal examinations should be reduced to an absolute minimum and not more than one sterile vaginal examination should be permitted during a trial labor.

MEDICAL PROGRESS

VITAMIN SUPPLEMENTATION IN HEALTH AND DISEASE (Concluded)*

PERRY J. CULVER, M.D.†

BOSTON

NEWER VITAMINS

During the last four years, an important place in medical literature has been given to the discovery and therapeutic uses of three newer vitamins that promise much for man. These three substances are folic acid, vitamin B₁₂, and rutin or vitamin P. At present it is impossible to ascertain whether the clinical response to these supplements is due to alleviation of a deficiency of the specific newer factor or whether benefit results from a pharmacologic effect.

Folic Acid

The fast-moving history of the discovery, identification, synthesis, physiology and therapeutic uses of folic acid was well reviewed by Sargent⁸ in 1947. To paraphrase his summary, folic acid is known chemically as pteroylglutamic acid, which is the active form of this newer member of the vitamin B complex. The vitamin occurs in many foods such as liver, green vegetables, kidneys and yeast, but it is usually in the physiologically inactive conjugated form, pteroylheptaglutamic acid (vitamin B₉ conjugate). An enzyme, vitamin B₉ conjugase, which liberates the active pteroylglutamic acid, is present in many mammalian tissues. Foods contain a conjugase inhibitor, which impedes the hydrolytic activity of the vitamin B₉ conjugase.

The amount of pteroylglutamic acid in the ordinary diet is far less than the usual therapeutic level of folic acid, which is estimated at 5 to 10 mg daily.

Pteroylglutamic acid has been effective in promoting a hematopoietic response in the various macrocytic anemias, in some of the sprue syndromes and in certain cases of "chronic diarrhea" due to nutritive failure. The natural heptapeptide, pteroylheptaglutamic acid, was found to be ineffective in Addisonian pernicious anemia, whereas the synthetic pteroylglutamic acid was utilized. The explanation of this observation is that patients with Addisonian pernicious anemia are unable to neutralize the conjugase inhibitor. Initial enthusiasm for the use of folic acid in Addisonian pernicious anemia was soon dampened by reports of the explosive appearance of neurologic complications in such cases, and for this reason the management of Addisonian pernicious anemia with pteroylglutamic acid was not recommended.

Folic acid was found to have no effect on the anemias associated with iron deficiency, cancer, leukemia and lymphoma, nor on aplastic anemia, agranulocytosis and thrombocytopenic purpura.

The numerous reports on folic acid that have appeared since Sargent's review primarily confirm the findings already summarized, but some clarify certain doubtful points and more definitely define the final place of folic acid in therapeutics.

There has been considerable discussion of the relative hematopoietic effect of folic acid as compared with liver extract. Frommeyer and Spies¹⁷¹

*From the Medical Clinics, Massachusetts General Hospital and the Department of Medicine, Harvard Medical School.

†Associate in medicine, Harvard Medical School, assistant in medicine, Massachusetts General Hospital.

of its diuretic action in 12 of 16 patients with normal blood pictures²⁰⁷ The investigators who report this finding speculate that large doses of vitamin B₁ may cause a vasodilation owing to the action of cobalt

The minimal and optimal dosage of vitamin B₁ has already become the subject of considerable difference of opinion On the basis of the original reports, it was believed that 1 gamma of vitamin B₁₂ was approximately equal to 1 *U S P* unit of liver extract,¹⁹⁴ and bioassay of several commercial liver extracts showed that vitamin B₁ might have an even greater potency¹⁹⁴ Subsequent clinical trials showed that 1 gamma of vitamin B₁ per day produced a maximum reticulocyte response in some cases^{200 201} and that, by comparison of the rates of increase in red-cell count, 1 gamma of vitamin B₁ was approximately equal to 1 *U S P* unit of liver extract¹⁹⁵

Sturgis²⁰⁸ reports that as little as 0.45 gamma of vitamin B₁ per day will produce a definite although substandard hematologic response The general consensus is that the rate of utilization of vitamin B₁ approximates 1 gamma per day and with daily administration at this level, there is no storage of the vitamin¹⁷⁹

Some investigators believe that the reticulocyte response does not parallel the rate of hemoregeneration and that the latter is a truer measure of vitamin B₁ activity^{179 209} By such determinations it is shown that more than 1 gamma of vitamin B₁ per day is necessary for a maximum rate of erythropoiesis,¹⁷⁹ and Jacobson²⁰⁹ believes that 3 or 4 gamma per day is needed to achieve the maximum rate of red-cell regeneration

Jacobson²⁰⁹ also suggests that 3 or 4 gamma of vitamin B₁₂ may be needed to equal the biologic activity of 1 *U S P* unit of liver He explains this observation, which is at variance with the bioassay measurement of vitamin B₁ in terms of *U S P* liver units,¹⁹⁴ by postulating the presence of accessory factors in liver extract that may be important for the therapeutic activity of vitamin B₁²⁰⁹

The controversy about the *U S P* liver-unit value of 1 gamma of vitamin B₁₂ appears to be merely one of definition — namely, the measure of 1 *U S P* unit of liver Since crystalline vitamin B₁ is administered in weighed amounts, it can be expected to produce more uniform clinical results than liver extract, whose potency may be rather variable because it is established by bioassay Moreover, the differences of opinion about the values for the minimal and optimal doses of vitamin B₁₂ could be explained easily on the basis of the differences in requirement among the various patients with pernicious anemia A safe working rule might be to administer 15 to 25 gamma of vitamin B₁

per week until the red-cell count had returned to normal and then to maintain the patient on a dose approximating 1 gamma per day

Vitamin B₁₂ has other advantages over liver extract in that the vitamin, which seems to be non-allergenic, can be safely administered to patients who are sensitive to liver extract,²⁰⁴ and much larger amounts of the antipernicious-anemia factor can be given in a single dose of vitamin B₁₂

The specificity of pteroylglutamic acid for certain anemias and of vitamin B₁₂ for others offers promise of a better understanding of the nature of the macrocytic anemias

Rutin (Vitamin P)

Vitamin P, first described in 1936 as a possible food factor associated with the integrity of the walls of blood capillaries,²¹⁰ did not get an adequate clinical trial until 1944, when Griffith et al²¹¹ reported that rutin had restored the increased capillary fragility to a normal state in 8 of 11 cases associated with hypertension

The term vitamin P encompasses several closely related flavone glucosides derived from plants Various forms of the vitamin have been known as citrin, hesperidin and rutin²¹² Citrin is a crude product containing vitamin C as well as hesperidin and other flavone glucosides Hesperidin and rutin are pure crystalline products The clinical response to vitamin P has been determined by changes in the capillary-fragility test^{211 212} and by clinical improvement The specificity of vitamin P for the treatment of increased capillary-fragility states seems well established by the recurrence of increased capillary fragility when vitamin P therapy is discontinued and subsequent restoration of normal fragility with readministration of the vitamin²¹¹ On the basis of a small number of observations, Shanno²¹² expressed the belief that rutin might be superior to hesperidin

The spectrum of therapeutic indications for vitamin P continues to broaden as an increasing number of clinical observations are published Shanno²¹² found that rutin was of value in preventing vascular accidents in patients with hypertension, maintaining normal capillary fragility in patients being treated with thiocyanate and controlling pulmonary bleeding of an unexplained nature but associated with increased capillary fragility Rutin offers hope of being a specific remedy for the treatment of familial hemorrhagic telangiectasia²¹³

The capillary fragility was improved by doses of vitamin P ranging up to as much as 300 mg per day in two series of diabetic patients who showed diabetic retinopathy, but in neither series was there any evidence that vitamin P improved the pathologic state of the eye grounds^{214 215} On the other hand, MacLean and Brambel²¹⁶ observed 21 patients with vascular retinopathies, other than diabetic, in which rutin and Dicumarol together

anemia, and the necessity for using folic acid in cases of pernicious anemia that are sensitive to liver extract no longer needs to be considered, since the discovery of vitamin B₁₂.

Vitamin B₁₂

After one false stop at folic acid, the twenty-year search for the antipernicious-anemia factor of liver extract appears to have achieved its goal with the discovery of vitamin B₁₂. In 1948 Rickes et al¹⁹⁴ reported the isolation from concentrated liver extracts of minute quantities of a red crystalline material, which Shorbf¹⁹⁶ found to be eleven thousand times more active than potent liver extracts by a bioassay method that appeared to be very specific for the antipernicious-anemia factor. The clinical effectiveness of this crystalline material was demonstrated by West,⁵⁰ who found that 3, 6 and 150 gamma of vitamin B₁₂ produced a positive hematologic response in 3 cases of Addisonian pernicious anemia. The crystals were named vitamin B₁₂ because that term was nonspecific and connoted only nutritional significance.¹⁹⁴ Although the chemical nature of vitamin B₁₂ is still undetermined, further investigation has shown it to be a cobalt complex.¹⁹⁶ This is the first time that cobalt has been shown to be an essential trace element in human nutrition. The red color of the crystals is explained in part at least by their cobalt content. The vitamin is heat stable but is inactivated at room temperature in dilute alkaline or dilute acid solutions.¹⁹⁶

Scarcity of vitamin B₁₂ greatly limited its clinical trial at first. The presence of vitamin B₁₂ activity in many foods led to the search for a more plentiful source of this factor, and *Actinomyces (Streptomyces) griseus* was found to produce a red crystalline substance that had the same physical, biologic and clinical properties as vitamin B₁₂ from liver.¹⁹⁷⁻¹⁹⁸ As a result, crystalline vitamin B₁₂ from *A. griseus* is now readily available and relatively inexpensive.

A rapidly growing number of reports confirm West's original observation of the hematologic effectiveness of intramuscular vitamin B₁₂ in patients with pernicious anemia,¹⁷⁹⁻¹⁹⁹⁻²⁰² and the vitamin produces responses equal to those obtained with liver extract in cases of nutritional macrocytic anemia,¹⁷⁹⁻¹⁹⁹⁻²⁰³ nontropical sprue¹⁷⁹⁻¹⁹⁹ and tropical sprue.²⁰³ Adequate doses of vitamin B₁₂ produce a maximal reticulocyte response in four to nine days²⁰⁰⁻²⁰³ and restoration of the red-cell count, white-cell count and platelets to a normal level in four to eight weeks, but in some cases, Hall and Campbell²⁰⁰ observed that after 8 weeks of therapy with as much as 160 gamma of vitamin B₁₂, the red-cell count reached a plateau at 4,000,000 to 4,500,000. This incomplete response was attributed to either inadequate dosage or the elderly state of the patients. The rapidity with which the bone

marrow changes from a megaloblastic to a normoblastic state is amazing. Within nine hours of the injection of 1 gamma of vitamin B₁₂, definite maturation of the megaloblasts was noted,²⁰⁰ and complete restoration of the bone marrow to a normal state occurred within forty-eight to ninety-six hours.²⁰⁰⁻²⁰² Clinical improvement in cases of pernicious anemia occurred within two to five days of the onset of therapy.²⁰²⁻²⁰³ Patients with tropical sprue showed a decrease in bowel movements and abdominal distention six or seven days after treatment was begun.²⁰³

The inadequacy of folic acid in preventing the development of central-nervous-system complications in patients with Addisonian pernicious anemia led to the postulation of a deficiency of two liver factors in pernicious anemia. One factor was folic acid, which promoted the maturation of erythrocytes, and the other a hypothetical nutrient required for the prevention of neurologic damage. Such a postulation became unnecessary when Berk et al²⁰⁴ found that vitamin B₁₂ caused a marked improvement in the neurologic symptoms that developed in a patient with pernicious anemia who was receiving pteroylglutamic acid. As a result of this observation, later confirmed by others,²⁰¹⁻²⁰³⁻²⁰⁵ Berk and his co-workers²⁰⁶ stated that a deficiency of vitamin B₁₂ may be closely related to the natural origin of both the blood and nervous changes of pernicious anemia. The glossitis of pernicious anemia also responds to vitamin B₁₂,²⁰¹⁻²⁰²⁻²⁰⁵ a fact that adds weight to the belief that vitamin B₁₂ is the antipernicious-anemia factor of liver extract.

A new concept of the pathogenesis of pernicious anemia and of the role of the intrinsic factor has resulted from experiments with oral administration of vitamin B₁₂ to patients with Addisonian pernicious anemia. Berk et al²⁰⁶ found that oral administration of vitamin B₁₂ was ineffective hematopoietically, but when given orally with neutralized gastric juice from a normal person, vitamin B₁₂ elicited a reticulocyte response of as much as 16 per cent with a rise in the red-cell count. A similar observation is reported by Spies and his associates.²⁰³ Fecal analysis for vitamin B₁₂ activity²⁰¹⁻²⁰⁶ showed an excretion of many times the amount of vitamin B₁₂ needed for treatment. These findings suggest that vitamin B₁₂ is closely related to the extrinsic (food) factor and that the purpose of the intrinsic (stomach) factor is to promote absorption of vitamin B₁₂ from the intestinal tract, rather than to react with the extrinsic factor to produce the erythrocyte maturation factor. Consequently, the fundamental defect in Addisonian pernicious anemia may be inadequate intestinal absorption due to a deficiency of intrinsic factor.

Another property of vitamin B₁₂, unrelated to the macrocytic anemias, is an unconfirmed report

polyuria, muscular weakness lassitude and headache. These represent earlier symptoms and are a warning to discontinue the drug.²³¹ More serious results of vitamin D intoxication include metastatic tissue calcification, renal insufficiency and death.²³¹⁻²³³ In general, the toxic symptoms of vitamin D poisoning are associated with a rise in serum calcium but toxic manifestations are also found without any evidence of serum calcium elevation.¹⁴⁷ This suggests that vitamin D itself is toxic aside from its effect upon calcium metabolism. It is safe to assume that any dose greater than 50,000 units per day is potentially dangerous. A high milk consumption may potentiate the toxicity of vitamin D, and the use of vitamin D is contraindicated in cases of arteriosclerosis, hypertension and renal disease.²³²⁻²³⁴ Treatment for vitamin D intoxication includes withdrawal of the medication, elimination of milk from the diet and liberal administration of physiologic saline solution intravenously.²³⁵

As for the other fat-soluble vitamins, large doses of vitamin E caused headaches, dizziness and vertigo¹⁶¹ and such symptoms as a sensation of heat, tingling, headache and tinnitus were temporary ill effects in some patients who received 100 mg of Synkavite or 180 mg of Hvitkinone intravenously.²³⁶

In view of these toxic manifestations although an infrequent occurrence with some of the vitamins, the promiscuous use of massive doses of purified vitamins is not considered justified on the grounds "that they cannot do harm." Another ill effect, although not actually toxicity from the use of large doses of purified vitamins is the appearance of deficiency manifestations that are believed to be on the basis of vitamin imbalance. This subject is discussed further below.

ANTIVITAMINS AND VITAMIN IMBALANCE

As a conclusion to this review of the therapeutic uses of vitamin supplements it is worth while to consider briefly the investigations of antivitamin and vitamin imbalance that may produce a "conditioned" vitamin deficiency.

An antivitamin is defined in an excellent review by Wright⁹ as any substance that interferes with the synthesis or metabolism of a vitamin. This interference may be due to inactivation or destruction of the vitamin or an irreversible combination between the vitamin and the antivitamin. In most cases, however, the antivitamin functions as a competitive inhibitor—that is, it is a substance that is so nearly similar in chemical structure to the vitamin that it can enter into biologic systems in place of the vitamin, but is physiologically inactive. The effect of the vitamin antagonist is dependent upon the ratio of the quantity of the analogue to that of the vitamin.²³⁷ The inhibitory effect of the antivitamin can be abolished

if there is a sufficient supply of the vitamin in question, apparently because there may be a greater natural affinity of the cellular enzyme system for the vitamin.

The original observation that suggested the possibility of antivitamin is the well known antagonism of paraaminobenzoic acid and sulfonamide. It is through the study of bacterial nutrition that many of the vitamin-antivitamin relations have been elucidated. In this way, the search for antivitamin aids in the development of chemotherapeutic compounds. Conversely, antivitamin, by blocking enzyme systems, may be used in establishing the role of various vitamins in metabolism.

In Wright's⁹ review most of the antivitamin mentioned were synthetic products and were primarily research tools.

So far very few antivitamin have been discovered in food, but the demonstration of an anti-niacin compound in corn²³⁸ lends support to the earlier postulation that pellagra was due to the toxic effect of corn and explains why there was an absence of pellagra in persons living on diets that contained much less niacin than those of corn eaters who developed pellagra. The isolation of another natural analogue, the hemorrhagic agent of sweet-clover disease,²³⁹ made it possible to discover vitamin K. Natural antivitamin for thiamine²⁴⁰ and biotin²⁴¹ have been isolated. The antithiamine content of certain raw fish may produce thiamin deficiency in man.²⁴²

More recently certain synthetic antivitamin have offered a ray of hope in the treatment of cancer. The most promising of these to date are the folic acid antagonists, of which the best known is aminopterin.²⁴³

It is theoretically possible for chemotherapeutic agents (antivitamin) to enter into enzyme systems in man and thus to manifest a "conditioned" vitamin deficiency.⁹ Whether antivitamin, through their effect upon intestinal synthesis of vitamins can cause vitamin deficiency in man is open to question, but positive proof of such an effect has not been produced as yet.⁹

The literature on antivitamin is voluminous. In this review discussion is limited to a mere indication of such aspects of antivitamin as are contingent upon the therapeutic use of vitamins.

Attention has been directed occasionally to the concept of vitamin imbalance,²⁴⁴⁻²⁴⁶ a concept that is a strong argument against the use of purified vitamin supplements particularly the members of the vitamin B complex. When pellagrins were given niacin they often showed signs of riboflavin or thiamine deficiency.²⁴⁴⁻²⁴⁶ It was said that niacin "unmasked" the other deficiencies and that most deficiency diseases were multiple. A more probable explanation of this phenomenon is that the use of supplements of niacin increased the

resulted in sufficient improvement to warrant further trial with this type of therapy. Twenty patients with long-standing arthritis who were shown to have increased capillary fragility were studied by Warter et al.²¹⁷ The patients were divided into three groups, one receiving 200 mg of vitamin C alone, a second 200 mg of vitamin P, and the third a combination of 100 mg of vitamin P and 100 mg of vitamin C. The group given vitamin C alone showed no improvement in capillary fragility after four months of therapy. The capillary fragility was improved by the vitamin P in both the other two groups. I can supplement these reports from my own experience with rutin. The daily administration of 60 to 120 mg reduced the bleeding tendency in several patients with liver disease in whom it was previously shown that there was no impairment of the prothrombin function, fibrinogen level or vitamin C status.

Several cases of unexplained bleeding of the gums have been shown to improve and relapse on several occasions as rutin was administered or discontinued.

The minimal requirement for vitamin P has not been determined. In the clinical studies reported above, the dosages have varied from 40 to 300 mg, with an average dosage of 60 to 120 mg per day. No toxic effects have been reported by any investigators, and as much as 15 gm has been given orally without any reaction.²¹⁸ Sulfonamides were shown by Kushlan²¹⁹ to interfere with the efficacy of rutin. As a result, he recommended that, if sulfonamides must be given, the dosage of rutin be doubled or trebled.

TOXICITY OF VITAMINS

Massive supplements of purified vitamins are given too often without concern about any possible toxic effect because it is generally believed that even if the vitamin supplement will do no good, at least it will do no harm. It is fortunate that most vitamins, with the exception of vitamin D, have such a low level of toxicity that the LD₅₀ for animals is in the range of several hundred milligrams per kilogram of body weight. Nevertheless, there are enough scattered reports of toxic manifestations from the use of various vitamins to make one pause before employing the large doses of vitamins that are sometimes given.

It has long been known among Arctic explorers that the ingestion of polar-bear liver will cause a serious illness, and this has been recently explained by demonstration of an excessive vitamin A content of the polar-bear liver. Wolbach²²⁰ studied the effect of excessive amounts of vitamin A upon animals. When 1000 or more international units of vitamin A per gram of body weight was given, absorption of bone occurred, with resulting fractures. There were also weight loss, skin lesions, liver damage due to excessive storing of fat and an increase in the size of the adrenal glands.²²⁰

Several reports of toxic manifestations in human beings have appeared in the literature. In 3 young children who had received doses in excess of 100,000 international units per day over a long period, the outstanding clinical features were anorexia, irritability, bone pain, dry, cracked lips, sparse, coarse hair and hepatomegaly. X-ray studies of the bones showed periosteal proliferation not unlike that seen with scurvy. The children all recovered when vitamin A supplementation was discontinued.^{221, 222} An adult who had taken 6,000,000 units of vitamin A for five successive days was reported to show vertigo, headache, vomiting, excitation and gastric irritability.²²³

The B complex has exhibited relatively few manifestations of toxicity. Among several reports of sudden death following the intravenous injection of thiamine is that of Reingold and Webb,²²⁴ who described a sudden death after the fourth intravenous injection of thiamine that they believed to be due to anaphylaxis. Because of the possibility of sensitivity to thiamine, the intravenous use of this vitamin represents a potential hazard.²²⁵

Powers²²⁶ reported circulatory collapse after the intravenous injection of approximately 30 mg of niacin, and 2 similar cases were described by Pelner.²²⁷ A scaly, follicular dermatitis has been observed to occur during the use of pyridoxine in the treatment of radiation sickness.²²⁸ The dermatitis disappeared upon withdrawal of the vitamin and recurred with resumption of pyridoxine therapy. Para-aminobenzoic acid may cause acidosis, leukopenia and abdominal distention, according to Ravenel.²²⁹ In addition to the leukopenia previously mentioned, Zarafonitis²³⁰ reported such toxic manifestations as drug fever, dermatitis medicamentosa, nausea, vomiting and a fatal case of toxic hepatitis. Transient vertigo, syncope and headache were occasionally observed after the intravenous administration of 150 mg of folic acid, a procedure that has now become obsolete.²³¹ To complete the summary of ill effects from the vitamin B complex, the observation of Alvarez²³² is well worth emphasis—namely, that in some people with unexplained abdominal cramps, the cause will be found to be vitamin capsules and the patients will have relief when the vitamin supplements are discontinued.

To judge from the numerous reports, the toxic manifestations resulting from large doses of vitamin D must be well known. Of all of the vitamins, this is potentially the most toxic, and the enthusiastic reports of benefit, either real or fancied, in the treatment of arthritis and certain skin diseases have led to the ingestion of tremendous quantities of vitamin D. Anning et al.²³³ observed toxic symptoms in 19 per cent of 200 patients who had received daily doses averaging 100,000 to 150,000 units. The symptoms of vitamin D toxicity include anorexia, nausea and vomiting, diarrhea,

Correction In the Medical Progress report by Dr George W Thorn and his associates entitled "Studies on the Relation of Pituitary-Adrenal Function to Rheumatic Disease," which appeared in the October 6 issue of the *Journal* the last six words in the final sentence of the first paragraph on page 536 should be changed to read "a finding recently confirmed in further experiments" 26 "

demand for riboflavin or thiamine in a person who was in a borderline state of nutrition with respect to the latter

Animal experimentation has suggested two other mechanisms for the production of "conditioned" vitamin deficiencies by the use of large doses of one or two purified vitamins. Antagonism between members of the vitamin B complex was offered by Richards²⁴⁶ to explain the development of pyridoxine deficiency in rats given large amounts of thiamine. Supplee et al²⁴⁷ demonstrated that administration of thiamine and pantothenic acid caused an increased urinary excretion of riboflavin.

Reports of some clinical evidence of vitamin imbalance have been reviewed by Richards²⁴⁶. A case of ariboflavinosis that developed after lengthy treatment with thiamine is described by Gripwall.⁶ The "burning-feet" syndrome and the leg pains of subjects experimentally deficient in vitamins were made worse when the patients were given purified supplements of the better known members of the vitamin B complex, but were relieved when the patients were fed a luxurious diet or given the whole vitamin B complex in the form of yeast.^{24, 25} I have observed several cases in which glossitis and cheilosis developed while the patients were receiving large doses of thiamine, riboflavin and niacin, and in which "cures" were obtained by discontinuance of the vitamin supplements. Creation of a vitamin imbalance is the probable basis for the ill effect of folic acid on the central nervous system.¹⁸⁵

These observations suggest a need for caution in the use of large doses of purified vitamin supplements, especially in patients who are in a state of subclinical deficiency.

SUMMARY AND CONCLUSIONS

The need for the widespread consumption of purified vitamin supplements is questioned. A critical review of the current vitamin literature shows that the minimal requirements for the vitamins essential to man are much less than the Recommended Dietary Allowances. Vitamin-deficiency states are now infrequent in the United States. The lack of objective evidence of any improvement in health, fitness or work capacity of large population groups who received purified vitamin supplements suggests that the average American diet is adequate enough to prevent subclinical vitamin deficiency. Many of the so-called signs of vitamin deficiency are nonspecific and are not alleviated by vitamin supplementation. The use of vitamins as supportive therapy in infections and chronic diseases is largely empiric. Therefore, there seems to be little need for vitamin supplements from the nutritional standpoint.

Although many claims for the therapeutic value of vitamins in certain pathologic states will not withstand the test of controlled study, there are

some conditions in which a specific vitamin has value by virtue of its pharmacologic properties.

Not only is the administration of large doses of purified vitamins often wasteful and foolish, but also serious consideration must be given to the possibility of a toxic effect or the development of a vitamin imbalance.

If a definite state of avitaminosis exists, long-term use of vitamin supplements is unnecessary. The best suggestion is that of Cowgill to "vitaminize" the patient for a few days with three to five times the requirements and then establish him on a good diet.

In conclusion, I believe that if a person takes a good diet, he will not benefit from vitamin supplements, and that if the patient does not take an adequate diet, the treatment is a good diet, not vitamins.

I am indebted to Miss Kate Spencer, who devoted many long hours to searching through the medical literature for articles on vitamins.

senting the state of New Hampshire in the National Congress, and that they be urged and respectfully requested to use every effort at their command to prevent the enactment of compulsory health insurance legislation

This motion was duly seconded and was carried. President Dunbar then stated that the Society needed organization, which would cost money. The problem was how to raise that money. Should the Society raise its dues to a certain amount, and fit the services to that amount? Or should it consider the services that it must have and make the dues fit the services?

Next to be considered was the cost of employing the Woodbury firm. Their budget called for \$14,391, but it was possible that some donations might be obtained to cover some of that, which would only make it necessary for the Society to raise \$6,891. Also, the matter of employing a law assistant to the Secretary should be considered. That matter would have to be taken up by the next president and the Committee on Public Relations.

It had been suggested that New Hampshire organize with Vermont and Maine, and it would take time to organize a system of that kind. The cost of such a program could not be estimated.

Dr Bowler moved that the dues be increased to \$40 a year.

The motion was duly seconded.

Dr Bowler then spoke as follows:

It is quite certain that the circle in the budget has to be cut into at some point. The question of the expenditure side of that budget is so undeterminable at the present time that it is impossible to estimate it accurately. The items that we know are the campaign which you heard Dr Dunbar say is in the neighborhood of \$15,000. There may be some offsets or some transfers that can be worked out during the year with other organizations. However, that does not seem to be a good basis for the budget. So that probably, at least at this point, it ought not to be considered as ours.

The next large question is the question of the full-time executive secretary, which was discussed last evening. The possibilities are quite wide and quite unknown or unexplored.

Dr Metcalf has said in his letter that the imposition of the Society on the willingness, charity and energy of one person regarding the work to be done is absurd.

We are in a situation today that is bound to mean more work. Speaking of the load, I hope that Dr Metcalf's letter can be tabled to the point where he will continue until this program is approved and worked out. There are possibilities of a tri-state program, and it might be something that the Society would be interested in.

We have been running on a tin-horn budget, as we all know, for some time, and now we are at the point where we shall have to do one thing or the other.

My motion for the dues of \$40 a year may seem to have been picked out of the air, and it is, to some extent, but if you look at it, it adds up to an income of around \$25,000. But, it is not a lot of money in terms of the items we shall have to account for.

Dr Feiner stated that Dr Dunbar had mentioned that the budget was about \$14,000 for public relations, and any efficient secretary would require a minimum salary of \$4000 or \$5000 a year, which would make a total of \$19,000. He did not know just what the total of paying members was.

Secretary Metcalf replied that it was about 600.

Dr Feiner then observed \$30 per member would be required for that one item of expense. He did not think that even \$35 was sufficient. He did not consider it too much to raise the dues to at least \$45 or even \$50 a year, rather than have to ask for more money again. He therefore moved that Dr Bowler's motion be amended so that the dues would be \$50 a year.

Dr Brown asked how much the American Medical Association would want next year.

Dr D G Smith answered that Dr Lull had said he thought there would be no assessment in 1950. To date, about \$2,000,000 had been collected, and Dr Lull did not believe that there would be an assessment in 1950.

The motion of Dr Bowler that the dues be raised to \$40 was duly seconded and was carried unanimously.

Dr Dye then proposed that the following amendment to Chapter X, Section 1, of the Constitution and By-laws be laid on the table: "An assessment of \$40 per capita on the membership of the component societies is hereby made the annual dues of this society." After further discussion the motion was amended to read "The House of Delegates shall determine the amount of the annual dues." The motion was laid on the table.

Dr Holyoke then spoke as follows:

I was asked by the Society of Clinical Pathologists of the State to present what we know are some of the problems that will come up in connection with blood banking in the State in the near future.

Of course, I think the fact that you passed a resolution last night indicates that you are aware of some of those problems. First of all, I think that we all agree that the establishment of many blood banks throughout the State is certainly advantageous, in that it makes available to the various hospitals a large supply of blood of various types for immediate use, so that anyone can be given a transfusion.

In 1937 the first blood bank was established. The first banks established were purely hospital banks, to supply a given hospital. Since that time literally thousands of banks have been established throughout the United States. The present trend is away from a single hospital bank toward a centralized bank. So that in one city, where there are several hospitals, there will be one bank supplying all the hospitals within the community.

There are actually several possibilities whereby that can be brought about. One hospital in the city may set up a bank and supply all other hospitals with blood, and it will be a co-operative effort.

Another effort, perhaps most widely used throughout the United States is to have the so-called community bank. These banks are usually under the direction of the county medical societies. They supply all the hospitals in a given area with blood.

One other possibility, and the reason why we, in the various county societies in the State, ought to think about the problem, is the establishment of a state-wide Red Cross blood bank. We shall not hear much from the Red Cross for probably a year, because they have their hands full in setting up other banks. But perhaps next year, they will sound out the various county societies and perhaps the state society as to whether it would like to have set up within the State a large blood bank to supply the State with blood.

Their system is to procure the blood and turn it over to the hospitals after it is drawn.

NEW HAMPSHIRE MEDICAL SOCIETY

PROCEEDINGS OF THE ONE HUNDRED AND FIFTY-EIGHTH ANNIVERSARY (Concluded)

House of Delegates, June 13, 14 and 15, 1949

Dr Crisp referred to a communication from the president of the New Hampshire Pharmaceutical Association, registering a protest against dispensing of drugs by physicians in groups. This matter had been discussed at the annual meeting of the Association, which also protested against the employment of pharmacists by physicians, private ownership and so forth.

The Secretary stated that his impression was that the druggists objected to the fact that doctors were passing out pills to their patients, and not writing prescriptions.

Dr Crisp replied that the druggists were also against the establishment of dispensing pharmacies employing pharmacists, and run by doctors.

Dr Gifford stated that several pharmacists had informed him that physicians have had their own dispensaries within the particular group, and that the patient must go there to get his medicine.

Dr Bowler said that he assumed that the protest was not aimed at the individual physician dispensing in his own office, which would be ridiculous. His group, however, would be interested in the development by hospitals of their own pharmacies, in the future, perhaps, because that had become an established method for some time.

President Dunbar referred to correspondence with Mr Smith, who was wholeheartedly with the medical profession in its campaign against socialized medicine and who had even sent his personal check as a contribution to the campaign. Dr Dunbar knew of only one clinic in the State that operated a drugstore, in the Winnepesaukee area.

Dr Walck was of the opinion that the medical profession should encourage all possible support from the pharmacists. Mr Smith had been one of the most energetic workers in Strafford County co-operating with the Committee and appeared to be wholeheartedly behind the whole program against socialized medicine.

Dr Jessup stated that the protest appeared to be directed largely against his group. He asked what the basic objection of the pharmacists was, since his group did not dispense but hired two fully qualified pharmacists to do all the work. The group had noted that a large percentage of patients did not use its own pharmacy. Prescriptions that could not be filled in pharmacies within the State were not used. The system had originally been started, in part at least, to facilitate the dispensing of medicines to patients, which all phy-

sicians do to some extent. Originally, it had been meant to be a small drug room, and since there were eleven or twelve doctors in the group, it seemed more to the point to consolidate the drugs in one room, rather than to have twelve dispensaries. It was a regularly chartered drugstore, with its own bookkeeping and is separated from the group. The building was owned by the clinic group.

Secretary Metcalf asked if that was the group in Laconia. Dr Walck replied that it was.

Dr Bowler moved that the protest be referred to the Committee on Public Relations.

This motion was duly seconded and was carried.

President Dunbar moved that the Committee on Public Relations give consideration to the organization of state-wide or local health conferences of doctors, laymen and consumers, similar to the conference held in Massachusetts last February.

This motion was duly seconded and was carried.

President Dunbar also moved that the Society participate in the Conference of Presidents, and that the House ratify the payment of \$10.00 for this purpose.

This motion was duly seconded and was carried.

President Dunbar then moved that the House of Delegates pass a resolution against compulsory health insurance, as follows:

WHEREAS, under a system of free enterprise and personal initiative, the American Medical profession has attained for the people of these United States the highest standards of scientific performance, treatment and research to be found in the world, and

WHEREAS, there exists in many forms voluntary health insurance whereby payments for health care may be effected on a purely voluntary budgetary basis, and

WHEREAS, under voluntary health care programs the people of this country are left free to select their physicians and hospitals and to carry such voluntary health insurance as they may wish, and

WHEREAS, under compulsory health insurance employees, employers and the self-employed, as well as those in other categories, would be faced with a compulsory tax on annual income, earning power or wages to support a governmentally controlled medical program, and

WHEREAS, the experience of all nations where government has assumed control of medical services has shown that there has been a gradual erosion of free enterprise and a progressive deterioration of medical standards and medical care to the detriment of the health of the people,

NOW, THEREFORE, BE IT RESOLVED, that the New Hampshire Medical Society does hereby go on record against any form of compulsory health insurance or any system of politically controlled medicine, firm in its belief that the American tradition of free enterprise may best be carried out by the people and for the people through voluntary means, and that a copy of this resolution be forwarded to the president of the United States and to Senators Styles Bridges and Charles W. Tobey and to Congressmen Chester E. Merrow and Norris Cotton repre-

Secretary Metcalf then pointed out the advantages of having the *New England Journal of Medicine* handle the publication, which was a big job. If the Publication Committee had to take over that work in three months, he would certainly resign from the Committee.

Dr Leonard withdrew the sentence referring to the suggestion of publishing the *Transactions* within three months.

Speaker Dube suggested that the matter be referred to the Publications Committee, of which the Secretary was the chairman.

The Secretary stated that certain portions of the book were valuable. The account of these meetings held in the last three days, the committee reports, the list of members, the obituaries, and other phases might be occasionally used.

Dr Bowler stated that he was in favor of supporting the continuance of the *Transactions*, if only for the historical value, and he moved the question.

Dr Leonard's motion was then read, excluding the suggestion that the transactions be published within three months.

Secretary Metcalf stated the present cost of the books was \$3 a volume, 660 copies had been received this year, at a cost, roughly, of \$2000.

Speaker Dube asked those in favor of the motion to signify assent by raising their right hands.

There were 13 "No" votes, and the motion was lost.

Dr Leonard, in accordance with the suggestion of the Delegate to the American Medical Association, moved that the term of the Delegates of the New Hampshire Medical Society begin on January 1 of the year after his election.

This motion was duly seconded and was carried.

Dr Leonard, also in response to the suggestion of the Delegate to the American Medical Association, moved that the New Hampshire Medical Society co-operate with the American Medical Association by requesting each county society to submit the name of one of its members as the "outstanding general practitioner of the year."

This motion was duly seconded, and was carried.

Dr Leonard, as a delegate from Rockingham County, presented the name of Dr Cleon W Colby for life membership.

This motion was duly seconded and was carried.

The financial report of the Trustees was then presented as follows:

JANUARY 1-DECEMBER 31 1948

Total			\$7 104 53

Dr George C Wilkins then spoke as follows:

I should like to have the privilege of speaking for the Board of Trustees about the Benevolence Fund, which was started in 1931, and discussed at the meeting Monday afternoon. That fund was started with the idea of building up a fund sufficient to give an income to help out any indigent physician in the Society.

At first, we took \$1 from each person's subscription, and that was allocated to the Fund. That was cut down to fifty cents, and then it was cut down to nothing. We have had no income except from the invested funds and from a very small contribution of \$25 to \$50 from the auxiliaries of three different county societies.

Twice within the last two years, I have been asked if some money was available to help out an indigent physician who has come upon hard times and was unable to do anything about it. However, we cannot use the principal. We only have \$7104 at the present time.

The Trustees would like very much to have the \$1 portion of the dues set aside for the Benevolence Fund, in order to build it up to a point where we could use the income to help someone out.

I think that in line with that, it is worth saying that their system of getting donors has worked very well in some locations. The Red Cross blood banks have been a great asset in some communities, and in others, they have not been so good.

In some places, a great stress is still laid on individual use of the blood, and on being morally bound to replace the blood from friends or members of families. Other banks have gone on the basis that the blood is free, it is yours, and you don't have to do anything about it. But I think the Red Cross banks that have had that system have not been a success.

In the State at present, there are only five banks set up. There are a few others in hospitals, which carry a fair supply of blood on the refrigerator shelves, but, it is not a definite thing, so that it would be conceivable that those hospitals might be short of blood.

Two of the banks in the State do make the blood available at times to doctors in surrounding towns or surrounding communities. But we have virtually no community blood banks at the present time in the State.

There is a Red Cross bank in Massachusetts that is functioning and doing, as far as I can tell, a fairly good job. It ought to do a better job, as time goes on.

In Vermont, within the next three or four months, there will be a blood bank set up under the auspices of the Red Cross. This bank is going to supply eastern New York and all of Vermont, and they are ready — if the members of the various county medical societies in New Hampshire wish them to do so — to supply part of the blood to them.

Also, there is in process the setting up of a blood bank for the city of Portland, Maine.

So that we shall have these large banks all around the perimeter of the State.

As to what the banks can do, I think we could sum it up and say that a large blood bank can ensure the people in the neighborhood of an adequate dose of blood. Certainly, it is an efficient way to obtain blood. It is a method whereby small hospitals and small users of blood can have available to them ample supplies of blood.

There is one thing in line with the national policy. It would have set up through the State a number of large blood banks, whereby we shall be able to help each other in times of disaster. Of course, the national Government is thinking a lot about that at the present time.

One other advantage in having a large blood bank is that it makes available to the doctors or the hospitals that are co-operating with the program plasma products, particularly albumin, that is important because the albumin prepared from plasma is virus free, and there is no need to worry about infectious hepatitis, which is becoming a tremendous problem for people using blood in any volume at all, or using blood products.

If you decide that you would like to co-operate with some of the Red Cross Bank programs, remember that must be done through the counties. Red Cross does not establish it anywhere, unless the county medical societies agree to have it done.

This problem will come up next year so that each county society and the State Society may consider and talk about it at the next meeting.

Upon motion duly made, seconded and voted, the second meeting of the House of Delegates adjourned at 10 30 a m.

The Third Meeting of the House of Delegates was called to order by Speaker Dube at 9 20 a m on June 15, 1949.

The following members responded to roll call.

The President, *ex-officio*
 The Vice-President, *ex-officio*
 The Secretary-Treasurer, *ex-officio*
 James Jessup, alternate for Roger Brassard, Laconia
 Samuel Feiner, Ashland
 W J Paul Dye, Wolfeboro
 Howard Sawyer, alternate for Francis J C Dube
 Marjorie A Parsons, Colebrook
 William H Gifford, Colebrook
 Leslie K Sycamore, Hanover
 Reginald K House, Hanover

Norman W Crisp, Nashua
 Harris E Powers, Manchester
 James B Woodman, Franklin
 Francis Brown, alternate for Warren H. Butterfield
 Ellsworth Tracy, alternate for William D Penhale
 Donald W Leonard, Exeter
 Fred Fernald, Nottingham
 Edna Walck, Dover
 Albert E Barcomb, Rochester
 B Read Lewin, Claremont
 Addison Roe, Newport

Dr Dye moved that Section 1 of Chapter X of the By-laws, which is headed "Assessments and Expenditures," be amended to read as follows: "The House of Delegates shall determine the dues of members of this Society."

This motion was duly seconded and was carried.

Dr Bowler then moved that the dues of the New Hampshire Medical Society be \$40.

This motion was duly seconded and was carried.

Dr Leonard, for the Committee on Officers' Reports, moved that the custom of sending delegates from the New Hampshire Medical Society to the annual meetings of the other New England state societies be renewed.

This motion was duly seconded and was carried.

In accordance with the suggestion in the report of the Secretary, he then moved that the Committee on Amendments to the Constitution and By-laws be instructed to prepare an up-to-date copy of the entire Constitution and By-laws, and that the Secretary be authorized to incorporate them in a printed booklet for the reference of the members.

This motion was duly seconded.

Dr Bowler offered an amendment that, on review and before printing, the copy be submitted to the next House of Delegates.

Dr Leonard accepted the amendment.

Upon a voice vote, the motion was carried.

Dr Leonard, for the Committee on Officers' Reports, moved that the *Transactions* be printed in an annual volume, omitting reprints of scientific and other papers presented at the annual meeting, except such essays as are awarded prizes by the Society and any other papers having specific application to the Society. It was also suggested in this motion that publication of the *Transactions* be made within three months of the annual meeting.

Secretary Metcalf remarked that the papers that go into the *Transactions* are printed previously in the *New England Journal of Medicine*, being spread out over a whole year. The papers are kept set up in print and simply transferred to the *Transactions*. In that way, the Society saved about a thousand dollars. If a volume was brought out in three months, the material would have to be specially set, at a cost of \$6 apiece.

Dr Leonard stated that the motion was to omit the scientific papers from the *Transactions*, except the prize essays and those of merit.

Dr Bowler then moved that the continuance of Mr Woodbury's services be approved, pending the report of the Budget Committee

This motion was duly seconded and was carried

Dr Feiner recommended that at the next year's meeting, the House of Delegate's meetings be started on a Sunday, so that the bulk of the

business could be finished before the scientific sessions began

Dr Dye moved that the House adjourn

This motion was duly seconded and was carried

Whereupon, the third meeting of the House of Delegates was adjourned at 11 o'clock in the forenoon

CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

Weekly Clinicopathological Exercises

BENJAMIN CASTLEMAN, M D, *Associate Editor*

EDITH E PARRIS, *Assistant Editor*

CASE 35521

PRESENTATION OF CASE

A sixty-two-year-old woman was admitted to the hospital for the fourth time with a complaint of coma following epileptic seizures

The patient had had recurrent epileptic seizures for about fifteen years. These attacks were variable in frequency, duration and nature, and recurred at any time of day or night. In some of them she was able to carry out co-ordinated motor activity in an automatic way for a few minutes to an hour or more while seemingly "in a daze." In others, she suddenly lost consciousness without warning and fell to the ground, where she lay motionless for a few minutes, sometimes with urinary incontinence. Rarely, there were tonic-clonic convulsions, with tongue biting. Some of the attacks were heralded by peculiar unlocalized "crawling" sensations in various parts of her body, often in the back of her neck. In all of them, there was total amnesia for the attack itself. These attacks occurred anywhere from once in two or three months to three or four times a week. Over the course of the years, she received many forms of anticonvulsant medication, which never controlled her seizures satisfactorily. Repeated electroencephalograms showed diffuse abnormalities consistent with epilepsy. Radiograms were normal except for osteoporosis of the left posterior clinoid process. Lumbar punctures were normal, and the neurologic findings were negative. During the six months before

admission, in addition to her previous attacks, she began having more frequent episodes of unresponsiveness and unconsciousness between meals, lasting up to three hours at a time, during which she was sometimes noisy and restless. They became progressively more severe and occurred at least three times daily, always occurring between meals or between supper and bedtime.

Physical examination revealed an obese woman, who was dazed and confused. There were a number of cutaneous scars from previous injuries and burns. The remainder of the physical examination and the neurologic examination were negative.

The temperature was 99°F, the pulse 82, and the respirations 20. The blood pressure was 120 systolic, 70 diastolic.

Examination of the blood showed a hemoglobin of 12 gm and a white-cell count of 14,670, with a normal differential. Urinalysis was normal. A fasting blood sugar was 47 mg per 100 cc, a repeat test on the following day was 35 mg per 100 cc. The nonprotein nitrogen was 21 mg, the calcium 9.4 mg, and the potassium 4.6 mg per 100 cc. The sodium was 141 milliequiv, and the chloride 105 milliequiv per liter. The carbon dioxide was 29.4 milliequiv per liter. A cephalin-flocculation test was negative in twenty-four and forty-eight hours. The total protein was 6.49 gm per 100 cc, with 4.43 gm of albumin and 2.06 gm of globulin. The bromsulphalein test showed 16 per cent retention of the dye. The phosphorus was 3.7 mg per 100 cc. A blood Hinton test was negative.

A glucose tolerance test revealed a high value of 208 mg per 100 cc in two hours and a low value of 58 mg in six hours. The response of the patient, with a fasting blood sugar of 47 mg per 100 cc, to an injection of 0.01 cc of epinephrine (in a dilution of 1:1000) per kilogram of body weight was 54 mg per 100 cc in fifteen minutes and 39 mg in sixty minutes.

The patient was fasted for twenty-four hours, at which time a convulsion occurred. A blood sugar determination at this time was 45 mg per 100 cc. She responded immediately to intravenous glucose therapy.

Two weeks after admission an operation was performed.

These cases do not come up very often, but when they do, it is rather a sad position for us to be in, to say that we cannot do anything to help them. Therefore, the Trustees would like very much to have that allocation made to the Benevolence Fund, if the House of Delegates believes that it should be done.

Dr Bowler moved that the question be referred to the budget committee for next year.

Speaker Dube stated that there was no budget committee.

Dr Bowler replied that, temporarily, the officers could be used as such. They would look over the budget, on the basis of the new dues, the campaign work, the question of the new executive secretary and so forth.

Secretary Metcalf remarked that the Trustees were responsible for the invested funds, and that the Treasurer acted as a budget committee, paying out the necessary expenses. The present rule was that nobody could spend any money unless the House gave its approval, so that the budget committee would be purely advisory.

Dr Bowler stated that the budget had to be set up. He assumed that a special meeting of the House would be called as early as these things were in shape to be recommended, meanwhile, work must be done.

Dr Feiner asked if it had to be a standing committee. If not, the by-laws would not have to be changed, because a special committee could be appointed by the Chairman, to report back at the next meeting of the House of Delegates.

Dr Bowler stated that at present there was no budget committee as an officers' committee. But, in the meantime, he supposed that the matter had to be handled by the officers in this preliminary work with the budget.

Dr Wilkins remarked that the request of the Trustees could only be granted by a vote of the House of Delegates.

Dr Crisp asked how much was needed to put the fund in working order.

Dr Wilkins replied that, originally, the plan had been that after the fund had reached \$10,000 the income could be used for any such purpose, and if the income from the fund was not used, it could be added to the principal. Of course the income from \$10,000 was not too much, and it would not go very far, but the fund should be that amount before any of the interest was taken away.

Dr Bowler re-phrased his motion to state that this item be referred to a committee to be appointed by the President, to be considered along with a study of the budget, the recommendations to be reported to the next meeting of the House of Delegates, and that Dr Wilkins's recommendation be referred to this Committee.

This motion was duly seconded and was carried.

President Dunbar then moved that the House of Delegates go on record as being in sympathy with the objectives of the American Diabetes Association,

— that is, to improve the treatment of diabetes, to bring the newest knowledge of the disease to all physicians, to encourage and support research in the field and to increase knowledge of diabetes among the general public, — that the incoming president appoint a diabetes committee of three to aid in this program and, that the Secretary inform the county societies of this action, recommending that each appoint a diabetes committee.

This motion was duly seconded and was carried.

Dr Sycamore moved that a vote of appreciation be extended to Dr Dunbar for the time and effort that he had put into the service of the Society during this past year, and for the inspiring leadership he had given.

This motion was duly seconded and was carried.

Dr Sycamore then made a similar motion with reference to the Secretary-Treasurer.

This motion was duly seconded and was carried.

Speaker Dube stated that the next item of business was the selection of a place for the next annual meeting.

Dr Bowler stated that he had been asked a year ago whether Hanover would be interested in having the Society next year. This would not be practical because of the so-called Hanover Holiday, which is the week between commencement and reunion. However, he suggested that Hanover be considered for the following year. He moved that Newcastle be chosen for 1950.

Dr Dye seconded the motion.

Dr Gifford suggested the Mount Washington Hotel, which had adequate floor space for the exhibits. This might inconvenience the physicians in the cities, who like to be able to dash in and see their patients and dash back to the meetings and catch a lecture or see what is going on.

Dr Barcomb seconded Dr Gifford's suggestion.

Dr Dye stated that the exhibits brought in a certain amount of income, and the Mount Washington Hotel had stated that they would be delighted to have the Society meet there, and also that they had adequate space and facilities for all the exhibits.

Speaker Dube stated the motion that the Society meet at the Wentworth Hotel in Newcastle next year.

Dr Dye seconded a motion by Dr Bowler that the members be polled by postal card, and amended that motion so that the officers of the Society would be empowered to act with reference to the final selection of the site.

Dr Bowler accepted the amendment.

Speaker Dube stated the motion before the House that the Secretary poll the Society, and that the officers be empowered to act upon the result of the poll, to select the future place of meeting next year. He asked all those in favor of this motion to signify assent by saying "aye."

There was a chorus of "ayes," with one dissenting "no," and the motion was carried.

method of determining blood insulin. In the case under discussion it would be most helpful in eliminating an erroneous diagnosis that could arise from misinterpretation of spells that seem to have been epileptic or neurotic.

DR ROBERT S SCHWAB: This electroencephalogram was taken before the operation and shows marked abnormalities that are underlined with pencil (Fig 1). We have evidence of localization in the right temporal region because of the large spikes

FIGURE 1

FIGURE 2

in the basal lead. Here is a normal electroencephalogram for comparison (Fig 2).

CLINICAL DIAGNOSIS

Islet-cell adenoma of pancreas

DR CHAPMAN'S DIAGNOSIS

Islet-cell adenoma of pancreas

ANATOMICAL DIAGNOSES

Islet-cell adenoma of pancreas

Epilepsy

Carcinoma of thyroid gland

PATHOLOGICAL DISCUSSION

DR OLIVER COPE: We reached the same diagnosis that Dr Chapman did and, accordingly,

opened the abdomen and looked at the pancreas. It was large and lobular, and no definite tumor was seen or felt. It looked a little bit larger than the normal pancreas. The woman was very obese, and the pancreas felt big and fat. I excised the tail and body of the pancreas down to the neck, leaving head and neck. After excision we incised the specimen longitudinally, starting at the tail and cutting into each lobule as we slit it down. There was one little lobule in the mid-body that looked like the rest but that, when cut into, proved to be a little adenoma. I had taken out more than was needed. The tumor was characteristic; it was the size of a small, seedless green grape, not as big as 2 cm in diameter. It was well circumscribed and of firm whitish tissue.

My face was scarlet red about this patient. She had been cared for by the Burn Service during the war, and we, like the neurologists, had failed to make the diagnosis. She had made many trips to this hospital; many electroencephalograms had been done, and she had seen many doctors. It was not until Dr Balboni saw her at home in an attack that suspicion was aroused as to what was wrong. He thought it was not an ordinary seizure and sent her in with the diagnosis of hyperinsulinism and said, "Please determine the blood sugar." He was convinced about the diagnosis. The patient was sent home, however, without a blood sugar determination, and two days later he sent her back and said, "Please do a blood sugar determination" (I do not think he said "please" the second time). What interested me was that many had seen this patient, and many noted that she suffered from a state of confusion, and yet the attack was never classified until Dr Balboni looked at the patient and said, "This is not an ordinary epileptiform seizure."

DR SCHWAB: The postoperative electroencephalogram was exactly the same as the preoperative. I would like to ask Dr Chapman how he explains the persistence of epileptic waves after removal of an islet-cell adenoma of the pancreas.

DR CHAPMAN: That is interesting because I think it happened in a patient who had, perhaps, a fundamental underlying disorder in the brain that was activated by hypoglycemia. It fits with Romano's patient who had fundamental personality changes that were not altered after removal of his adenoma. However, he stopped having the epileptic attacks after operation.

DR SCHWAB: Would the original disease be the cause of the seizures indirectly? People who have hypoglycemia usually do not have convulsions, but they do faint and fall and such falls may damage the brain and produce scars. The scars then cause the seizures. I do not know whether we have an answer to this speculation.

DR BENJAMIN CASTLEMAN: Following operation she had more attacks. She had one on the ninth postoperative day and one on the tenth.

DIFFERENTIAL DIAGNOSIS

DR EARLE M CHAPMAN* It seems clear from the history and data presented that this patient suffered from hypoglycemia. That is a positive clinical diagnosis.

What are the main causes of hypoglycemia? There may be four main causes, and it is for us to go through them to determine which seems most likely to fit this patient. First, I think we have to consider abnormality of the liver cells. If a failure of gluconeogenesis in the liver takes place, hypoglycemia can occur. Did this patient have enough evidence to support a diagnosis of severe liver disease to explain this syndrome? When a normal liver is removed profound hypoglycemia may result, but 80 per cent must be removed before hypoglycemia is produced. So I cannot believe that the evidence here indicates that 80 per cent of this patient's liver was impaired. All the liver-function studies were normal, with the single exception of 16 per cent retention of bromsulfalein. I am inclined to discount this as one of the minor variations in laboratory data that tend to confuse one.

Secondly, I think a decreased gluconeogenesis can result from diminishing output of anterior pituitary hormone, thyroid hormone or cortical or medullary secretions of the adrenal gland. On review of the data, there is no evidence on which I can base a diagnosis of endocrine disease of the pituitary, thyroid or adrenal glands. It is true that the basal metabolic rate is not reported. It is likewise true that x-ray examination disclosed some osteoporosis of the posterior clinoid process. I will have to depend on Dr Wyman to tell me whether he thinks there is a significant abnormality in the region of the pituitary body.

DR STANLEY M WYMAN I do not believe that the skull films are definitely abnormal for a person of this age. Osteoporosis of the posterior clinoids seems to be rather general, and there is no evidence of erosion and no evidence of increase in size of the sella turcica. Otherwise, the bones of the skull appear within normal limits. I should be inclined to discount the reported osteoporosis of the clinoids. There are other films available that you may like to see. The films of the chest are grossly unsatisfactory, they are examinations of a heavy person taken with a portable machine. They do show tortuosity of the aorta but no other definitely localized intrinsic disease. In the one film of the abdomen the liver shadow appears to be within normal limits in size and shape. The kidneys are well seen and appear normal, the left lies lower than usual. There are no masses above it, however.

DR CHAPMAN I will accept your word that there is little or no evidence for pituitary disease in the x-ray films.

A third cause of hypoglycemia is that produced by long-endured or violent exercise. Occasionally, severe and prolonged exercise will produce hypoglycemia. I have seen one such case in a young boy who did very hard work over a long period and had a fainting spell in which we established the diagnosis of hypoglycemia and he recovered immediately. I would like to read from an article by Romano¹ that bears on this point of attacks of low blood sugar occurring after violent exertion.

The day following the New England hurricane in September, 1938, he engaged in a kind of wood-chopping contest with a number of neighbors who were clearing fallen timber from their property. After some fifteen minutes of vigorous chopping, he suddenly clutched his axe menacingly, and with a dazed and glassy-eyed expression, wandered about the neighborhood, terrifying people. He was again taken to the Peter Bent Brigham Hospital, where house officers were struck by his confusion, mumbling speech and constant grotesque, ataxic and purposeless movements. Convinced of the hysterical character of his disorder, house officers sprayed a fine stream of ethyl chloride on his bare abdomen to startle him out of his attack. He appeared to respond promptly to this interesting therapy, for he came to himself immediately. He professed amnesia for the entire episode, and the diagnosis of hysteria seemed definitely confirmed. (The probable effectiveness of a large glass of ginger ale, which the patient had been persuaded to drink just before the ethyl chloride treatment, was not appreciated.)

This patient was subsequently proved to have periodic hypoglycemia.

This leads me to the fourth possibility and the one that probably explains this patient's condition which was followed for over fifteen years in our Out Patient Department—the inhibitory action of insulin on the gluconeogenesis of the liver itself, in other words, hyperinsulinism. The history is typical of hyperinsulinism. The data of low blood sugar and response to epinephrine are characteristic, and, in the end, an operation was performed. My guess is that the abdomen was explored and that possibly an islet-cell tumor of the pancreas was discovered and if an enlarged pancreas was found, a subtotal resection was performed. I remember a case in Baltimore seen by Dr Edward Jarrett, in which an extremely large pancreas was discovered, and the surgeon held it up and said "How much will we take off?" And he said "Oh, about there," and they chopped it off about "there," and the patient had no more attacks. No islet-cell tumor was discovered in that case. It would be helpful if they discovered a tumor in the case under discussion.

There are four types of islet cells, and the beta cells that occupy the periphery are smaller than the others and are considered the producers of antidiabetic hormones.

This case illustrates another point to me the need of a method to determine the level of blood insulin. When I visited the Banting Institute last spring, I was impressed with the amount of intensive work going on in this problem. Dr Best is devoting a good share of his efforts in working out a practical

*Associate physician Massachusetts General Hospital

lymphedema" was made, she returned to her physician. At this time she was receiving codeine because of the pain. She stated that the swelling decreased when she stayed in bed, and that during her last two menstrual periods the pain and swelling were aggravated. Rectal examination revealed an increase in size of the fixed pelvic mass.

The menstrual history was negative, her periods occurring every twenty-six to twenty-eight days, lasting four days and without pain. She had a history of four miscarriages at two to four months during the past eight years.

At the age of eighteen, six months following an appendectomy, a "tumor of the abdominal wall" was excised. At that time she was told by the surgeon that she would probably be unable to have children.

Physical examination revealed a well developed and well nourished woman. In the mid thigh the right leg measured 54 cm, and the left 45 cm, at the calf the right was 42 cm, and the left 34 cm. The right ankle measured 28 cm, and the left 24.8 cm. On pelvic examination a hard, tender mass was felt high in the pelvis. The rest of the examination was negative.

The blood pressure was 130 systolic, 80 diastolic.

Examination of the blood and urine was negative. A prothrombin time was 22 seconds (normal, 18 seconds). An x-ray film of the chest was normal.

On the day following admission an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR IRAD B. HARDY*: We have here the problem of moderately advanced unilateral lymphedema coming on rather rapidly in a young woman. Of course, we must decide what the pelvic mass was and whether it had any causal relation to the swelling. In the first place, I think we can very quickly rule out the systemic causes of swelling of the legs simply on the basis that this was a unilateral affair and such conditions as nutritional edema, renal disease, heart disease and hyperthyroidism can be discarded. Also, among the mechanical causes of edema any lesion above the bifurcation of the iliacs can be ruled out because this was a unilateral process.

I suspect all we have in the way of x-ray studies is a chest film. May we see it?

DR STANLEY WYMAN: I do not believe there is anything to add to the record, Dr Hardy. It appears to be within normal limits.

DR HARDY: No intravenous pyelogram?

DR WYMAN: No.

DR HARDY: To review the protocol, there are some things we might point out briefly. For several years this woman had mild swelling in both ankles by the end of the day. I do not believe that is very

significant, it is a very common complaint. I doubt if it had much bearing on this particular case.

Ten months before being seen in the hospital she began to have some cramps in her leg and later in her thigh, and finally she noted that the leg was red and that a red line had appeared on the inner aspect of the thigh. There was no mention of any special degree of swelling, and I presume there was none. This may have represented an initial episode of mild cellulitis, possibly the red streak was lymphangitis or superficial thrombophlebitis. At any rate, this redness and streaking were not mentioned again, and I think we can assume, if it was an initial episode of cellulitis and infection, that at least it was not repeated over the following months. Several months later (we do not know how much later or how soon before she came in) she had swelling in the groin, and we again have to assume that the swelling had become progressive. She also had an irregular, firm, fixed pelvic mass.

She was then lost track of and upon returning to her physician, which was just about the time she entered the hospital, she had been taking codeine for the relief of pain, which had apparently developed somewhere along the line. I think that, although swollen legs are certainly uncomfortable, the necessity for codeine is not very common. The usual therapy to relieve the pain associated with simple lymphedema is aspirin, an elastic support or elevation. I suspect that this necessity for codeine may indicate that there was some process going on that was involving the nerves as well as the lymphatic drainage.

We then find that the menstrual cycle was essentially normal but that she had had over a period of eight years several miscarriages in the early months. I wonder whether that means a mechanical obstruction in the pelvis, which prevented full-term pregnancies. However, I am of the opinion that that was not the case and that there was probably a hormonal imbalance that prevented her from going on to full term. Later, the mass in the pelvis was apparently of fairly rapid development and probably did not account for the fact that she had not been able to have full-term pregnancies for as far back as eight years previously.

On admission to the hospital the physical examination, such as we have to go on, shows that she had a moderately diffuse swelling located in the right groin. There is no mention of any marked venous stasis, and no mention of a great deal of induration, pigmentation or dilated veins to suggest a postphlebotic state. There is no mention of any redness or cellulitis, which we would have expected to be present if she had had an inflammatory process going on all this time. Since it is not mentioned, I shall assume that it had not been present. No palpable lymph nodes are recorded.

*Assistant in surgery, Massachusetts General Hospital.

DR CHAPMAN And so she had two diseases

DR COPE That is the question that Dr Schwab brings up whether or not one disease gave rise to another

DR CASTLEMAN At autopsy

DR CHAPMAN At autopsy¹ I thought they cured her

DR CASTLEMAN We were kind enough not to inform you of that

She was operated on in April of this year and just died a few months ago. We were unable to find anything grossly in the brain to account for the epileptic attacks. On the other hand, we did find something more. She had a large thyroid tumor that was very hard, measured about 10 by 8 by 4 cm and extended down into the mediastinum to about 3 cm above the arch of the aorta. She was very obese, and that is probably why the tumor could not be felt. Microscopically it was a very anaplastic tumor with giant cells and in places looked like a fibrosarcoma. It is the type of malignant lesion that is often called carcinosarcoma—a lesion that is probably primarily epithelial. It had metastasized to the lungs but not to any of the regional lymph nodes.

DR COPE I think that I am right in saying that she suffered respiratory distress for forty-eight hours before death and died at home. The respiratory distress was of short duration.

DR CHAPMAN Death came rapidly, in other words

DR SCHWAB Is there any microscopical report of the temporal region of the brain?

DR CASTLEMAN Yes, but the findings did not differ from other regions of the cerebral cortex. According to Dr Kubik, there was an increase in astrocytes in the deeper layers of the cortex and in scattered areas in the white matter, but these findings were probably of recent origin. I am afraid we did not disclose any focus to explain the seizures.

DR SCHWAB One would not expect the sections to show much unless the dura was involved under the temporal lobe, was there any pigmentation there?

DR CASTLEMAN No

DR SCHWAB I would like to comment briefly on the low blood sugar. It does not produce convulsions. It has to be at extremely low levels to produce convulsions with a normal brain. Insulin has recently been tried in the diagnosis of epilepsy. Some people have seizures at a level of 30 mg and others, at a level of 60 mg per 100 cc. That is a differential method of diagnosing epilepsy but not a general rule. The low blood sugar does not produce convulsions in normal people.

DR CHAPMAN With apologies to the Peter Bent Brigham Hospital, I should relate the following. In 1930 a patient had severe hypoglycemia. She fell, fractured her arm, and came to our Emergency Ward. The fracture was treated and, later,

she had another seizure and still another seizure, and finally at the Brigham Hospital, Dr Pokorny made the proper diagnosis of hypoglycemia. She was explored, and the islet-cell tumor removed. This is the first case of this disorder reported in New England.²

DR CASTLEMAN In the case under discussion, after the tumor was removed, the blood sugar ranged between 150 and 200 mg per 100 cc, always above 100 mg, whereas previously it was around 45 mg.

A PHYSICIAN What did the pancreas show at autopsy?

DR CASTLEMAN It was perfectly normal. There was no increase in the number of islets in the remainder of the pancreas either at operation or at autopsy.

DR SCHWAB Does this disturbance in the thyroid function intensify the effect of islet-cell tumor in reducing blood sugar?

DR CHAPMAN In general, when there is more thyroid hormone, the diabetes is worse.

DR COPE It is possible that the thyroid lesion was not palpable at the time of operation on the pancreas, it was rapidly growing and presumably developed within a relatively short time. This poor woman was plagued by both these diseases. I think the thyroid carcinoma was probably not related to the other two.

CASE 35522

PRESENTATION OF CASE

A thirty-eight-year-old married office worker entered the hospital with a complaint of swelling of the right leg.

For the past several years she had experienced mild swelling of both ankles at the end of the day, more marked after being on her feet for long hours. Ten months prior to admission she began to experience cramps in her right foot at night, apparently waking her and subsiding in five or ten minutes. No change in appearance of the extremity was noted at this time, but later the cramps recurred higher in the leg, the leg became red, and a red "line" appeared on the inner aspect of the thigh. Several months following this episode she was seen in a physician's office. At that time swelling of the right leg was as high as the groin. Pelvic examination revealed a firm, fixed, irregular mass, high on the right in the region of the uterosacral ligament. About five months later, after visiting at least one hospital, where a diagnosis of "idiopathic

PATHOLOGICAL DISCUSSION

DR ULFELDER Dr Hardy was quite correct in classifying this as a case of noninflammatory secondary, unilateral lymphedema because that is exactly what she had. She had occlusion of the right external iliac vein by a very firm and fibrous mass intimately connected with the lymph nodes in this area. The only unusual feature of the case and in my experience it is unique, was the nature of the disease within and outside the lymph nodes, because this was also endometriosis. She had endometriosis of the lymph nodes in the operative area surrounding the external iliac vein. Endometriosis was also present outside the lymph nodes and at the time of operation it was very easily demonstrable that this was the cause of the difficulty. The peritoneum was opened on this side, and dissection carried down along the vessels. The external iliac artery was adherent posteriorly to it but was not involved in the pathologic process. The ureter was not involved in the disease process. It could easily be separated from the peritoneum but the external iliac vein on the right side was completely surrounded by the diseased tissue and was in turn adherent to the pelvic wall. I was not able, of course, to dissect this out because it was too fixed a process, but I was able to free the vein from the pelvic wall and I obtained a biopsy of the fibrous tissue along the pelvic wall. I was also able to remove a number of lymph nodes in the immediate vicinity. The pelvic tumor was entirely separate. It was an endometrioma of the rectovaginal pouch in the usual position behind the cervical segment and with the bowel adherent to it.

DR ALFRED KRAVES Was not the absence of dysmenorrhea quite unusual?

DR ULFELDER Dysmenorrhea is classically the symptom of endometriosis, particularly increasing dysmenorrhea. On the other hand, in any analysis of series of cases in which this diagnosis has been made histologically it is usually noted that about 40 to 50 per cent of patients have not had pelvic pain, it is not by any means a *sine qua non*.

DR MALLORY I have a slide I would like to demonstrate. This is from one of the lymph nodes in the region of the iliac vein and here one can quite clearly see a gland lined with columnar epithelium. Around it is hemorrhagic stroma of the endometrial type. This gland lies just at the margin of the node and is a very clear-cut focus of endometriosis within the node strongly suggestive of a metastasis. I believe metastasis does occur in this condition infrequently but not extremely rarely. There was recently reported from the Gynecological Clinic at Cornell a series of 5 cases showing metastases of endometriosis to lymph nodes and various places around the pelvis.²

There was only one lead in the story as written, and that was the accentuation of symptoms at the time of the menstrual periods. That is a rather flimsy lead I grant, because so many women have accentuation of every kind of symptom at that time.

DR KRAVES Was she relieved of her edema?

DR ULFELDER It is not fair to judge so soon. She was operated on recently and of course her rest in bed brought about a marked decrease in the edema.

DR MALLORY In handling this case you thought that it was necessary to remove both ovaries?

DR ULFELDER Yes I did, for two reasons. I could not tell grossly that this was endometriosis, although that was my impression, it has never been described as producing this picture. So from a diagnostic point of view, I thought I was dealing with a malignant lesion, with metastasis to that site, or with endometriosis, either one of which in this situation would have demanded removal of all the pelvic organs, including both ovaries.

DR MALLORY One can be quite sure that after sterilization, it would not progress, but one cannot be sure how much the fibrosis will regress.

REFERENCES

1. Allen E. V. Lymphedema of extremities. *Proc. Staff Meet. Mayo Clin.* 9:112-115, 1954.
2. Javert C. T. Pathogenesis of endometriosis based on endometrial homeoplasia: direct extension, exfoliation and implantation, lymphatic and hematogenous metastasis. *Cancer* 2:399-410, 1949.

In deciding just what type of lymphedema we are dealing with I will run through very briefly one of the better classifications of lymphedema that might be able to help us. I have picked Dr. E. V. Allen's¹ classification, because I think it is the best and easiest to fit into this picture. He divides unilateral lymphedema into noninflammatory and inflammatory groups. Under the noninflammatory group we have the primary and secondary cases. In the primary cases, we have what he calls lymphedema praecox — lymphedema of unknown etiology that comes on in adolescence, usually in females. There is no known obstruction. The lymph vessels are just not capable of handling things, and a gradual process of fibrosis and further obstruction and swelling develops. There is usually no story of cellulitis or recurrent sepsis to account for it. In addition to the praecox type, there is a congenital type of primary lymphedema. But we can rule that out because this occurred in her thirty-eighth year and there was no previous sign, except a little bit of swelling, which I do not believe was true lymphedema.

Under the secondary type of noninflammatory lymphedema, we have occlusion of the lymph system by malignant growth such as metastatic involvement of lymph nodes, or following eradication of the lymph nodes, such as we frequently see after a radical axillary or groin dissection. The cases that follow x-ray or radium treatments are also in this group.

The second division is the inflammatory group of lymphedema, and here also there are infections in the leg brought on for no apparent cause, there being no obvious focus of entry. The episodes are initiated by chills and fever and other symptoms that we have not seen in this case, and therefore I assume that it does not fit into that group.

In the secondary type of inflammatory lymphedema are the cases associated with venous stasis due to old phlebitis and those in which there is marked venous insufficiency and obvious routes of entry for secondary sepsis. The fungous infections and filariasis are considered to be of this group. Also, there are the cases of lymphedema following severe local injury and trauma.

In reviewing all the groups under the classification, I believe this woman of thirty-eight with rapidly increasing swelling in whom there was no evidence of recurrent chills or fever, no significant findings to suggest venous disease or fungous infection and no local injury, probably fits into the secondary group of noninflammatory cases. There may have been occlusion of the lymph channels and lymph nodes in the pelvis and iliac region that was due probably to some type of malignant tumor. We cannot rule out inflammatory disease itself, but I would think if a lesion of this sort were purely inflammatory and widespread enough to cause that

amount of swelling there would have been more reaction such as chills and fever.

From the beginning, it has been my impression that this mass was some kind of retroperitoneal condition rather than a pelvic lesion. The examiners were apparently able to outline a normal ovary, a normal uterus and this mass. The retroperitoneal location does not eliminate an ovarian tumor because the ovary may have been in ectopic position or may have become adherent so that the tumor would invade in that direction and plug the lymphatics, it is very farfetched reasoning. I wonder why the doctor at the time of her second operation, when she was eighteen years old, told her that she would have no children after he had operated on the tumor of the abdominal wall. It is just possible that she had an ovary in the inguinal canal.

Another condition that I have to mention, in spite of the negative abdominal examination, the absence of lymph nodes and the normal chest film, is a localized lymphosarcoma involving the pelvic iliac nodes and causing obstruction to the lymph outflow. Although there were several years between, she had had a considerable amount of surgery, some of it rather extensive, and she could have had interference with lymph structures from postoperative scar formation. This may not have manifested itself for several years. Another possibility is some type of local tumor of the lymph vessels such as lymphangioma. However, I think I will have to say that she probably had a lymphosarcoma of the iliac lymph nodes with obstruction to account for the lymphedema.

DR. TRACY B. MALLORY: Are there any questions or suggestions? Dr. Ulfelder, do you want to tell us the opinion on the wards?

DR. HOWARD ULFELDER: The protocol could not make it as obvious as it was to us who saw the patient that this pelvic mass was very suggestive of endometriosis. It lay in the posterior cul-de-sac as far as we could tell and could be easily palpated both by pelvic and by rectal examination, and on combined examination it seemed to lie against the posterior aspect of the cervix and anterior to the rectum. It was my impression on the basis of this examination that this mass was more likely to be endometriosis in the region of the uterosacral ligaments than anything else.

CLINICAL DIAGNOSIS

Endometriosis

DR. HARDY'S DIAGNOSES

Lymphosarcoma of iliac nodes
Lymphedema

ANATOMICAL DIAGNOSES

Endometriosis of pelvis and retroperitoneal tissues
Endometrial metastasis to iliac lymph node

the world requires time in which to accept a more dynamic philosophy of service and to alter its course accordingly. Being human, it has made its mistake., being decently human, it is willing to acknowledge them and try to mend its ways.

It must always be remembered, however, by those who clamor for action, that many of the problems of health and disease and the proper distribution of medical care are quite insoluble until patient study, day by day and month by month and year by year gradually reveals some of the answers. Even the Alexanders of bureaucracy cannot dissolve these knotty problems simply by cutting them.

So far the best answer to the distribution of medical service appears to lie in the voluntary health insurance plans and the education of the public in the tremendous difficulties, responsibilities and often disappointments, as well as the great achievements, day in and day out, that attend the practice of medicine. These difficulties the doctors themselves are constantly trying to overcome, and are even taxing their own incomes to help in the attempt.

The health protection for all that is being purchased with the funds of the American Medical Association may be considered as the gift of the profession to the people of America.

OLD FARMER'S ALMANAC

THE New Year in New England is fittingly heralded by the appearance of *The Old Farmer's Almanac*, published in Dublin, New Hampshire, and now in its one hundred and fifty-eighth year of continuous publication. Introducing the seasons, the months and the days of the year with astronomical fidelity, forecasting the weather for fifty-two weeks ahead with inflexible accuracy and in the utmost detail, reminding its readers of past events and of present duties, and warning them of seasonal dangers on the same superlatively abbreviated pages, the *Almanac* in its familiar yellow cover still holds its place of esteem in those households that recognize man's dependence on the soil.

From these pages it may be learned that bloomers, as an article of female attire, were introduced to

an eagerly expectant populace on January 2, 1849, and that January 2, 1950, will be a very cold day, that in the middle of the month the danger of chimney fires is imminent and that on January 24, to be marked by a thaw in 1950, the Chilean earthquake occurred in 1939.

It is the homely traditions of New England, of which the *Almanac* is a tough and persistent symbol, that bind these states together as by a blood relationship. Its fisheries, its forests and its ship-building contributed to the early development of New England and its superb waterpower made it one of the important industrial sections of the country but it was the New England farm that gave New England its characteristic atmosphere.

The rugged, all-purpose New England farm, where the sheep's noses had sometimes to be trimmed down on a grindstone before they could get the grass between the boulders, represented not a cash business but a way of life. It was a way of life filled with hard work, but also with certain amenities, the recollection of which has been preserved by John Greenleaf Whittier, a New England farm boy, and by Robert Frost. It was a way of life that is responsible for a nostalgic sympathy with what *The Old Farmer's Almanac* represents, and for an independence of mind and an individual endurance that make New England still a stronghold of democracy and free enterprise.

"BUT FEAR ITSELF"

THE reassurance once issued to the American people by their president that they had nothing to fear "but fear itself" would not suit every occasion, appropriate as it might have been at that time. There are reasonable fears and unreasonable fears, healthy fears and unhealthy ones.

It is with the latter that Terhune* is concerned in discussing his experiences with a group of patients suffering from the "phobic syndrome." This group, comprising 86 persons, represented 25 per cent of his psychoneurotic patients. Women in the group outnumbered the men two to one. They were mostly under forty years of age and though

COMMUNICATIONS should be addressed to the *New England Journal of Medicine*, 8 Fenway, Boston 15, Massachusetts. Telephone KE 6-2094.

WISE MEN BEARING GIFTS

THE House of Delegates of the American Medical Association, thereby incurring the disapproval of the *Boston Herald* as expressed editorially on December 11, has voted to levy annual dues of \$25 on its members. This new source of revenue, provided for in the by-laws, will supplement the now inadequate income that the Association receives from its publications, and will be used to defray the expenses of its various activities in the interest of better medical care for all.

It would appear that the establishment of these dues is part of the legitimate internal affairs of the Association. When acceptable evidence is brought to light that funds are being improperly or even unwisely used, then it may be hoped that such a friend of the ethical profession of medicine as the *Boston Herald* has been will not withhold its criticism.

To those who are interested in examining all sides of a controversial matter, the constructive activities of the American Medical Association must soon become apparent. Its influence in establishing high standards of medical education and hospital service is a matter of history, and its efforts at maintaining these standards through the Council on Medical Education and Hospitals are part of the record. The Council on Pharmacy and Chemistry is tireless in its positive opposition to "fraud, undesirable secrecy, and objectionable advertising in connection with proprietary medicines." Were the newspapers of the country as truly interested in protecting the health of the public as many of them profess to be, they might have consulted the Council on Pharmacy and Chemistry before accepting some of the full-page advertisements of wonder-working drugs that have recently been flung before the public as an open invitation to self-dosing with insufficiently tested remedies.

The representatives of the Fourth Estate, with conspicuously few exceptions, have done well in holding up the hands of the medical profession, represented by the American Medical Association, in its efforts to protect the public health and its own autonomy by combating compulsory health insurance. Many of the Association's friends, however, and all of its enemies, need to know more about its positive and constructive activities.

In addition to the two mentioned above, they need to know about the councils on scientific assembly, foods and nutrition, physical medicine, medical service, industrial health and national emergency medical service. They need to know about the committees on therapeutic trials and scientific research and on rural medical service, the bureaus of medical economic research and health education that the Association maintains.

With a full knowledge of these and many other activities, they will then be in a better position to weigh the charge of "accenting the negative" that has been expressed or implied so frequently in recent months.

Great bodies move slowly, and the American Medical Association, representing the rank and file of one of the most conservative professions in

the world, requires time in which to accept a more dynamic philosophy of service and to alter its course accordingly. Being human, it has made its mistakes, being decently human, it is willing to acknowledge them and try to mend its ways.

It must always be remembered, however, by those who clamor for action, that many of the problems of health and disease and the proper distribution of medical care are quite insoluble until patient study, day by day and month by month and year by year, gradually reveals some of the answers. Even the Alexanders of bureaucracy cannot dissolve these knotty problems simply by cutting them.

So far the best answer to the distribution of medical service appears to lie in the voluntary health insurance plans and the education of the public in the tremendous difficulties, responsibilities and often disappointments, as well as the great achievements, day in and day out, that attend the practice of medicine. These difficulties the doctors themselves are constantly trying to overcome, and are even taxing their own incomes to help in the attempt.

From these pages it may be learned that bloomers, as an article of female attire, were introduced to

an eagerly expectant populace on January 2, 1849, and that January 2, 1950, will be a very cold day, that in the middle of the month the danger of chimney fires is imminent and that on January 24, to be marked by a thaw in 1950, the Chilean earthquake occurred in 1939.

It is the homely traditions of New England, of which the *Almanac* is a tough and persistent symbol, that bind these states together as by a blood relationship. Its fisheries, its forests and its ship-building contributed to the early development of New England, and its superb waterpower made it one of the important industrial sections of the country, but it was the New England farm that gave New England its characteristic atmosphere.

The rugged, all-purpose New England farm, where the sheep's noses had sometimes to be trimmed down on a grindstone before they could get the grass between the boulders, represented not a cash business but a way of life. It was a way of life filled with hard work, but also with certain amenities, the recollection of which has been preserved by John Greenleaf Whittier, a New England farm boy, and by Robert Frost. It was a way of life that is responsible for a nostalgic sympathy with what *The Old Farmer's Almanac* represents, and for an independence of mind and an individual endurance that make New England still a stronghold of democracy and free enterprise.

"BUT FEAR ITSELF"

THE reassurance once issued to the American people by their president that they had nothing to fear "but fear itself" would not suit every occasion, appropriate as it might have been at that time. There are reasonable fears and unreasonable fears, healthy fears and unhealthy ones.

It is with the latter that Terhune* is concerned in discussing his experiences with a group of patients suffering from the "phobic syndrome." This group, comprising 86 persons, represented 25 per cent of his psychoneurotic patients. Women in the group outnumbered the men two to one. They were mostly under forty years of age and though

*Terhune W. B. Phobic syndrome: study of eighty-six patients with phobic reactions. *Arch. Neurol. & Psychiat.* 62:162-172, 1949.

outstandingly intelligent and from financially secure families were only moderately successful, chiefly because handicapped by fear

These patients were, on the whole, anxious, dependent, emotionally immature young adults who were trying to realize their ambitions and become self-reliant, successful members of society. They were physically healthy, though soft. Reassuring and of prognostic importance is the fact that none of the 86 ever acquired a psychosis. They did have, however, cyclothymic tendencies and "hyperactive vegetative nervous systems that cause unpleasant symptoms which they do not understand and which then give rise to further fear." They were suggestible, imaginative, sensitive persons, with considerable drive, high standards of conduct, active intelligence and ambition. Fearful of situations that might bring on unconquerable panics within them, their instinct for escape was strong. As the author astutely puts it, "They refuse to enter any place from which they cannot escape quickly and with dignity."

A person with a strongly developed anxiety reaction betraying itself in phobic form may be pitiable indeed. He will not or cannot attend parties or enter any public place. Fearing the somatic avalanche of "faintness, weakness, fatigue, palpitation, perspiration, nausea, tremor and difficulty in breathing" that overwhelms him when he finds himself conspicuous in his inadequacy, he dreads equally the crowded theater and the quiet, but peopled church, the city sidewalk whose crowds he has to face alone and the lonely country road that aggravates his sense of insecurity. He fears the high bridge, the water-girt island and the tunnel, from which there seem to be no escape.

It is not difficult to understand that emotional immaturity must be the basis of such unreasoning phobia—that the phobic person, finding himself unable to cope with the apparently dangerous realities of existence, suffers frustrations, becomes "unfavorably conditioned to specific situations," and retreats to a childish level of adjustment. Consciously he may realize that "there is nothing to fear but fear itself," but what a devastating fear that may become!

The phobic patients representing only 25 per cent of the psychoneurotic persons that Terhune has encountered, emphasize by their relative small numbers the varieties of adjustments that human kind must make, the majority of the having as their basis immaturity of emotional development. Few people there must be, indeed, who regularly enjoy complete emotional maturity. With or without specific phobias, emotional immaturity must account for a great deal of the failure and unhappiness in the world, particularly in environments so complicated that full maturity almost indispensable if they are to be coped with successfully.

The hopeful part of Terhune's paper deals with the apparent success that has rewarded the treatment of the phobias by giving the patient an understanding of his difficulties, socializing him, building up his confidence in himself and reconditioning his fears. By these processes 67 per cent of the group have been permanently relieved of their apprehensions, 24 per cent have been greatly improved to the point where they can work and live efficiently, and only 9 per cent have shown little or no improvement.

Most effective and most efficient of the conditioning mechanisms, however, must be the prevention of these personality disorders. The present road and the road ahead are too rough to be trodden barefoot. If the world's children are to overcome the difficulties that the world presents, they must be conditioned to them from the start.

DR FISHBEIN RETIRES

THE resignation of Dr Morris Fishbein as editor of the *Journal of the American Medical Association* after his service of twenty-five years in that capacity has been accepted by the board of trustees.

During much of this period Dr Fishbein has been a prominent figure on the American scene, considered by many as the standard-bearer of organized medicine. Physically and intellectually tireless, Dr Fishbein early assumed an unofficial leadership in the affairs of the Association that was apparently unchallenged until recent years.

As he leaves the headquarters of the Association, possibly with his energetic tongue held temporarily in his cheek, there remain behind him unquestioned monuments to his vigor and sagacity — the *Journal* and the other publications of the American Medical Association and the real contributions that he has made toward raising the standards of medical practice.

Mr Davis, the man of revelations, is said to be preparing an extraordinary work on medicine, the result of recent interviews with Galen! He was in Boston last week, but whether he met with Galen or Hippocrates here, has not been divulged

Boston M & S J, December 26, 1849

Fourth-year students in approved medical schools are reminded of the *Journal's* prize essay competition on "Recent Advances in the Recognition, Treatment and Control of Poliomyelitis"

*Five-year median.

COMMENT

This month dog bite, poliomyelitis and typhoid fever were above the seven-year median. Diseases below the seven-year median were German measles, measles, mumps and scarlet fever. There were 751 cases of dog bite this month, which was 10% below the 789 cases of November, 1948, when there were 789 cases

Poliomyelitis continued to decline steadily from the high level of August, with 76 cases this month compared to a seven-year median of 24 cases

Scarlet fever was at the lowest incidence ever recorded in November. Measles was at the lowest since 1907, and German measles at the lowest in ten years

The incidence of whooping cough is rising, being at the highest level since December, 1947

GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASES

Diphtheria was reported from Ayr, 1, Boston, 12, Leominster, 1, Malden, 1, Somerville, 6, Wilmington, 1, total, 22

Dysentery, bacillary, was reported from Boston, 4, Brookline, 1, Cambridge, 1, Somerville, 1, Worcester, 1, total, 8

Encephalitis, infectious, was reported from Lynn, 1, Mansfield, 1, Palmer, 1, Springfield, 1, total, 4

Infectious hepatitis was reported from Revere, 1, total, 1

Malaria was reported from Northampton, 1, total, 1

Meningitis, meningococcal, was reported from Boston, 1, Salem, 1, Springfield, 1, total, 3

Meningitis, Pfeiffer-bacillus, was reported from Belmont, 1, Brockton, 2, Hovoke, 1, total, 4

Meningitis, pneumococcal, was reported from Needham, 1, Worcester, 1, total, 2

Meningitis, streptococcal, was reported from Ashland, 1, total, 1

Meningitis, undetermined, was reported from Danvers, 1, Fall River, 2, Greenfield, 1, Longmeadow, 1, Lowell, 1, Needham, 1, South Hadley, 1, Spencer, 1, Woburn, 1, total, 10

Poliomyelitis was reported from Ashburnham, 1, Attleboro, 1, Boston, 7, Bourne, 1, Brookline, 1, Cambridge, 3, Chelmsford, 2, Concord, 3, Dedham, 1, Dracut, 2, Fitchburg, 1, Greenfield, 1, Hamilton, 1, Hingham, 1, Holliston, 1, Hopedale, 1, Lee, 1, Lexington, 1, Lincoln, 1, Longmeadow, 1, Lowell, 4, Marion, 1, Marshfield, 1, Medford, 2, Milton, 1, Nahant, 1, Nauck, 1, Needham, 1, New Bedford, 1, Newton, 2, North Attleboro, 1, Norwell, 1, Oakham, 1, Orange, 1, Palmer, 1, Pittsfield, 1, Quincy, 1, Saugus, 1, Somerset, 1, Taunton, 1, Tyngsboro, 1, Waltham, 6, Wellesley, 1, Weston, 1, West Springfield, 1, Winchester, 1, Worcester, 6, Wrentham, 1, Plymouth, 1, total, 76

Salmonellosis was reported from Cambridge, 1, Fall River, 1, Norwood, 1, total, 3

Septic sore throat was reported from Boston, 2, Braintree, 1, Fall River, 1, Worcester, 1, total, 5

Tetanus was reported from Gloucester, 1, Pittsfield, 1, total, 2

Typhoid fever was reported from Brookline, 1, Ipswich, 1, Plymouth, 1, total, 3

Undulant fever was reported from North Adams, 1, total, 1

CORRESPONDENCE

LAISSEZ FAIRE

To the Editor Although inactivated myself from the practice of medicine and conscious of a consequent inability to sense the emotions of the man who is in active practice, I feel moved to protest these twenty-five dollar assessments, which seem on the way to becoming a permanent medical liability.

In making this protest may I state that I have no sympathy for the compulsory insurance program but I should like to observe that opposition to the program and contributions to make this opposition effective are by no means the exclusive responsibility of physicians. Physicians will be hurt no more than the average citizen. There is nothing to indicate that a physician's income will be seriously less than at present though his satisfactions and his morale stand to be lowered through loss of incentive. There is reason to predict a dismal future for scientific achievement in the field of medicine. The results of these changes will be felt by the average citizen in higher taxes and a distinct loss in the standards of individual consideration that he now expects from his physician.

Now that the A M A has spent its millions in its educational campaign this year, making these facts clear to the nation, if the majority still wish to have Government hand-

outs, Government bankruptcy and socialized medicine — if they wish to have a look at the inside of a bog — I say, "Let 'em."

I am willing to contribute to a campaign waged by people of all trades and professions but I will not willingly contribute to a fund raised solely by physicians.

ALLAN R. CUNNINGHAM, M.D.

Winchester, Massachusetts

BOOK REVIEWS

Practical Lessons in Psychiatry, By Joseph L. Fetterman, M.D. 8°, cloth, 342 pp., Springfield, Illinois: Charles C. Thomas, 1949. \$5.75.

The author, who has been an executive officer of the School of Military Neuropsychiatry, wrote this book as an outgrowth of lectures at this school and of seminars given in Cleveland. A wealth of material is presented in concentrated form, arising from the author's military and civilian experience. The level, style, together with the very numerous examples, makes this book pleasant reading.

In the introductory chapter on the patient and his personality the author shows that learning never should exclude common sense. Psychoneuroses and their treatment are given rather thorough consideration. The possibilities of "short psychotherapy" are discussed and illustrated by histories. The author expresses his opinion concerning disputed questions and attempts to formulate new interpretations. For instance, he emphasizes the organic factors in the etiology of endogenous depression, and in schizophrenia he adds to the usual types the subdivision of schizoaffective disorders. This last group runs a cyclic course and responds well to shock therapy. The author states, "Those cases which fail to respond and ultimately require confinement to state hospitals are usually true Schizophrenias." The book deals thoroughly with insulin and "electro-coma therapy," which are best suited to the affective disorders. His own working hypothesis is that the mood is cyclic and tends to return to the baseline of average normality. This tendency is also present in manic-depressive states in which the cycle may take a year or more. Electrocoma therapy accelerates this tendency to return to the average state. "The passage of the current through the brain and the convulsion effect the physiological change which proves to be both a stimulus to improve bodily function and a removal of self-attacking mechanisms!" In schizophrenia "this restoration of the mood towards normal may carry with it a change in ideation."

The book deals with all manifestations of mental disorders, and much consideration is given to the military, industrial, legal and social aspects. Dr. Fetterman says in the preface that he planned this book for general practitioners, nurses, psychologists, personnel advisers and social workers, but, the psychiatrist, too, will appreciate many of the opinions, which are borne out by the author's great experience.

Pathology and Surgery of Thyroid Disease. By Joseph L. DeCoursey, M.D., and Cornelius B. DeCoursey, M.D. 8°, cloth, 476 pp., with 93 illustrations. Springfield, Illinois: Charles C. Thomas, 1949. \$10.00.

Recent developments in the treatment of thyroid disease have been unusual. The utilization of ever-increasing varieties of antithyroid drugs and of radioactive iodine in the study and treatment of certain affections of the thyroid gland has been responsible, in a measure, for the publication of several new textbooks relating to the general subject of thyroid disease. This volume brings still another shade of opinion to bear on this, as ever, controversial subject.

These authors, in presenting their convictions in this regard, draw heavily upon their large personal experience in the surgical treatment of thyroid disease. These convictions, in the main, are conventional, and are attested to by the cumulative experience of other recognized ones in the field.

This treatise, consisting of 476 pages with is divided into sixteen chapters. The deal with the anatomy, embryology, physiology of the thyroid gland are adequate in terms of accuracy. The description of the clinical various diseases of the thyroid gland

certain aspects, however, the position of the authors is more novel, and therefore will be subjected to some question in quarters having a comparably large experience with the management of thyroid disease.

It is essentially in the field of therapy that significant differences in points of view will be manifest.

The authors apparently consider iodine (Lugol's solution) as the treatment of choice in the preoperative preparation of the average thyrotoxic patient for thyroidectomy, although they cover, with ample discussion and thorough documentation, the historical development and clinical application of the various thiourea derivatives in the preoperative management of thyrotoxic patients. The authors utilize certain thiourea drugs in conjunction with iodine in the preparation of selected patients with diffuse toxic goiter for thyroidectomy. They state specifically (p. 214), however, that "toxic nodular goiter should not be treated with thiouracil, but should (also) be removed surgically." It is not entirely clear to the reviewer whether the authors mean to say that patients with toxic nodular goiters should not be given thiouracil even as a preliminary adjunct to subsequent thyroidectomy or whether they are merely opposed to its utilization as a substitute for surgery. In the opinion of the reviewer, based upon the experience of the Lahey Clinic, propylthiouracil is currently the preparation of choice in the preliminary restoration of normal metabolism in the presence of either diffuse or nodular toxic goiter. Iodine in the form of Lugol's solution, is employed during the last two or three weeks of thiouracil therapy to induce involution of the hyperplastic gland in the patient with primary hyperthyroidism (diffuse toxic goiter). No iodine is used routinely in the nodular toxic goiters.

The reviewer is in thorough agreement with the authors in their convictions regarding the necessity of treating patients with diffuse and nodular toxic goiters by subtotal thyroidectomy and the importance of iodine in conjunction with thiourea derivatives in the preparation of patients with diffuse toxic goiter (primary hyperthyroidism) for surgery, and is in opposition to the thesis that radioactive iodine will replace surgery in the treatment of thyrotoxicosis.

DeCoursey and DeCoursey advocate routinely the use of small doses of thyroid extract postoperatively for a period of approximately a year in all cases of hyperthyroidism. They base this advocacy on the theory that "by keeping sufficient thyroid in the blood stream following operation, the thyroid remains at rest." They believe that their low incidence of recurrent hyperthyroidism is due, in some measure, to this practice. Some surgeons and internists, with wide experience in the treatment of thyroid disease, will question the validity of this contention, and will believe that the authors' low rate of recurrent hyperthyroidism following subtotal thyroidectomy is probably due to the thoroughness with which the operation is performed. Many will fear the routine use of thyroid extract after operation because of the conviction that, in certain cases, thyrotoxicosis apparently has been induced by its injudicious administration. One might also point out the theoretical possibility that the concentration of iodine in thyroid extract could be responsible for any therapeutic benefit that might derive from the administration of desiccated thyroid in this connection.

In performing thyroidectomy, the authors do not routinely divide the strap muscles, expose the recurrent laryngeal nerve, demonstrate the parathyroid glands or ligate the inferior thyroid artery — technical considerations that are believed to add to the safety of the operation.

This book is well organized, generously illustrated and carefully documented. To this increasingly controversial field of medical and surgical therapy it brings considerable support to certain conventional concepts, and novel convictions in some regards, which may tend to widen the area of conflicting opinion.

Cardiovascular Disease: Fundamentals, differential diagnosis, prognosis and treatment. By Louis H. Sigler, M.D. 8°, cloth, 51 pp., with 149 illustrations. New York: Grune and Stratton, 1949. \$10.00.

Recent, refresher courses for physicians are in the of practically every teaching institution. Here at would serve well as a refresher course in cardiovascular diseases. It covers briefly the fundamentals, differential diagnosis and prognosis. Another

valuable point is the view of the author, who looks upon the heart as a unit affecting the entire organism even though limited clinically to localized structures and organs.

The book covers practically the entire field of cardiology. It starts with a chapter on the general incidence of cardiovascular disease and runs through the whole gamut including congenital heart disease and psychosomatic cardiovascular abnormalities and contains a final chapter on surgery and cardiovascular disease. This book also has a number of very informative illustrations and is well documented. There is, however, one fundamental fault in some places the author is too brief and important other subjects are completely omitted. For example, electrocardiography, which is essential in heart disease, is covered in only one paragraph—making a reference to an article that covers the subject. At least one chapter should have been devoted to this subject. The reviewer found it a very profitable book that briefly covers most of the essentials in the field of cardiology.

BOOKS RECEIVED

The receipt of the following books is acknowledged and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

From Thirty Years with Freud. By Theodor Reik. Translated by Richard Winston. Second printing. 8°, cloth, 244 pp. New York: International Universities Press, Incorporated, 1949. \$3.75.

This volume is a second printing of a book first published in 1940. The material is divided into four parts: Freud and his followers, including biographic material on Freud; a well-known lecture of Freud's, Freud as a critic of culture; and essays on diverse subjects. To those not owning the 1940 original this reprint presents the opportunity of purchasing this work on psychoanalysis.

Conference on Metabolic Aspects of Corpulence. Transactions of the Sixteenth Meeting, New York, New York, October 21-25, 1947. 8°, cloth, 168 pp., with 39 illustrations. \$3.00. *Transactions of the Seventeenth Meeting, New York, New York, March 29-30, 1948*. 8°, cloth, 246 pp., with 79 illustrations. \$4.00. Edited by Edward C. Reifenstein, Jr., M.D. New York: Josiah Macy, Jr., Foundation, 1948.

In both these conferences a number of papers were presented on the adrenocorticotrophic hormone and adrenal conditions and on protein metabolism. Detailed tables of contents take the place of indexes. The volumes should be in all medical libraries and available to all research workers in the field of metabolism.

Obesity. By Edward H. Ryncarson, M.D., Division of Medicine, Mayo Clinic, and associate professor of medicine, Mayo Foundation and Clifford F. Gastineau, M.D., fellow in medicine, Mayo Foundation, Rochester, Minnesota. 8°, cloth, 134 pp., with 9 illustrations and 16 tables. Springfield, Illinois: Charles C. Thomas, 1949. \$3.50.

This monograph, prepared for the practicing physician, considers the various aspects of obesity. The introduction presents valuable weight tables for men and women of ages twenty-five and over, percentage of overweight and underweight, deaths per 100,000 from all causes and all ages by weight classes, influence of overweight on mortality in persons aged forty-five to fifty years, and the influence of body weight on mortality. In order the physiology, etiology, contraindications to reduction and treatment including diet, psychotherapy, drugs, heat, and exercise and massage are discussed. The chapter on diets was written by Alice Karelake Irmisch and contains many diet tables. There is a bibliography of 422 easily obtainable references. Surprisingly there is not an index. The book should be in all medical libraries and should prove useful to the practicing physician.

Facts About the Course of Life. By E. C. Hamblen, M.D., professor of physiology and associate professor of obstetrics and gynecology, Duke University School of Medicine.

and chief of the endocrine division and endocrinologist, Duke Hospital, Durham, North Carolina. 12°, cloth, 86 pp. Springfield, Illinois: Charles C. Thomas, 1949. \$2.50.

This small book is written for women and presents in simple language the information that they need concerning the menopause, with the object of dispelling unnecessary fears during this period. The anatomy and physiology of the female sexual organs and the endocrine system, hygiene and the nervous and mental conditions incident to this period are discussed. There is a chapter on cancer in which the author points out that the occurrence of cancer during the menopause is chronologic and casual.

Applied Psychoanalysis. Selected objectives of psychotherapy. By Felix Deutsch, M.D. 12°, cloth, 244 pp. New York: Grune & Stratton, 1949. \$3.75.

The Boston Psychoanalytic Society, during the years 1942-1947, conducted a psychiatric clinic for the treatment of neuroses. The knowledge gained during this period is summarized in this small volume. The material is divided into four parts: goal-limited adjustment (sector therapy, with an analysis of two cases, one with fourteen interviews), psychiatry and social work (including psychoanalysis), mental health in industry—job phobia, and family disruption (separation neurosis). A short bibliography is appended to the chapter on mental health in industry. There is a good index. The small volume is well published.

Problems of Early Infancy. Transactions of the Second Conference, March 1-2, 1948, New York, New York. With Supplement: Opening Special Meeting, July 18-19, 1947, New York, New York. Edited by Milton J. E. Senn, M.D., departments of pediatrics and psychiatry, Yale University School of Medicine. 8°, cloth, 120 pp. New York: Josiah Macy, Jr., Foundation, 1948. \$1.00.

The main themes of this conference were the psychological problems of pregnancy and neurotic conditions in children in war. Eighteen persons delivered papers at the meeting. The volume should be in all medical libraries, as well as all the libraries sponsored by the Macy Foundation.

Help Your Eyes. Better Sight. By Margaret D. Corbett, M.D. 8°, cloth, 21 pp. New York: Prentice-Hall, Incorporated, 1949. \$2.50.

In this volume, written for the laity, the author describes the Bates method of relaxation for rebuilding vision in defective eyes.

Outliving Your Years. By Clarence W. Lieb, M.A., M.D. 12°, cloth, 278 pp. New York: Prentice-Hall, Incorporated, 1949. \$2.75.

This popular book, written for persons in their fifties and over, discusses hygiene, work, exercise, hobbies, and the so-called diseases of old age, including heart disease, high blood pressure and cancer. It is pointed out that cancer is not part of the aging process but is prevalent in women of forty to sixty and in men over sixty. Also, the painful condition of arthritis is considered. The text is well written in a simple manner and abounds with common-sense advice.

Public Health Statistics. By Marguerite F. Hall, M.A., Ph.D., associate professor of public-health statistics, School of Public Health, University of Michigan. Second edition, revised. 8°, cloth, 441 pp., with 41 illustrations. New York: Paul B. Hoeber, Incorporated, 1949. \$7.50.

In this revision of a special work, part of the text has been rewritten and the material brought up to date. The statistical tables have been revised, and some tables have been added. There is a new chapter, illustrating three of the most useful applications of life-table techniques to the materials available in public-health activities. A section has been added to the chapter on correlation to give greater emphasis to correlation technique. Likewise, the author has attempted to simplify the basic theory of the application of the normal curve to statistical processing of public-health data. Much of the material in the original chapter on estimates of popula-

tion has been deleted as obsolete because of the new techniques originating with World War II. The section on sampling emphasizes three variables that must be known before the size of the sample can be determined. The publishing is excellent. The book should be in all large public libraries and in all collections on public health and statistics.

Textbook of Medicine. By various authors. Edited by Sir John Conybeare, K B E., M C., D M. (Oxon), F R C P., physician to Guy's Hospital, London. Ninth edition. 8°, cloth, 875 pp., with 28 illustrations. Baltimore: Williams and Wilkins Company, 1949. \$8.00.

This composite textbook, the work of eighteen British physicians, was first published in 1929. Its long life is good evidence of its soundness and popularity. The volume is well published. The paper, type and printing are excellent. There is a good index. The printing was done in Great Britain. The work should be in all the large medical libraries.

The American Nurses Dictionary. The definition & pronunciation of terms in the nursing vocabulary. By Alice L. Price, B S., R N., instructor of nursing arts at Columbia Hospital, Milwaukee 12°, cloth, 656 pp. Philadelphia: W B Saunders Company, 1949. \$3.75.

This new dictionary defines approximately 25,000 words and indicates their pronunciation, a very valuable feature. The text is concluded with a number of tables, including abbreviations, prefixes and suffixes, chemical symbols and elements. The book is well published and should prove generally valuable. It should be in all public and medical libraries.

Vocabulary Guide. A teacher's supplement to the American Nurses Dictionary. 8°, cloth, 101 pp. Philadelphia: W B Saunders Company, 1949.

The separate supplement is designed for nurses and is arranged topically.

NOTICES

SPRINGFIELD HOSPITAL CONFERENCES

The following conferences will be held at the Springfield Hospital, Springfield, Massachusetts, during January, 1950:

Saturday, January 7, 12 noon: Symposium on Diseases of the Thyroid Gland.

I. Diagnosis and Treatment of Simple Goiter and Inflammatory Diseases of the Thyroid Gland (Staff Conference Room).

Saturday, January 14, 12 noon: Symposium on Diseases of the Thyroid Gland.

II. Diagnosis and Treatment of Graves's Disease (Staff Conference Room).

Tuesday, January 17, 8:30 p.m.: Clinical Pathological Conference (Staff Conference Room).

Saturday, January 21, at 11:00 a.m.: Springfield Hospital Guest Speaker Conference. Dr. Samuel Levine, Boston.

Topic: "Auscultation of the Heart."

Saturday, January 28, 12 noon: Symposium on Diseases of the Thyroid Gland.

III. a. Diagnosis and Treatment of Thyroid Neoplasms.

b. Complications following Therapy of Thyroid Disease.

Conferences are open to all interested physicians.

NEW ENGLAND CARDIOVASCULAR SOCIETY

A meeting of the New England Cardiovascular Society (formerly the New England Heart Association) will be held in the amphitheater of the Dowling Building, Boston City Hospital, on Monday, January 9, at 8:00 p.m., Dr. Laurence B. Ellis presiding.

PROGRAM

The Use of an Oral Mercurial Diuretic in Ambulatory Patients. Drs. Elliot Bresnick, Johns Abramson and Peter L. Safra.

Khellin in the Treatment of Angina Pectoris. Drs. Harold Osher and Kermit H. Katz.

The Effect of Intravenous Digoxin on the Dynamics of the Circulation in Congestive Heart Failure. Drs. Richard A. Bloomfield, Garth A. Graham, Henry Kraus and Paul H. Pfeiffer.

The Effect of Digitalis on the Oxygen Consumption, Ventilation and Pulse Rate during Exercise in Normal Subjects and Patients with Heart Disease. Drs. Herbert S. Sise and Kenneth Chesky.

Evaluation of Surgical Treatment of Angina Pectoris. Drs. Dwight E. Harken, Robert C. Farrand and Leona R. Norman.

The Use of Cation-Exchange Resins in Patients with Cardiac Edema. A preliminary report. Dr. Henry Kraus.

Interested physicians and medical students are cordially invited to attend.

AMERICAN COLLEGE OF ALLERGISTS

The sixth annual congress of the American College of Allergists will be held at the New Hotel Jefferson, St. Louis, Missouri, January 15 through 18. The subjects of allergy of the eye, dangers of cosmetics, snake venom in the treatment of urticaria, shortening the treatment of hay fever, allergy in France, England and Ireland, relation of allergy to character problems in children, marital adjustments in parents of allergic children and many others will be discussed. Dr. Paul Kallos, of Helsingborg, Sweden, will be awarded the von Pirquet medal for outstanding achievement in allergy.

BOSTON HEALTH DEPARTMENT EXAMINATIONS FOR TUBERCULOSIS

Gastric examinations for tuberculosis may be obtained by appointment on Mondays, Wednesdays and Thursdays at the laboratory of the Boston Health Department, Haymarket Square (Telephone, CA 7-1300). Examinations may be obtained for their patients by all physicians, but the patients must live in Boston.

VETERANS ADMINISTRATION RESIDENCY TRAINING IN NEUROPSYCHIATRY

A limited number of openings are available for July 1, 1950, appointment to the Veterans Administration residency training program in neuropsychiatry. This program is under the jurisdiction of the deans of the Boston medical schools (Harvard, Tufts and Boston University). Training in this program, which may be from one to three years, is given at the following institutions:

Cushing Veterans Administration Hospital, Framingham, Massachusetts.

Bedford Veterans Administration Hospital, Bedford, Massachusetts.

The Mental Hygiene Clinic of Boston, Regional Office of Veterans Administration, Boston, Massachusetts.

West Roxbury Veterans Administration Hospital, West Roxbury, Massachusetts.

White River Junction Veterans Administration Hospital, White River Junction, Vermont.

Emphasis in the entire program is on psychiatry with dynamic orientation and includes closed-ward, open-ward, outpatient and child psychiatry and neurology. Training in child psychiatry is given at the Children's Medical Center, Massachusetts General Hospital and Hahn Clinic, Boston.

All stations are within commuting distance of the Boston Psychoanalytic Institute, in the event that applicants have been accepted for analytic training.

Further information may be obtained from: Dr. [Name], Chief, Professional Services, Bedford Veterans Administration Hospital, Bedford, Massachusetts; Dr. [Name], Chief, Neuropsychiatric Clinic, West Roxbury Veterans Administration Hospital, Framingham. (Notes concluded.)

INDEX

CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

1949

The date of publication of any case may be determined from the case number. The first two figures of each case number indicate the volume number, 35. The third and fourth figures give the number of the week, dating from January 1. The last figure gives the case number for the week. For example, Case 35251 is the first case for the twenty-fifth week of Volume 35.

- Abscess of appendix, 35472
 - of heart, multiple, 35182
 - of lung, 35331
 - peritoneal, 35382
 - retroperitoneal, 35051
- Adenocarcinoma, see Carcinoma
- Adenoma of breast (fibro-), lactating, 35332
 - of bronchus, 35112, 35272, 35431
- Adrenal gland, amyloidosis of, 35391
 - carcinoma of, 35481
 - metastatic, 35052
- Amyloidosis of adrenal gland, 35391
 - of blood vessels (primary), 35141
 - of heart and valves (primary), 35141
 - of kidney, 35042, 35391
 - of liver, 35042, 35391
 - of lung (primary), 35141
 - of lymph nodes, 35391
 - (primary), 35141
 - of spleen, 35042
- Aneurysm, arteriosclerotic, ruptured, of abdominal aorta, 35501
 - (wired) of abdominal aorta, 35192
 - cirsoid, of branch of gastropiploic artery, with rupture and massive hemorrhage, 35492
- Anomaly, congenital, of intestine, defect of mesentery, with volvulus and perforation of ileum, 35372
 - persistent omphalomesenteric duct, 35201
- of kidney (hamartoma of cloacal tissue in renal pelvis), 35221
 - single pelvic, 35242
 - of vas deferens (absence of), 35311
- Aorta, aneurysm of, ruptured, abdominal, 35501
 - (wired) abdominal, 35192
- Appendix, carcinoma of (adeno-), metastatic, with abscess formation, 35472
- Arteriosclerosis, generalized, with ruptured aneurysm of abdominal aorta, 35501
 - mesenteric, 35082
 - with thrombosis, 35071
 - pulmonary, 35062
- Bence-Jones proteinuria (kidney)?, 35041
- Bile duct, carcinoma of (adeno-), 35191, 35471
 - stone in, 35132, 35502
- Bladder, carcinoma of, cured by radiation, 35511
 - fibrosis of, radiation, 35511
- Blood vessels, amyloidosis of (primary), 35141
- Bone, benign chondroblastoma of (femur), 35172
 - fibroma of, nonosteogenic (fibula) 35011
 - myeloma of, diffuse, 35041
 - multiple, 35142
 - osteoma, osteoid of (femur), 35181
 - osteoporosis, 35071
 - sarcoma, fibro- (femur), 35262
- Brain, carcinoma of, metastatic from colon, 35282
 - cyst of, epidermal (suprasellar), 35341
 - glioblastoma multiforme of, with metastases to spinal cord and spinal nerves, 35491
 - hemorrhage of, cerebral, 35072
 - infarction of, cerebral (venous), 35072
 - see also Sinus
- Breast, adenoma of (fibro-), lactating, 35332
 - carcinoma of, adeno- (papillary), 35312
 - sarcoma of (hemangio-), 35321
- Broad ligament, hematoma of, 35032
- Bronchus, adenoma of, 35112, 35272, 35431
 - stenosis of (calcified tuberculous lymph nodes), 35401
- Carcinoma of adrenal gland, 35481
 - of ampulla of Vater (adeno-), 35191, 35471
 - of appendix (adeno-), metastatic, with abscess formation, 35472
 - of bladder, cured by radiation, 35511
 - of breast (adeno-), papillary, 35312
 - of colon (adeno-), 35102
 - with metastases, 35192, 35282
 - with probable perforation, 35042
 - of gall bladder, 35342
 - with metastases, 35462
 - of intestine (cecum), with intussusception, 35122
 - of kidney, papillary, 35511
 - with metastases, 35301
 - renal-cell, 35482
 - of liver (hepatoma), with extension into vena cava and heart, 35422
 - metastatic to lung, 35422
 - of lung (adeno-), 35052, 35212
 - (oat-cell), with metastases, 35211
 - (squamous-cell) 35021, 35151
 - (undifferentiated), with metastases, 35402
 - of ovary, metastatic from bladder, 35061
 - of pancreas (adeno-), with metastases, 35132, 3526
 - 35441
 - of rectum (colloid), with metastases, 35451
- Chiari's syndrome, 35241, 35342
- Cholelithiasis, 35502
- Cirrhosis, see Liver
- Colitis, see Intestine
- Colon, see Intestine
- Cyst of brain, epidermal (suprasellar) 35341
- Duodenum, see Intestine
- Embolus, femoral, 35452
 - mesenteric, 35452
 - pulmonary, massive acute, 35392
 - multiple, 35081, 35381
 - with organization and recanalization, 35081, 3543
- Emphysema, pulmonary, 35062
- Empyema, left pleural cavity, 35231
- Endocarditis, see Heart
- Endometriosis of sigmoid, 35131
- Esophagus, ulcer of, 35422
 - peptic, with stricture, 35031
 - with perforation, 35231
 - varices of, with rupture, 35371
- Femur, chondroblastoma of, benign, 35172
 - osteoma of, osteoid, 35181
 - sarcoma of (fibro-), 35262
- Fibroma, of fibula (nonosteogenic), 35011
 - of ovary, with infarction, 35352
- Fibrosis, radiation, of bladder and ureters, 35511
- Fibula, fibroma of (nonosteogenic), 35011
- Gall bladder, carcinoma of, 35342
 - with metastases, 35462

Testis, azospermia of, 35311
 lymphoma of, malignant (reticulum-cell sarcoma type), 35152
 Thrombosis of hepatic vein, 35241, 35342
 of portal vein, 35292, 35342, 35422
 of pulmonary artery, 35441
 with organization and recanalization, 35081
 of superior mesenteric artery, 35071
 of superior mesenteric vein, 35292
 of vena cava, 35241
 neoplastic, 35342
 Thyroid gland, atrophy of, with myxedema, 35071
 Thyroiditis (Hashimoto type), 35161
 Tuberculosis of endometrium, 35442
 of lung, 35021
 of lymph nodes, chronic, 35401
 of peritoneum, 35442
 of salpinx, 35442
 Ulcer, of esophagus, with perforation, 35231
 peptic, with stricture, 35031
 of stomach, peptic, 35461
 Urter, carcinoma of (papillary), metastatic from kidney, 35301
 fibrosis of, radiation, 35511
 Uterus, tuberculosis of (endometrium), 35422
 Varices of esophagus, with rupture, 35371
 of stomach, 35371
 Vas deferens, absence of, 35311
 Vein, phlebitis of, thrombo- (cerebral), 35072
 thrombosis of (hepatic and vena cava), 35241
 mesenteric 35292
 portal, 35292

SPEAKERS IN DISCUSSION OTHER THAN
TRACY B. MALLORY,
BENJAMIN CASTLEMAN
AND
STANLEY M. WYMAN

The numbers in heavy type refer to cases in which the speaker has presented the Differential Diagnosis
